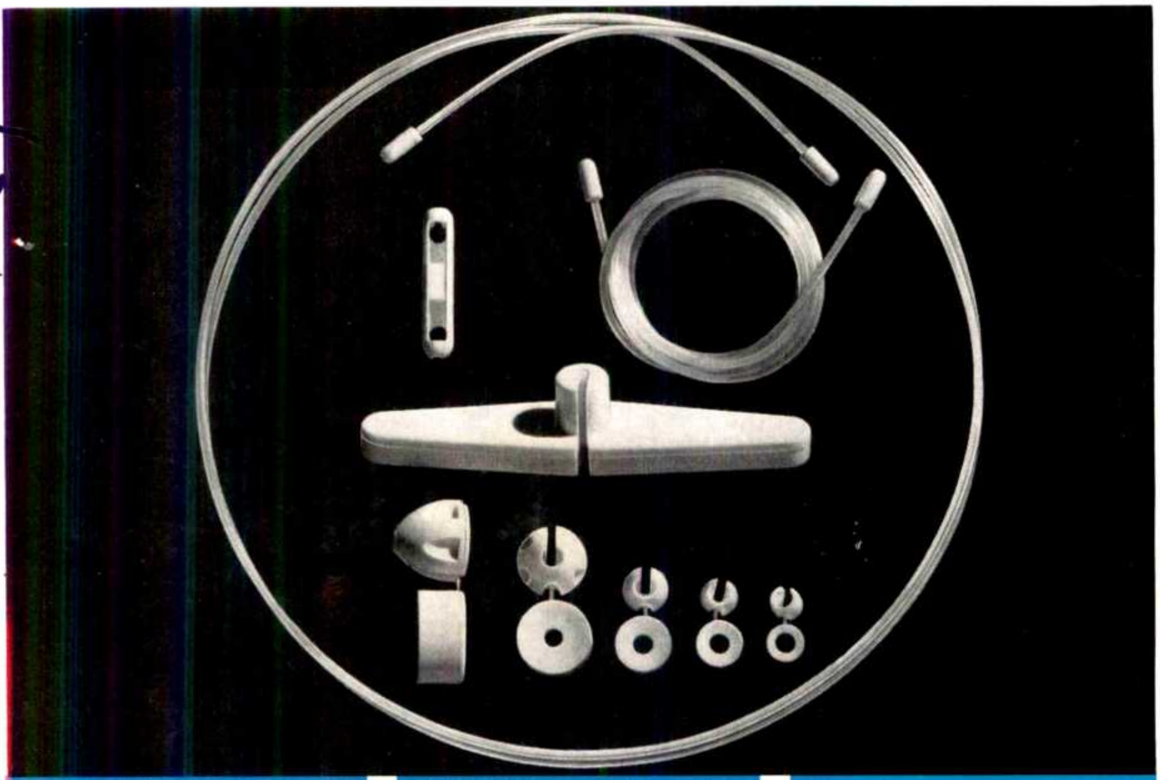
new

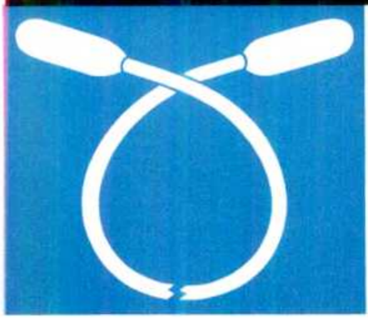
Armour Vein Stripper

Sterile, disposable, non-toxic and pyrogen-free

Eliminates time-consuming preparation and cleaning

Sterilised by irradiation



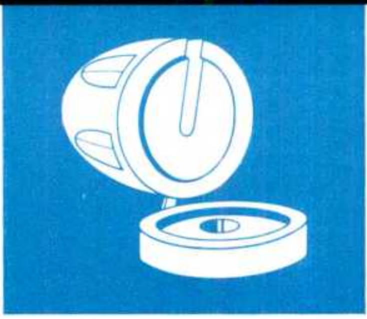


Nylon Cable

Has optimum handling quality.

Every end stop individually tested for firmness of attachment.

Breaking load of cable in excess of 150 lb.

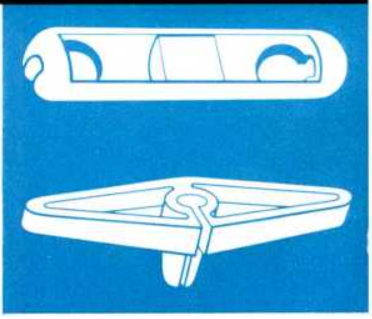


Nylon Olives

Snap fit for convenience of assembly.

Clean, well-defined cutting edge.

Hole without edge access prevents cable detachment.



Nylon Coupler and Draw Handle

Smooth, compact, coupling, ensures security of union.

Light, strong, well shaped.

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·10	£2·80	£3·20	£3·80	£4·30	£4·80	£5·90	£6·90
4	2·70	3·90	4·60	5·40	6·16	6·90	8·40	9·90
6/8	4·50	5·80	7·10	8·30	9·60	10·80	13·40	15·90
10/12	7·20	9·80	11·70	13·70	15·70	17·70	21·80	25·40
14/16	8·70	11·10	13·50	15·90	18·30	20·70	25·50	30·30
18/20	11·40	15·10	18·20	21·30	24·50	27·70	33·90	39·00
COVERS	1·50	2·10	2·70	3·30	3·90	4·50	5·70	6·90

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 58. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St. Martin's House,* 159 *Clapham High Street, London, S.W.4.*

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

“…not only are the two primary pathogens, *Strep pneumoniae* and *H influenzae*, sensitive, but so are the secondary invaders such as klebsiella which often replace them after antibiotic treatment.”[1]

“Of the easily administered primary treatments for urinary tract infection, this combination is probably the best.”[1]

“…clearly superior to either of the other treatments…”[2]

“…one is struck by the tremendous success rate, certainly superior to any antibacterial we have tested…”[3]

“…indeed one cannot remember any other drug performing so well…”[3]

“It rapidly cleared purulent sputum with improvement in all 50 cases.”[4]

SEPTRIN* Tablets, Adult Suspension, Paediatric Suspension and Paediatric Tablets contain trimethoprim and sulphamethoxazole.

This girl has completed two years of her training.

Should she bear the responsibility for mixing drugs?

Increasingly, parenteral solutions are being used as a vehicle for drugs. The addition of supplemental drugs is an aspect of drug distribution which raises problems – is the nurse aware of the stability of the supplemented solution and of adjustments in infusion rates that are often entailed? Can the prescriber be sure about the pharmaceutical or pharmacological interactions that may take place between the constituents? Are conditions on the ward such that an aseptic technique can be maintained?

One answer is a centralised I.V. additive service operated within the hospital pharmacy.

The Admixture System

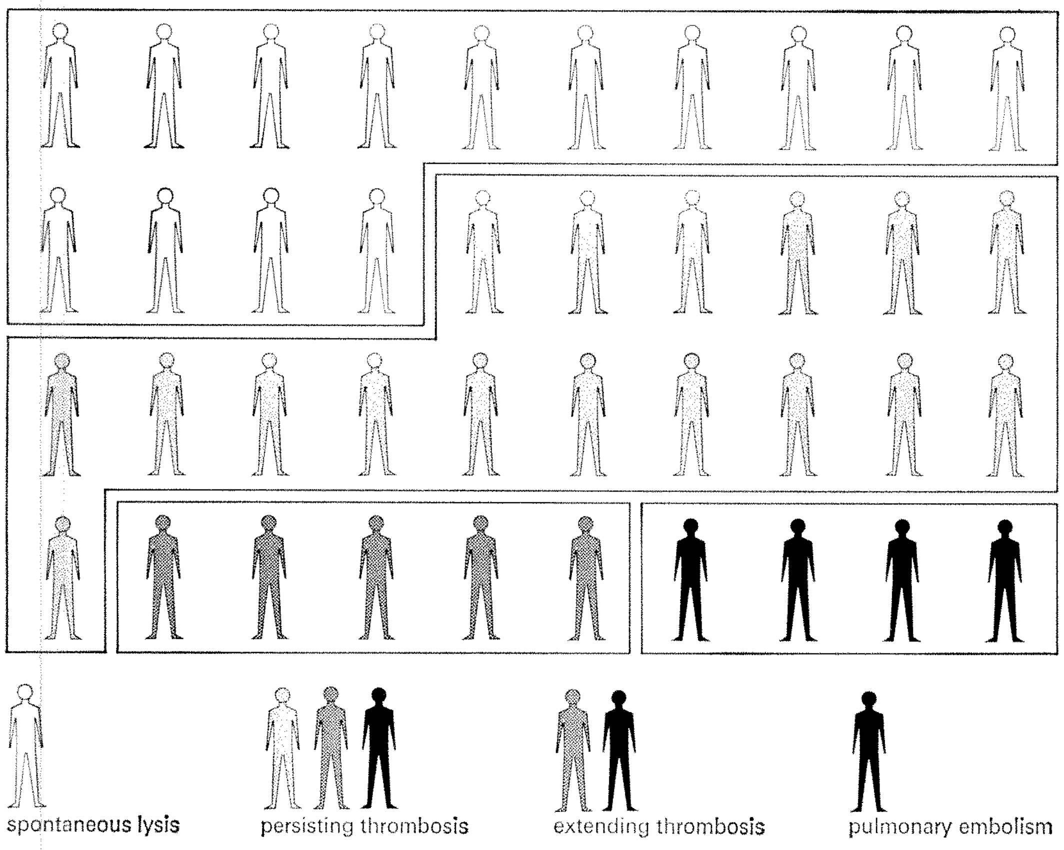
More than 20% of patients with deep-vein thrombosis are in the'high-risk group' for pulmonary embolism. Lighten the prospect with the timely use of Kabikinase®



Of 132 patients aged 40 years or more, 40 developed post-operative deep-vein thrombosis; of 9 with extending thrombi, 4 suffered pulmonary embolism.[1]

Although surgical clearance of thrombi may be considered, the attendant hazards and inconvenience outweigh the possible benefits, which rarely are greater than those attained by thrombolysis with Kabikinase, a highly purified streptokinase, which potentiates the body's *natural* ability to dissolve clots.

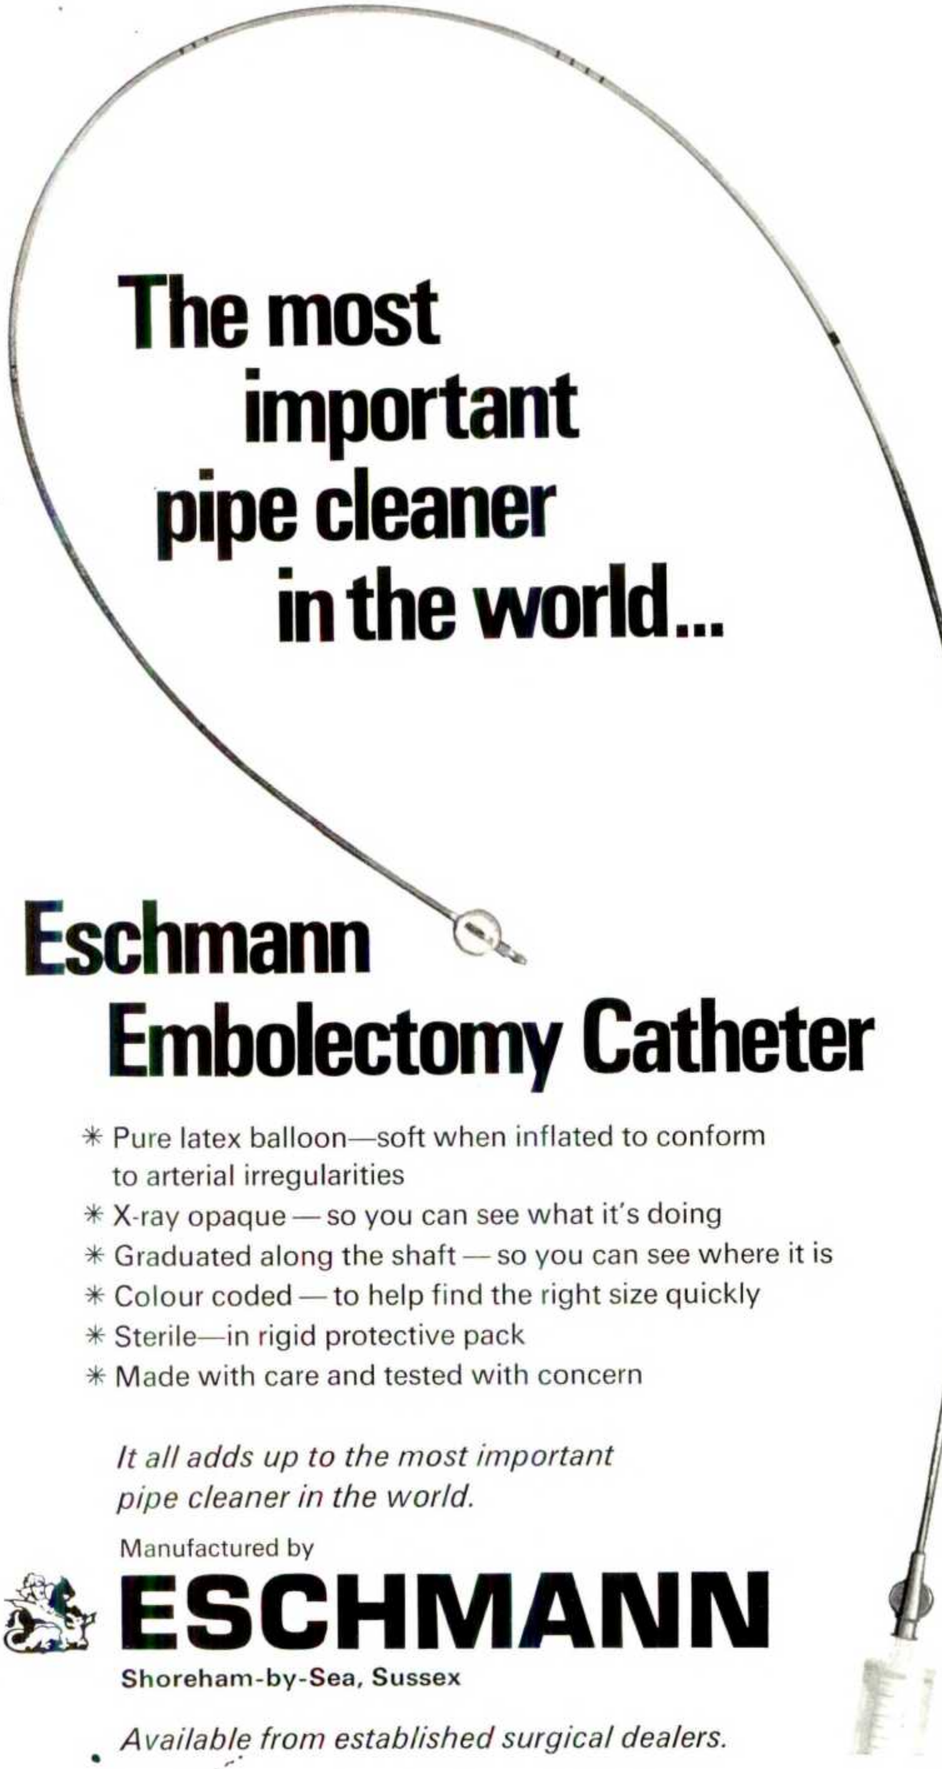
1. Lancet, **2**, 230, (1969)

Kabikinase® (pure streptokinase for intravascular infusion) is manufactured by AB Kabi, Stockholm, Sweden and is available only from:

KABI

Kabi Pharmaceuticals Ltd
Bilton House
Uxbridge Road
Ealing, London W5 2TH
Telephone: 01-567 4717 or 01-579 1871

A new handbook of information about thrombolytic therapy with Kabikinase will shortly be available. May we reserve you a copy?



The most important pipe cleaner in the world...

Eschmann Embolectomy Catheter

- ✳ Pure latex balloon—soft when inflated to conform to arterial irregularities
- ✳ X-ray opaque — so you can see what it's doing
- ✳ Graduated along the shaft — so you can see where it is
- ✳ Colour coded — to help find the right size quickly
- ✳ Sterile—in rigid protective pack
- ✳ Made with care and tested with concern

It all adds up to the most important pipe cleaner in the world.

RIALS CONFIRM FLOXAPEN'S EXCELLENT PERFORMANCE

Treatment succeeded clinically in 26 patients with staphylococcal infections and failed in four. It as unsuccessful either clinically or bacteriologically in two of three patients with pneumococcal nfections.

There were no serious side-effects; three patients showed gastro-intestinal upset and two pyrexia due to penicillin hypersensitivity. No undue pain was experienced at the site of the injection.

It is concluded that flucloxacillin is a useful addition to the therapeutic armamentarium against benzylpenicillin-resistant staphylococci.

and cloxacillin has made any dramatic cures of staphylococcal infection with new agents less impressive and remarkable than would have been the case 10 years ago. Nevertheless, highly satisfactory responses were obtained with flucloxacillin at a dosage of 1·0 g daily, and cures obtained late in the trial in very ill patients using higher dose régimes can only be assessed as excellent by comparison with any other currently-available compounds and indicate the efficacy of flucloxacillin. It became apparent as the trial continued severe staphylococcal infection contained by the tions

ve: Clinical Trials J. (1970) 7, 375.
it: Clinical Trials J. (1970) 7, 372.

loxapen, like Orbenin (cloxacillin B.P.), is active gainst virtually all staphylococci and all treptococci and pneumococci irrespective of their ensitivity to traditional penicillins, tetracyclines, usidic acid, erythromycin and lincomycin.

he standard dose of Floxapen is only 250 mg. and vill attain similar serum levels by oral or njectable routes. Therapy is therefore simpler and nore effective than with Orbenin.

loxapen offers the penicillin advantages of low oxicity and bactericidal action. It is also ideal for ontinuing outpatient treatment because of its onvenient oral dosage.

urther information is available on request.

Indications: Infections due to sensitive Gram-positive organisms, including resistant staphylococci: skin and soft tissue infections, otitis media, sinusitis, infected wounds and burns, osteomyelitis and septic arthritis, pneumonia empyema, septicaemia, endocarditis and meningitis.

Dosage Oral and intramuscular:
Adults: 250 mg. q.i.d.
Children: 2-10 years—$\frac{1}{2}$ adult dose.
Under 2 years—$\frac{1}{4}$ adult dose.
Oral doses should be taken one hour before meals.
In severe infections dosages may be increased if required.

Availability Syrup 125 mg./5 ml.
Capsules (black/caramel) and
Vials, each containing 250 mg. flucloxacillin.

Contra-indications Penicillin hypersensitivity.
Subconjunctival injection.

Side-effects As with other penicillins.

Floxapen *simplifies antibiotic treatment in hospital and after*
flucloxacillin

Floxapen* (flucloxacillin) is a British product originated by

OPERATIVE TREATMENT OF HIGH GASTRIC ULCER WITH SPECIAL REFERENCE TO PAUCHET'S METHOD

By ADAM LEWIS AND GEORGE QVIST

ROYAL FREE HOSPITAL, LONDON

SUMMARY

A high gastric ulcer may be treated by excision, or the ulcer may be retained and healing encouraged by other means. If the ulcer is retained there is a small but definite risk of malignancy. Neither gastric drainage, nor the Kelling–Madlener operation, nor vagotomy and pyloroplasty ensures healing in a high gastric ulcer. Local wedge resection of the ulcer is attended by very poor results, and a high mortality and morbidity preclude the use of subtotal or total gastrectomy. Pauchet's procedure combines the advantages of limited gastrectomy and gastroduodenal anastomosis with complete removal of the ulcer. It is the recommended operation for high gastric ulcers.

BENIGN gastric ulcers situated high on the lesser curvature tend to occur in elderly patients (Veselý, Kubíčkova, and Dvořáková, 1968) with achlorhydria (Baron, 1963) who possess a hereditary predisposition to this type of ulcer (Johnson, 1965). Operations for high gastric ulcer comprise those in which the ulcer is removed and those in which the ulcer is left in situ. Removal of a high gastric ulcer may involve a difficult juxta-oesophageal dissection and thus result in a higher mortality and morbidity than those procedures that avoid this manœuvre. On the other hand, ulcers left in situ may not heal (Levin, Palmer, and Kirsner, 1954; Shipman, 1965; Woodward, Eisenberg, and Dragstedt, 1967), and despite an apparently adequate biopsy may later prove to be malignant. The choice of operation for high gastric ulcer thus involves balancing the risk of a difficult subdiaphragmatic dissection in an often elderly patient against the risk of recurrence or malignancy in a retained ulcer.

PROCEDURES WHICH DO NOT INVOLVE THE REMOVAL OF THE HIGH ULCER

Gastric Drainage.—Results are poor whether drainage is achieved by pyloroplasty (Kennedy and George, 1967; Woodward and others, 1967) or by gastro-enterostomy (Maingot, 1969). There is no doubt that gastric ulcers may remain unhealed or may recur in patients with an entirely adequate pyloroplasty (Qvist and Fox, 1969) or gastro-enterostomy (Tanner, 1964), and therefore these procedures are rarely, if ever, indicated for high ulcers.

Vagotomy and Gastric Drainage.—Conservative surgery by vagotomy and pyloroplasty has been strongly advocated by some surgeons (Hendry, 1961; Weinberg, 1961; Burge, Gill, and Lewis, 1963; Farris and Smith, 1963; Dorton, 1964; Wasuna, Kennedy, Gillespie, and Kay, 1971), but ulcers in the region of the cardia often remain unhealed or recur (Colp and Druckerman, 1946; Lewis and Qvist, 1971). Ulcers that fail to respond to vagotomy and drainage do particularly badly on medical treatment (Bank, Marks, Louw, and Brom, 1969), and although occasionally silent (Qvist, Davis, and Fox, 1969) they remain liable to complications. In a poor-risk patient with an uncomplicated high gastric ulcer, the risk of recurrence may be worth accepting, but, in general, vagotomy with drainage is not recommended for high ulcers.

Kelling-Madlener Operation.—This operation (Kelling, 1918, 1938; Madlener, 1923) leaves the ulcer in situ and entails a gastric resection below it (*Fig.* 1). A relatively modest gastrectomy is feasible and a difficult juxta-oesophageal dissection is avoided. Excellent results have been claimed for this operation (Madlener, 1923; Zukschwerdt and Horstmann, 1936; Kelling, 1938; Colp and Druckerman, 1946; Finsterer, 1954), which must be preceded by a biopsy of the ulcer in order to exclude malignancy. The technique of the Kelling-Madlener operation is similar to that of standard partial gastrectomy, the operation being completed by gastrojejunal or gastroduodenal anastomosis. Although vagotomy may be added to this procedure (Zollinger, 1958), it is of doubtful value. The resection of variable amounts of stomach has been recommended, from a pylorectomy (Smoler, 1934) to a three-quarters gastrectomy (Maingot, 1969), but the efficacy of this operation appears to be more dependent on the provision of adequate drainage than on the amount of stomach resected (Burge, 1966). The operation involves more extensive surgery than other procedures in this group and by no means do all the ulcers heal (Colp and Druckerman, 1946; Levin and others, 1954). Many surgeons (Lewisohn, 1947; Marshall, Jensen, and Davison, 1961; Maingot, 1969) avoid the Kelling-Madlener operation altogether, and others reserve it for those patients who are not considered likely to survive a difficult subdiaphragmatic dissection (Tanner, 1952; Wells, 1960).

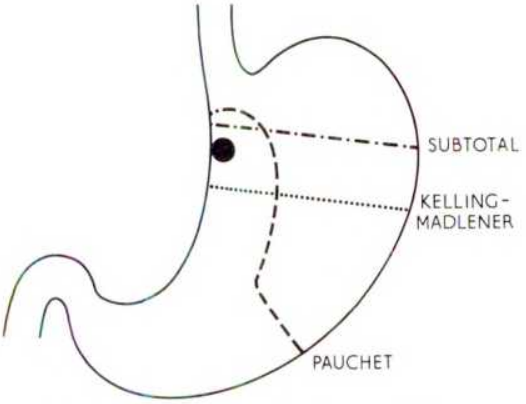

FIG. 1.—Types of gastrectomy for high gastric ulcer.

PROCEDURES WHICH INVOLVE THE REMOVAL OF THE HIGH ULCER

Wedge Resection.—The results of wedge resection alone are very poor (Judd and Rankin, 1923), and the technical difficulties of a high dissection still largely remain. Even when combined with vagotomy and pyloroplasty a wedge resection does not prevent recurrence of a high gastric ulcer (Lewis and Qvist, 1971), and thus cannot be recommended for routine use. It may, however, be the only practicable course available for a bleeding ulcer in a poor-risk patient.

Partial Gastrectomy.—Partial gastrectomy, preferably the Billroth-I operation, is generally accepted to be the best operation available for chronic gastric ulcer (Tanner, 1967; Maingot, 1969). In the case of a high gastric ulcer, subtotal resection may be necessary (*Fig.* 1), and gastrojejunal rather than gastroduodenal anastomosis is then required. The main technical difficulty in gastrectomy for high gastric ulcer is experienced in the resection of the stomach without endangering the cardia. The procedure may be facilitated and major gastric resection avoided by the methods of Tanner or of Pauchet.

Tanner's Rotation Manœuvre (Tanner, 1952, 1969).—Tanner's rotation manœuvre may be performed for high posterior gastric ulcer if the ulcer is not too high for clamps to be applied above it. The ulcer is rotated from its posterior position and held as if on the lesser curve. The true lesser curve now lies anteriorly and the greater curve posteriorly, and the ulcer is clearly exposed below the cardia. Clamps are applied as for Billroth-I gastrectomy, and transection distal to these clamps allows the specimen to be removed together with a tongue of posterior gastric wall which includes the ulcer. Having reconstructed the 'lesser curve' and released the clamps, the upper end of the suture line will rotate back to the posterior wall. Depending on the amount of stomach removed, gastroduodenal or gastrojejunal anastomosis may then be performed.

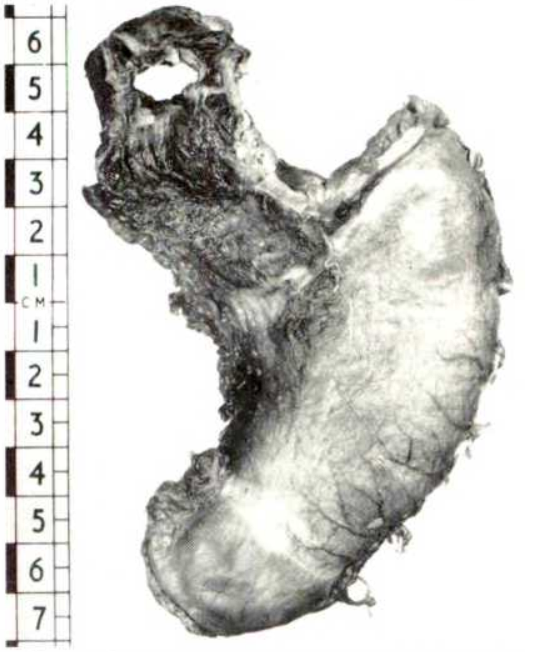

FIG. 2.—Gastrectomy specimen excised by Pauchet's method.

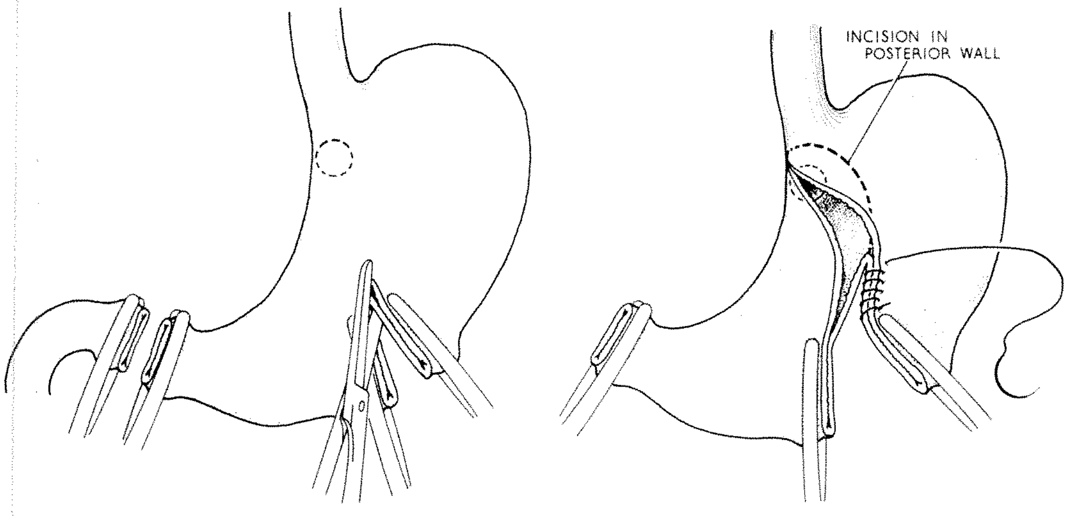
Pauchet's Procedure (*Fig.* 1).—Pauchet's procedure facilitates the safe resection of lesser-curve gastric ulcers that are too high for clamps to be placed above them. The method was first described by Victor Pauchet, a Paris surgeon, in 1924 (Pauchet, 1924), an English translation of his work appearing a year later (Pauchet, 1925). The method is a modification of the Schoemaker procedure (Schoemaker, 1911) and consists of a lower gastrectomy which is extended to include a rim of lesser curve up to and including the ulcer (*Fig.* 2). In his original description Pauchet advocated preliminary transection of the stomach between the clamps below the ulcer. The upper clamp is then removed and the tongue of the lesser curve containing the ulcer is excised separately with scissors. Pauchet's method of excising a high gastric ulcer has been applied to modern gastrectomy technique (Maingot, 1969; Tanner, 1969), and the essential steps in the operation are as follows (*Fig.* 3).

The stomach is mobilized in the usual manner and the duodenum is divided between clamps. The lesser omentum is divided from below upwards to free the lesser curvature of the stomach.

Ligation of the left gastric artery or its branches at this stage may be difficult in the case of a very chronic high gastric ulcer, and it is often necessary to complete the division of the upper end of the lesser omentum later on, *pari passu* with excision of the upper end of the lesser curvature, at which stage the forward and upward displacement of the stomach gives an excellent exposure of the left gastric vessels *Fig.* 3 C).



A B

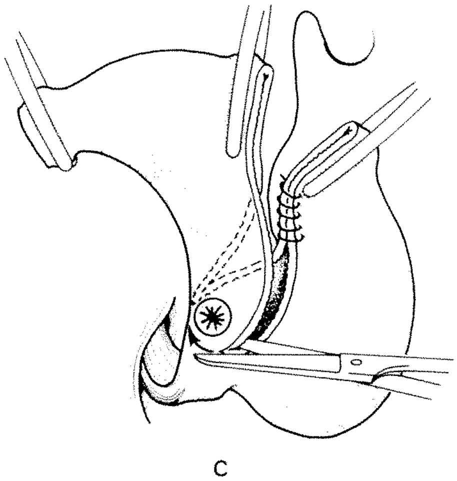
FIG. 3.—Stages of Pauchet's operation.

Two small Payr clamps are now placed side by side horizontally across the stomach at the junction between the antrum and the body and with their tips just short of the lesser curve. The stomach between these two clamps is incised with a knife and the clamps are widely separated (*Fig.* 3 A). Using scissors, the anterior and posterior walls of the stomach are now divided from the tips of the Payr clamps towards the ulcer, thus removing a strip of the lesser curve *Fig.* 3 B). When the ulcer is reached the excision is continued on to the anterior or posterior wall, according to the position of the lesion, and the ulcer is emoved in continuity (*Fig.* 3 C). Care should be taken to confine the upper part of the excision strictly o the margin of the ulcer. In this way a flap of the opposite gastric wall will remain and may be used to epair the defect left by the excision of the ulcer. Bleeding is greatly reduced if the lesser curve is esected bit by bit, a continuous 0 chromic catgut uture being inserted to reconstruct the lesser curve after each short segment is removed. The lesser curve s then reinforced with a layer of interrupted 0 chromic catgut, and the operation is completed by a gastroduodenal anastomosis.

Total Gastrectomy.—This procedure is attended by a high mortality and morbidity (Armstrong and Denick, 1960) and, except in cases of repeated ecurrence (Wells, 1960), is unjustifiable when dealing with benign ulcers (Tanner, 1952; Maingot, 969).

DISCUSSION

Before deciding on the correct procedure to adopt or the treatment of a high gastric ulcer, it is clearly ssential to establish the benign nature of the ulcer. There seems little doubt that the higher a gastric ulcer occurs on the lesser curve the more likely it is to be malignant (Jordan, 1958; Glassman, 1970). If, therefore, it is proposed to leave the ulcer in situ, an adequate four-quadrant biopsy (Zollinger, 1958) should be undertaken. Unfortunately, even a carefully performed biopsy is not infallible (Farris and Smith, 1963), and thus only total removal of the ulcer will ensure that a malignant lesion has not been missed.



C

There has been much difference of opinion in the past concerning the incidence of malignant change in a previously benign ulcer (Wilson and MacCarty, 1909; Mallory, 1940). Publications to date (Glassman, 1970) indicate that malignancy may occur in between 2 and 8 per cent of gastric ulcers, although there is no absolute proof on this point. Whichever figure is accepted, the prognosis of carcinoma of the stomach is extremely poor, and it seems reasonable to eliminate the risk of this complication by excision of the ulcer whenever possible.

complete the division of the upper end of the lesser omentum later on, *pari passu* with excision of the upper end of the lesser curvature, at which stage the forward and upward displacement of the stomach gives an excellent exposure of the left gastric vessels *Fig.* 3 C).

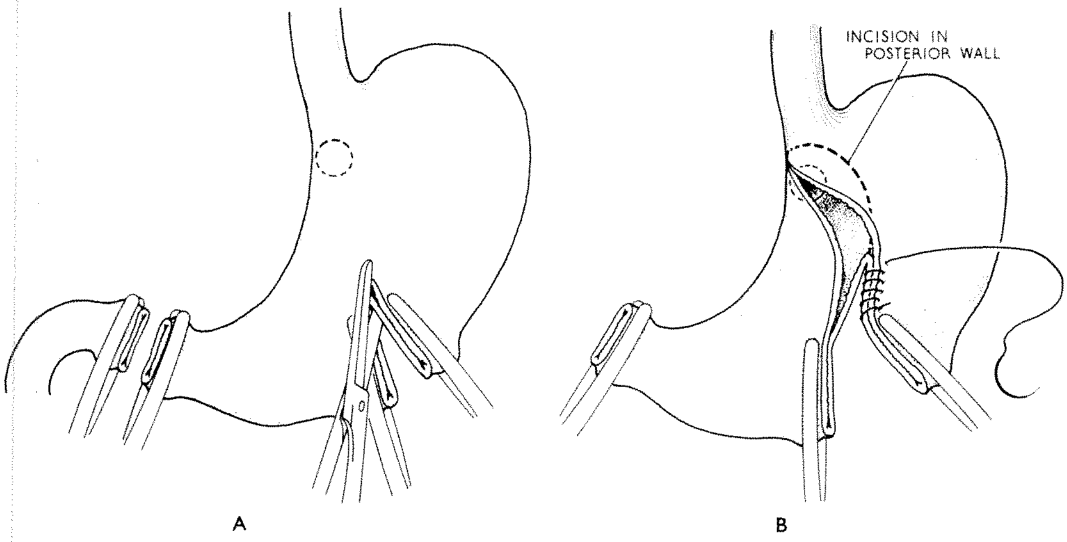


FIG. 3.—Stages of Pauchet's operation.

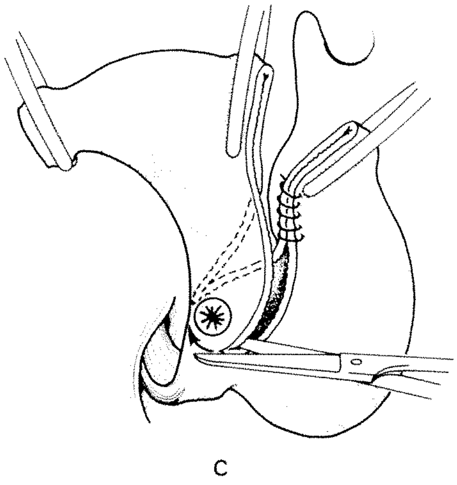

Two small Payr clamps are now placed side by side horizontally across the stomach at the junction between the antrum and the body and with their tips just short of the lesser curve. The stomach between these two clamps is incised with a knife and the clamps are widely separated (*Fig.* 3 A). Using scissors, the anterior and posterior walls of the stomach are now divided from the tips of the Payr clamps towards the ulcer, thus removing a strip of the lesser curve *Fig.* 3 B). When the ulcer is reached the excision is continued on to the anterior or posterior wall, according to the position of the lesion, and the ulcer is emoved in continuity (*Fig.* 3 C). Care should be taken to confine the upper part of the excision strictly to the margin of the ulcer. In this way a flap of the opposite gastric wall will remain and may be used to repair the defect left by the excision of the ulcer. Bleeding is greatly reduced if the lesser curve is esected bit by bit, a continuous 0 chromic catgut uture being inserted to reconstruct the lesser curve after each short segment is removed. The lesser curve s then reinforced with a layer of interrupted 0 chromic catgut, and the operation is completed by a gastroduodenal anastomosis.

Total Gastrectomy.—This procedure is attended by a high mortality and morbidity (Armstrong and Denick, 1960) and, except in cases of repeated ecurrence (Wells, 1960), is unjustifiable when dealing with benign ulcers (Tanner, 1952; Maingot, 969).

DISCUSSION

Before deciding on the correct procedure to adopt or the treatment of a high gastric ulcer, it is clearly ssential to establish the benign nature of the ulcer. There seems little doubt that the higher a gastric ulcer occurs on the lesser curve the more likely it is to be malignant (Jordan, 1958; Glassman, 1970). If, therefore, it is proposed to leave the ulcer in situ, an adequate four-quadrant biopsy (Zollinger, 1958) should be undertaken. Unfortunately, even a carefully performed biopsy is not infallible (Farris and Smith, 1963), and thus only total removal of the ulcer will ensure that a malignant lesion has not been missed.

There has been much difference of opinion in the past concerning the incidence of malignant change in a previously benign ulcer (Wilson and MacCarty, 1909; Mallory, 1940). Publications to date (Glassman, 1970) indicate that malignancy may occur in between 2 and 8 per cent of gastric ulcers, although there is no absolute proof on this point. Whichever figure is accepted, the prognosis of carcinoma of the stomach is extremely poor, and it seems reasonable to eliminate the risk of this complication by excision of the ulcer whenever possible.

EROSIVE GASTRITIS: ITS DIAGNOSIS, MANAGEMENT, AND SURGICAL TREATMENT

By A. M. DESMOND and K. W. REYNOLDS
ST. JAMES'S HOSPITAL, BALHAM, LONDON

SUMMARY

Three hundred and thirty-one patients with severe haemorrhage resulting from erosive gastritis, representing 10 per cent of 3938 patients admitted with severe gastroduodenal bleeding during the past 30 years, are presented. The problems of diagnosis and management are discussed; particularly, the role of immediate gastroscopy, and the indications for surgical treatment and the surgical procedure best designed to control the haemorrhage.

Forty-seven patients required 51 emergency surgical procedures, and it was found that the Billroth-I gastrectomy was far superior to any other operation. Polya gastrectomy, vagotomy, and gastric vasoligation were used, with a high incidence of recurrent bleeding and often necessitating a further emergency surgical operation—usually total gastrectomy. It is suggested that a possible explanation of this is the prevention of biliary reflux into the stomach, which is what the Billroth-I gastrectomy seems to achieve. In 1 case presented, a patient with a Polya gastrectomy and erosions who had severe haemorrhage, bleeding was controlled by conversion to a Billroth-I anastomosis.

BETWEEN 1940 and 1970, 3938 patients with gastroduodenal haemorrhage were admitted to the Gastroenterological Unit at St. James's Hospital, Balham. The purpose of this communication is to present some conclusions which were reached as a result of a study of these cases. Particular attention is paid to the problem of diagnosis and management of severe haemorrhage resulting from erosive gastritis.

Table I.—THE DIAGNOSIS IN CASES OF MASSIVE GASTRODUODENAL HAEMORRHAGE, 1940–70

Diagnosis	*No. of Cases*
Gastric ulcer	1407
Duodenal ulcer	1438
Anastomotic ulcer	157
Oesophageal ulcer	10
Erosive gastritis	331
Hiatus hernia	131
Portal hypertension	110
Carcinoma of the stomach	103
Other gastric neoplastic growths	12
Mallory-Weiss syndrome	37
Carcinoma of the pancreas or bile-ducts	9
Aortoduodenal fistula	2
Pancreatitis	2
Retrograde jejunal intussusception	2
Carcinoma of the oesophagus	2
Miscellaneous	16
Unknown	169
Total	3938

Table I lists the diagnosis in 3938 patients. Three hundred and thirty-one cases, or approximately 10 per cent of all admissions with gastroduodenal haemorrhage, were due to erosive gastritis.

Surgeons are primarily concerned with the place of emergency surgery in gastroduodenal haemorrhage. The role of surgery in the management of haemorrhage from erosive gastritis has latterly been our interest.

Much has been written concerning the emergency surgery of bleeding peptic ulcers, and in most centres today the indications for surgery are more or less stereotyped. Our experience of this problem will be discussed briefly.

Since 1953 it has been our policy to select for emergency surgery those cases who are likely to continue bleeding or to have recurrent haemorrhage. Thereby we hope to reduce mortality.

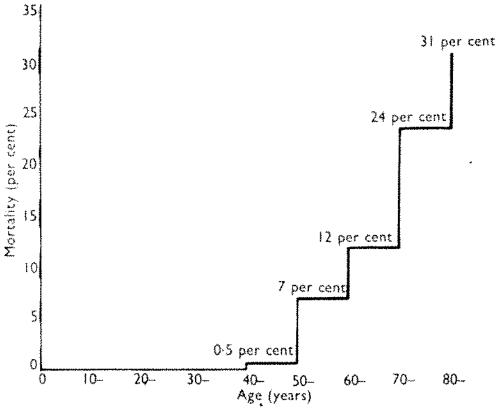

FIG. 1.—The relationship between age and mortality of patients with gastroduodenal haemorrhage.

Table II.—RELATIONSHIP OF SEVERITY OF FIRST HAEMORRHAGE TO MORTALITY IN 200 CONSECUTIVE CASES

HAEMORRHAGE	NO. OF CASES	MORTALITY (per cent)
Initial haemorrhage		
Severe	82	21·0
Mild	118	7·6
Total	200	13·0
Died at first haemorrhage	3	11·5*
Died at repeat bleed	23	88·5*

* Expressed as a percentage of the total number of deaths.

It is generally accepted that mortality is increased in the following circumstances:—

1. In patients over 50 years of age. This is confirmed by our series (*Fig.* 1).
2. When the initial haemorrhage is severe enough to cause oligaemic shock (*Table II*).

3. When pain persists after the initial haemorrhage despite bed-rest.

4. When haemorrhage is associated with steroids, anticoagulants, or anti-inflammatory drugs such as aspirin, indomethacin, or butazoladin.

5. When haemorrhage persists or recurs after 48 hours. Mortality increases with delay in treatment, as shown in *Fig. 2*.

Table III outlines the policy of this unit towards severe gastro-intestinal haemorrhage secondary to peptic ulceration. We believe, contrary to many, that a similar aggressive approach must be made when dealing with bleeding erosive gastritis. The current practice of this unit is to perform a 50 per cent Billroth-I operation for all bleeding chronic gastric ulcers. The ulcer is always removed, high lesser-curve ulcers being removed by the Pauchet manœuvre, thus obviating the need for very high gastric resections.

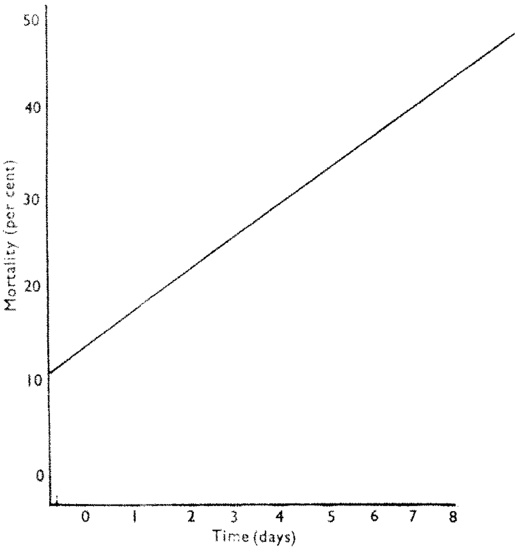

FIG. 2.—The relationship between mortality and the period from admission to operation.

Chronic duodenal ulcers are treated by a standard two-thirds partial gastrectomy, valved with an antecolic gastrojejunal anastomosis. Conservative surgery in the form of vagotomy and drainage together with oversewing of the bleeding point has been used in small or acute duodenal ulcers, but in a callous penetrating ulcer with a large vessel in its base we perform a Polya gastrectomy.

There still remain those cases in whom thorough laparotomy including Kocher mobilization of the duodenum fails to reveal a source of haemorrhage. In the past these have been managed by closure of the abdomen or by blind gastrectomy (Gray, 1953), or by the addition of vagotomy to both these procedures. It is our opinion that none of these procedures is entirely satisfactory. There is a high incidence of continuing haemorrhage after any of the above procedures. If the stomach is opened widely by a gastrotomy, inspection and palpation of the interior wall will, in many instances, reveal an acute mucosal lesion. These lesions are often high on the lesser curve, and if solitary can be under-run, as described by Markby (1965) and Banning, Baron, Kopelman, Lam, and Warren (1965).

Diffuse mucosal lesions in the form of acute gastric erosions do not respond to this simple procedure. We believe that a 50 per cent Billroth-I partial gastrectomy is the treatment of choice in these cases.

MATERIALS AND METHODS

The series consists of 331 cases of erosive gastritis. Forty-eight patients required emergency surgical procedures, and 57 operations were performed. The age and sex distributions of erosive gastritis are analysed. The improved diagnostic rate with the introduction of certain diagnostic criteria is considered. Finally, an analysis of surgical procedures and the results between 1940 and 1970 are given.

In 1969 we introduced the following diagnostic criteria: (1) associated aetiological factors, (2) immediate gastroscopy, (3) a normal barium meal, and (4) cases diagnosed by exclusion of other causes of gastroduodenal haemorrhage. The results of these are analysed in order to establish how they apply to our cases, and they are compared with similar data which were retrospectively collected prior to 1969.

We have defined immediate gastroscopy as gastroscopy between 0 and 12 hours after admission, and for this the fibre-optic gastroscope and duodenoscope have been used, often at the bedside. Prior to this the practice had been to use the rigid Hermon–Taylor gastroscope when the haemorrhage had subsided or at a convenient time. Consequently, the investigation was often delayed for 48 hours or more,

Table III.—OUTLINE OF THE MANAGEMENT OF HAEMORRHAGE FROM PEPTIC ULCERATION

Age	*Evidence of Ulcer*	*Severity of Bleed*	*Time of Surgery**
Over 50	Good evidence of presence of an ulcer	Severe bleed	Emergency surgery probable
		Non-severe bleed	Consider if bleeding recurs
	Insufficient evidence of presence of an ulcer	Severe bleed	Consider if bleeding recurs
		Non-severe bleed	Emergency surgery if medical treatment fails
Under 50	Good evidence of presence of an ulcer	Severe bleed	Consider if bleeding recurs
		Non-severe bleed	Emergency surgery if medical treatment fails
	Insufficient evidence of presence of an ulcer	Severe bleed	
		Non-severe bleed	

* Absolute indications for emergency surgery:—
1. With perforation in most cases.
2. With pyloric stenosis.
3. Continuous bleeding.

* Added incentives for emergency surgery:—
1. Persistence of severe ulcer pain after bleed.
2. Severe pain radiating to back.
3. Patients with ulcers and taking cortisone.
4. Patients using anticoagulants.

by which time acute mucosal lesions had often healed and the gastroscopy was normal.

Apart from local abnormalities of the oropharynx or oesophagus there are no contra-indications to fibre-optic endoscopy. Failure to obtain good views of the stomach occur when it is filled with blood-clot which cannot be removed by gentle lavage. It is our experience that when this latter state of affairs exists emergency surgery is nearly always indicated.

Table IV.—COMPARISON OF IDIOPATHIC AND DRUG-ASSOCIATED EROSIVE GASTRITIS, 1966–70, AND THEIR ASSOCIATION WITH SURGERY

TYPE OF EROSIVE GASTRITIS	1966	1967	1968	1969	1970	TOTAL
No. of drug-associated erosions	6 out of 14	7 out of 14	7 out of 23	3 out of 19	9 out of 13	32 out of 83
No. of drug-associated erosions coming to surgery	2 out of 6	1 out of 7	1 out of 7	0 out of 3	3 out of 9	7 out of 32
No. of idiopathic erosions	1 out of 14	5 out of 14	15 out of 23	16 out of 19	4 out of 13	41 out of 83
No. of idiopathic erosions coming to surgery	0 out of 1	0 out of 5	3 out of 15	2 out of 16	1 out of 4	6 out of 41

Table V.—ANALYSIS OF 'EARLY' AND 'LATE' POSTOPERATIVE CASES OF EROSIVE GASTRITIS

YEAR	NO. OF CASES	DETAILS
1966	2	1. Early: associated with septicaemia 1. Late: following previous Polya operation
1967	3	All immediately after prostatectomy. All massively transfused
1968	1	Early: postappendicectomy and advanced renal failure
1969	3	1. Early: postprostatectomy 2. Late: both following previous Polya operations
1970	5	1. Early: following abdominoperineal excision of rectum 4. Late: All following previous Polya operations

Prior to the introduction of the diagnostic criteria, many cases had been diagnosed as erosive gastritis by exclusion of other lesions in the stomach or duodenum. The effect of the diagnostic criteria, and particularly immediate gastroscopy, in decreasing the number of cases diagnosed by this means is analysed.

RESULTS

Age and Sex Distribution.—Analysis of 147 patients admitted between 1960 and 1967 shows a peak incidence in the fifth, sixth, and seventh decades, with 65 per cent of the series being over 50 years of age (*Fig.* 3). Sixty-one per cent of the series were male, but the age distribution was similar for both sexes. Similar figures are found for patients admitted between 1968 and 1970.

On reviewing the series as a whole, 60 per cent of the patients who required emergency surgery for uncontrolled or continuing postoperative bleeding were over the age of 60 years.

Aetiological Factors.—Careful retrospective study of the case histories between 1940 and 1960 reveals very little detail of associated aetiological factors such as recent drug ingestion.

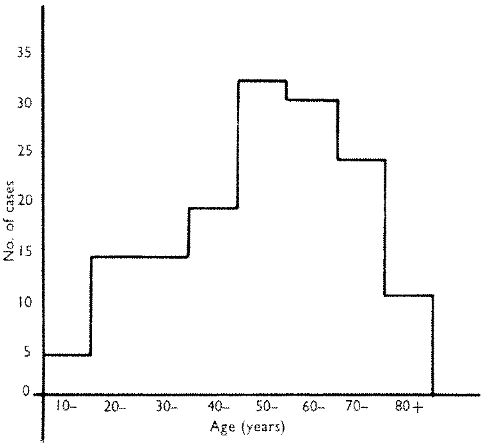

FIG. 3.—The age distribution of 147 cases of erosive gastritis, 1960–6.

Table VI.—THE DIAGNOSTIC CRITERIA USED IN ESTABLISHING THE DIAGNOSIS OF EROSIVE GASTRITIS, 1966–70

DIAGNOSTIC CRITERIA	1966	1967	1968	1969	1970	TOTAL
Ingestion of known associated factor	13	11	8	11	11	54
Positive fibroscopy	2	6	6	5	11	30
Negative fibroscopy	1	1	6	9	2	19
Negative barium meal	9	11	21	19	12	72
Operative diagnosis and post-mortem diagnosis	5	3	4	2	5	19
Diagnosis by clinical methods and exclusion	8	6	14	14	2	44
Total No. of cases	14	14	23	19	13	83

Since 1967 a careful record has been made during history-taking of all possible associated factors, including a detailed history of all the drugs which were taken. On reviewing the case notes the incidence of associated factors in the 1960–6 group was 26 per cent, but from 1967 to 1969 the incidence rose to 55 per cent and to 85 per cent in 1970. Cases where no associated factors are known are termed 'idiopathic'. Analysing the cases from 1967 to 1970 we found that emergency surgery was indicated more frequently in the group with associated factors than in the idiopathic group (*Table IV*). Twenty-five per cent of the group with associated factors came to emergency surgery, and 14 of these cases had had previous surgery. These are divided further into 'early' and 'late' postoperative cases (*Table V*). 'Early' signifies haemorrhage due to erosive gastritis occurring during the immediate postoperative phase, following surgery for diseases other than those of the gastroduodenal system. The 'late' group had had previous gastroduodenal surgery, often many years previously. There were no patients who had previously had Billroth-I operations in this group.

The Diagnostic Criteria.—The results of the diagnostic criteria are shown in *Table VI*. The data for the period 1966–8 were retrospectively extracted from the notes. Between 1969 and 1970, however, with these criteria in mind, searching histories and immediate gastroscopy have decreased the number of cases diagnosed by exclusion of other lesions causing gastroduodenal haemorrhage. This greatly improved diagnostic rate is shown in *Table VII*. The data for the two periods, 1960–6 and 1967–9, are compared with those obtained in 1970.

Table VII.—COMPARISON OF THE DIAGNOSTIC CRITERIA BETWEEN THREE PERIODS OF TIME

DIAGNOSTIC CRITERIA	1960–6 (87 cases)		1967–9 (56 cases)		1970 (13 cases)	
	No.	Per cent	No.	Per cent	No.	Per cent
Ingestion of a known associated factor	—	—	43	76	11	85
Erosions confirmed by gastroscopy	14	16	19	33	11	85
Negative gastroscopy	21	24	16	28	2	15
Normal barium meals	65	74	52	93	12	92
Diagnosis confirmed at operation	10	—	9	—	5	—
Diagnosis by exclusion*	44	50	35	62	2	15

* Factors excluded included positive ingestion history, negative late gastroscopy, normal barium meal, and no dyspeptic history.

In 1960–6 and 1967–9 immediate gastroscopy was not performed, but in 1970 every case had immediate gastroscopy. Immediate gastroscopy resulted in an 85 per cent positive diagnosis rate for erosive gastritis.

Analysis of Emergency Surgical Procedures for Erosive Gastritis, 1940–70.—Forty-eight patients required emergency surgery. This represents 14 per cent of the series. A total of 57 operative procedures were performed (*Table VIII*).

The mortality rate for those patients requiring emergency surgery was 16 per cent. The overall mortality of the series was 7 per cent. This compares with a mortality of 7 per cent in cases admitted during the same period with gastroduodenal haemorrhage from causes other than erosive gastritis (*Table IX*). The mortality of cases requiring emergency surgery in the latter group was 20 per cent.

Table X shows the surgical mortality of erosive gastritis in the three periods which were studied. The causes of death in 8 cases are shown in *Table XI*, and can be compared with the causes of 14 operative deaths (representing a 20 per cent mortality) between 1966 and 1969 in cases of massive haemorrhage not due to erosive gastritis (*Table XII*).

Table VIII analyses the 48 cases requiring emergency surgery and their final outcome.

Commentary on the Surgical Procedures.—Reference to *Table VIII* shows that 9 cases were treated by vasoligation (that is, ligation of the right and left gastric arteries and the right and left gastro-epiploic arteries). Five suffered continuing haemorrhage. This procedure was used extensively in the early 1940's in an attempt to control bleeding in patients in whom thorough laparotomy revealed no lesions. It was subsequently abandoned because of the high rate of continuing haemorrhage. It is of interest to note, however, that there was only 1 case which required further surgery, all the other cases being eventually controlled by conservative measures. There were no deaths in this group.

Table VIII.—ANALYSIS OF SURGICAL PROCEDURES, 1940–70

OPERATION	NO. OF OPERATIONS	CONTINUING OR RECURRENT BLEEDING	TYPE OF FURTHER SURGERY	OUTCOME
Laparotomy alone	1	1	Billroth-I partial gastrectomy	Bleeding controlled
Vagotomy + pyloroplasty	1	1	None	Controlled after prolonged transfusion
Vasoligation	9	5	Billroth-I partial gastrectomy in 1 case	All eventually controlled
Billroth-I partial gastrectomy	28	1	Total abdominal gastrectomy	Died septicaemia; 4 deaths in controlled cases
Polya gastrectomy	8	4	1. Vagotomy, higher gastrectomy, total gastrectomy 2. Total gastrectomy 3. Higher gastrectomy 4. Total gastrectomy	Controlled eventually Controlled Rebleed; death Controlled 2 deaths in the 4 cases originally controlled
Roux gastrectomy	1	—	None	Controlled
Total	48	12	9 operations in 7 cases	8 deaths (16 per cent)

In this series the Billroth-I 50 per cent partial gastrectomy emerges as the operation of choice. A total of 30 operations was performed, 28 as primary procedures and 2 for recurrent haemorrhage following other forms of emergency surgery. Only 1 case continued to bleed postoperatively, and this was associated with a Gram-negative septicaemia and peritonitis. The patient eventually died. There were 4 other postoperative deaths, giving a mortality of 16 per cent. Of these 4 cases, continuing haemorrhage was not a cause of death in any. One died of a leaking anastomosis and was thus a technical fault. The other 3 deaths occurred in patients all over 70 years of age.

The causes of death are shown in *Table XI*. Although the operative mortality of 16 per cent is high, it compares with the mortality of 20 per cent for emergency surgery for gastroduodenal haemorrhage due to other causes (*Table IX*).

Table IX.—COMPARATIVE MORTALITY OF MASSIVE HAEMORRHAGE DUE TO EROSIVE GASTRITIS AND ALL OTHER CAUSES OF HAEMORRHAGE, 1967–70

CAUSE OF HAEMORRHAGE	NO. OF CASES	MORTALITY	
		No.	Per cent
All haematemesis and melaena cases admitted as emergencies excluding erosive gastritis	537	38	7
Emergency surgical procedures in haematemesis and melaena cases excluding erosive gastritis	104	21	20
Erosive gastritis cases admitted as emergencies	69	5	7
Emergency surgical procedures in erosive gastritis cases	14	2	14

Table X.—MORTALITY OF EMERGENCY SURGICAL TREATMENT OF EROSIVE GASTRITIS

PERIOD	TOTAL NO. OF CASES	NO. OF EMERGENCY SURGICAL PROCEDURES	OPERATIVE MORTALITY	
			No.	Per cent
1940–59	175	24	6	25
1960–6	87	10	—	—
1967–70	69	14	2	14
Total	331	48	8	16

Table XI.—ANALYSIS OF CAUSES OF DEATH IN 8 CASES OF EROSIVE GASTRITIS (1940–70)

OPERATION	AGE (years)	FURTHER SURGERY	CAUSE OF DEATH
Billroth-I	43	Total gastrectomy	Leaking anastomosis
Higher partial gastrectomy for rebleed	69	None	Continued haemorrhage
Billroth-I	71	None	Coronary
Billroth-I	81	None	Cardiovascular accident
Polya	65	None	Intestinal obstruction
Billroth-I	74	None	Bronchopneumonia
Polya	80	None	Renal failure
Billroth-I	72	None	Peritonitis; leaking anastomosis

One of the last cases to be included in the Billroth-I series was a patient with a long-standing Polya gastrectomy who developed severe bleeding from erosions following aspirin ingestion. Haemorrhage was controlled by conversion to a Billroth-I type of anastomosis without further gastric resection.

CASE REPORT

E. S., aged 64 years, was admitted as an emergency on 17 Sept., 1970, with melaena. He had had a partial gastrectomy in 1942 for chronic duodenal ulcer. During the week before his present admission he had taken 2–3 Anadin tablets daily. He had no history of dyspepsia since his operation in 1942.

On admission, his haemoglobin was 8 g., electrolytes were normal, and urea was 20 mg. per cent. He was treated by sedation, bed-rest, milk, and transfusion. Twenty-four hours after admission he collapsed with further melaena. He continued to bleed slowly during the next 48 hours and then he had a massive haematemesis and again collapsed. By this time he had received 17 units of blood.

The patient underwent laparotomy on 21 September through an upper midline incision. The previous Polya–Hofmeister partial gastrectomy was noted to be normal, with no evidence of gastric or stomal ulceration. The duodenal stump was normal. A wide gastrotomy revealed diffuse bleeding erosive gastritis. The Polya anastomosis was dismantled and converted to a Billroth-I gastroduodenal anastomosis without any further resection. This procedure brought about control of the haemorrhage.

Table XII.—ANALYSIS OF CAUSES OF DEATH IN 14 CASES OF GASTRODUODENAL HAEMORRHAGE DUE TO LESIONS OTHER THAN EROSIVE GASTRITIS, 1966–9

OPERATION	AGE (years)	FURTHER SURGERY	CAUSES OF DEATH
Polya	61	None	Coronary thrombosis
Billroth-I	67	None	Pulmonary embolus
Billroth-I	69	None	Small-bowel obstruction
Polya	73	None	Bronchopneumonia
Polya	73	None	Bronchopneumonia
Radical Polya	73	None	Bronchopneumonia
Billroth-I	73	None	Congestive cardiac failure and bronchopneumonia
Polya	53	None	Septicaemia
Polya	83	None	Bronchopneumonia
Polya	82	None	Congestive cardiac failure
Radical Polya	46	None	Bronchopneumonia; renal failure
Billroth-I	82	None	Congestive cardiac failure
Billroth-I	80	None	Haemorrhage
Radical Polya	76	None	Hepatic failure
Billroth-I	80	None	Bronchopneumonia

The number of operations during this period was 70, the number of operative deaths was 14, and the mortality was 20 per cent.

Of the patients treated by Polya gastrectomy, 3 out of 8 cases died, a mortality of 37 per cent. Of the 8 cases, 4 suffered continuing haemorrhage, and 3 of these were eventually controlled by total abdominal gastrectomy. All 3 cases survived, but this operation is a very serious and major undertaking with a high mortality and morbidity. The other patient died of recurrent haemorrhage from the gastric remnant after a higher gastrectomy. Considering these facts it is surprising that the mortality was not greater. It can be seen from *Table VIII* that neither the addition of vagotomy nor of higher gastrectomy has any place in the treatment of continued haemorrhage after a Polya partial gastrectomy. Roux gastrectomy as advocated by other surgical centres, notably Bristol, has been used once in this series. This was a patient who many years previously had had a retrocolic gastrojejunostomy for a duodenal ulcer. For technical reasons a Roux gastrectomy was performed, with no postoperative bleeding.

DISCUSSION

The Diagnosis of Erosive Gastritis.—In agreement with the reports from many other centres we have found that erosive gastritis is the third commonest condition requiring emergency admission to hospital with massive gastro-intestinal haemorrhage. In 89 unselected cases of upper gastro-intestinal bleeding analysed by Mailer, Goldberg, Harden, Grey-Thomas, and Burnett (1965) the three main causes were peptic ulcers, acute erosions, and oesophageal varices. Obviously the number of gastric and duodenal ulcers far outnumber that of acute erosive gastritis in our series. The latter, however, constitutes approximately 10 per cent of the admissions. Undoubtedly in this and other published series many cases of erosions were lost to the 'miscellaneous' group of causes of haematemesis and melaena.

Because of the difficulty in diagnosing erosive gastritis we introduced the diagnostic criteria mentioned earlier. The results of these criteria are shown in *Table VII* and we would like to consider them here in more detail.

Associated Aetiological Factors.—A detailed history of all the drugs taken by the patient is essential in all cases of haematemesis and melaena, and it is necessary to check this again when the patient has been resuscitated. Careful retrospective review of case histories between 1940 and 1960 reveals very little detail of associated aetiological factors such as recent drug ingestion. Between 1960 and 1966 such associated factors were found in 26 per cent of cases. In 1967 we started to record all the drugs which had been taken by patients who were admitted with gastroduodenal haemorrhage in an attempt to establish drug-associated acute mucosal lesions as a cause of haemorrhage.

Table VII compares these three periods in the series and shows the effect of the introduction of the diagnostic criteria in 1969. In the period 1969–70, 85 per cent of cases of proved erosive gastritis gave a history of ingesting a known associated aetiological factor.

Banning and others (1965), in a 5-year follow-up study of gastroduodenal haemorrhage, found aspirin-associated bleeding in 33 per cent of the whole series. It should be noted, however, that 40 per cent of their cases were acute ulcers, a higher percentage than in most published series. Mailer and others (1965) obtained a history of aspirin ingestion in 5 out of 7 cases of gastric erosions in a series of 89 unselected cases. Between 1967 and 1970 we have found aspirin-associated bleeding in 20 per cent of all the patients who were admitted with haematemesis and melaena. We have also seen acute gastric erosions in patients who were known previously to have peptic ulcers. Neither a previous Polya gastrectomy nor vagotomy and drainage protects the patient. This has also been the experience of Bartlett and Ottinger (1966) and Croft and Wood (1967). We have not, however, seen erosive gastritis develop in the gastric remnant of a patient who had had a previous Billroth-I partial gastrectomy.

Immediate Gastroscopy.—The position of gastroscopy in the diagnosis of gastric lesions is clearly established. Mailer and others (1965) showed that gastroscopy gave a 57 per cent correct diagnosis in both acute and chronic ulcers and was the only way of diagnosing acute gastric erosions. Bartlett and Ottinger (1966) obtained a positive endoscopic diagnosis in 8 out of 9 cases of bleeding gastritis.

The introduction of fibre-optic endoscopy and its subsequent developments have made the direct visualization of the digestive tract from the crico-pharyngeal sphincter to the ampulla of Vater both safe and comparatively easy. Reference to *Table VII* shows that between 1960 and 1966, 16 per cent of cases who were subsequently proved to have acute erosions had positive gastroscopies, while between 1967 and 1969, 33 per cent had positive gastroscopies. However, many cases did not have a gastroscopy until 48–72 hours after admission, and others were unsuitable for the procedure with the rigid Herman–Taylor type of gastroscope.

In 1969 immediate gastroscopy was introduced. With the fibre-optic instrument, gastroscopy is easy to perform and can be done at the bedside with topical oropharyngeal anaesthesia. With immediate gastroscopy the diagnostic accuracy in the acute gastric mucosal lesion has risen to 85 per cent. We believe that immediate gastroscopy is essential in the diagnosis of erosive gastritis, as these lesions often heal in 48 hours with bed-rest. Subsequent gastroscopy is then essentially normal. For this reason we have included a negative, often late gastroscopy in the diagnostic criteria. Unheralded haemorrhage associated with drug ingestion, a normal barium meal, and a normal late gastroscopy strongly suggest acute erosive gastritis. Such cases are included under the designation 'diagnosis by exclusion' and the value of immediate gastroscopy in eliminating this group is shown in *Table VII*.

Barium Studies.—Within the context of the diagnostic criteria a normal barium meal is considered to be one in which there is no radiologically demonstrable lesion of the stomach or duodenum. Patients who have had previous gastroduodenal surgery are regarded as having abnormal barium studies.

Mailer and others (1965), in discussing the use of emergency radiology in the diagnosis of upper gastro-intestinal bleeding, demonstrated lesions in 79 per cent of cases. The results, as would be expected, were best in cases of chronic duodenal and gastric ulceration. They concluded that barium studies were useless in the diagnosis of acute erosions as all cases who were proved endoscopically had normal barium meals. This has also been our experience, but within the context of the diagnostic criteria we consider negative radiology to be of importance.

Surgical Attitudes to Erosive Gastritis.—The management of massive haemorrhage due to peptic ulceration is now standardized in most centres, with an early surgical bias in patients with a good ulcer history who are over 50 years of age. Despite this and improved facilities in resuscitation and anaesthesia the mortality remains high.

During the decade 1960–70, 7 per cent of all the cases who were admitted to our specialized gastric unit died. Of these bleeding peptic ulcer admissions, 20 per cent required emergency surgery, and this was associated with a mortality of 20 per cent. There was a similar mortality for the cases of erosive gastritis over the same period (*Table IX*). Despite these figures there appears to be, even in specialized units, considerable variation in the selection of patients for surgical treatment of erosive gastritis, and in the procedures used to control the haemorrhage. The current trend, if any, is towards more conservative operations, such as vagotomy and drainage. Carruthers, Giles, and Clark (1967), in discussing conservative surgery for bleeding peptic ulcers, had 13 cases of acute erosions in a series of 117 patients who were treated by emergency surgery. Of these 13 patients with erosions, 4 had partial gastrectomies, 3 of which continued to bleed postoperatively, and 1 died. The remaining 9 were treated by vagotomy and pyloroplasty, with a mortality of 33 per cent. These 13 cases represent 11 per cent of the series and their mortality was 30 per cent owing to continuing haemorrhage. Carruthers and others (1969) conclude that the conservative approach, that is, vagotomy and drainage, 'is not entirely satisfactory'. They also point out that continuing haemorrhage was only seen in cases of erosive gastritis and it was this that accounted for the high mortality.

Gray (1953), in the Lahey Clinic series, found that 11 per cent of his cases continued to bleed after blind partial gastrectomy and 63 per cent did so after laparotomy alone. Bartlett and Ottinger (1966) also reported 7 cases of continuing haemorrhage out of 14 cases of erosive gastritis who were treated by the Polya type of partial gastrectomy. The mortality was 28 per cent. Walt (1969) considered the problem of erosive gastritis in relation to hepatic trauma. Gastric erosions frequently complicate severe hepatic trauma and 7 out of 30 cases in his series did so. Five patients required emergency vagotomy and drainage procedures and 3 of these (60 per cent) suffered fatal continuing haemorrhage. Katz and Siegel (1968) stated: 'Gastroscopically proven acute mucosal lesions are generally amenable to conservative therapy', and of their series, 9 per cent required emergency surgery, with a mortality of 45 per cent; all the cases were treated by vagotomy and drainage. In their discussion these authors related their mortality to hepatic decompensation in cirrhotic patients. All the fatal cases, however, died from active haemorrhage due to the erosions. Erosive gastritis frequently complicates severe burns, and Foley (1969) found that 51 per cent of a series of 335 autopsy cases had acute erosions and that 41 (25 per cent) died of haemorrhage from these. He urges that the management of haemorrhage in a burned patient should closely parallel that in a non-burned patient.

The most conservative attitude is put forward by Banning and others (1965) and Markby (1965), who consider oversewing the bleeding point to be the operation of choice. However, these authors described solitary, or at the most two, high lesser-curve lesions.

We have always regarded erosive gastritis as a multifocal pathology in the gastric mucosa, and we have purposely excluded from this series of erosive gastritis the solitary, localized, acute, high lesser-curve lesions.

From the work so far quoted two facts emerge:—

1. The management of erosive gastritis lacks uniformity both in indications for and technique of surgical intervention.

2. The mortality in most published series owing to continuing haemorrhage is unacceptably high.

We believe that the management of erosive gastritis should parallel that of haemorrhage from peptic ulcers, with the same bias towards early surgery in patients over 50 years of age.

We believe that the results in *Table VIII* indicate that early aggressive surgery in the form of the Billroth-I partial gastrectomy would largely eliminate the problem of continuing haemorrhage. It would also appear that any lesser procedure than a total gastrectomy for continuing haemorrhage after a vagotomy or Polya gastrectomy is associated with a prohibitive mortality. Total gastrectomy itself is a formidable surgical procedure with a high intrinsic mortality. Recent personal experience with 1 case of converting a Polya to a Billroth-I type of anastomosis with dramatic control of haemorrhage introduces the possibility of a procedure with a lesser mortality in continuing haemorrhage.

Aetiological Concepts of Erosive Gastritis.— The association of aspirin ingestion and both occult and massive gastro-intestinal bleeding was first recognized by Douthwaite and Lintott (1938). Parry and Wood (1967) have shown that the tendency to overt bleeding bears no relationship to the tendency to occult bleeding. Croft and Wood (1967) suggest that the two disorders should be considered separately. In their series 78 per cent of the cases suffered occult bleeding when given aspirin and these results were reproducible 6–8 weeks later. They also studied the effect of repeated doses of aspirin on the gastric mucosa in 5 cases who were subsequently to undergo partial gastrectomy. The stomachs were studied immediately on removal and all the cases receiving aspirin had lesser-curve erosions. These authors suggested that aspirin may cause excessive exfoliation of gastric epithelial cells. To test this hypothesis they studied the rates of accumulation of DNA in gastric washings. In all the cases who had initially bled when given aspirin there was a significant increase in the rates of DNA accumulation when aspirin was given again. Patients who had not bled when first given aspirin did not show this increase in DNA accumulation in the gastric washings. As a result of these studies they proposed that aspirin stimulated epithelial shedding in excess of the ability of the mucosa to replace the surface cells. To support this hypothesis further they pointed out that cases of atrophic gastritis who never bled when given aspirin had a higher surface-cell turnover than normal. Neither vagotomy nor partial gastrectomy affected the susceptibility to bleed.

Anatomically, the majority of erosions occur in the upper stomach in the region of the high lesser curve. This predilection has been studied by Markby (1965), who considers the distribution of erosions to be related to the vascular anatomy in the region. Barlow, Bentley, and Walder (1951) studied the mucosal arteries in this region and showed that they differed from all the other areas of the stomach. In the upper lesser curvature there is no submucosal arterial plexus, the mucosal arteries arising as branches from the left gastric artery at the point where it divides into ascending and descending branches. The mucosal capillaries join to form veins which run vertically through the mucosa and pierce the muscularis to form large veins which accompany the mucosal arteries. They postulated that a local impairment of the mucous barrier is responsible for acute erosions and that the haemorrhage is of venous origin owing to the vascular anatomy in this area.

Much work has been done to support the concept of systemic as opposed to local factors in the causation of drug-associated gastro-intestinal haemorrhage. Wolf and Wolff (1947), in their classic work on their subject, Tom and his gastric fistula, were not able to injure his exposed mucosa by the direct application of aspirin. They were, however, able to produce mucosal erosions with topical irritants, including hydrochloric acid, after they had wiped or washed away the protective mucous layer.

Menguy and Masters (1965, 1967) and Menguy and Desbaillets (1967) have been responsible for much of the research on gastric mucus and its modification, both quantitatively and qualitatively, by drugs such as aspirin, phenylbutazone, and indomethacin. Gastric mucus is secreted by the surface cells and foveola of the gastric glands and is particularly abundant in the glands of the prepyloric region. Native mucus is thick, highly viscous, and cohesive, with a high pH. It can be separated into: a mucoid fraction consisting of polymers of glycoprotein molecules, a protein fraction immunologically identical with serum proteins, and a third fraction of as yet unidentified polypeptides.

The glycoprotein polymers consist of long filaments which have a polypeptide backbone to which are attached oligosaccharide side-chains. Normal glycoproteins are only slowly hydrolysed by proteolytic enzymes such as pepsin. This resistance to proteolysis is due to the spatial configuration of the oligosaccharide side-chains. Menguy and Masters (1965, 1967) and Menguy and Desbaillets (1967) have extensively studied the effect of acute inflammatory drugs on gastric mucus and basically two facts emerge:—

1. Inflammatory drugs decrease the rate of secretion of gastric mucus and therefore the rate of renewal of the mucous barrier.
2. The mucus which is secreted is chemically altered. Particularly, the carbohydrate content of the glycoproteins is reduced.

It has been shown experimentally that if the carbohydrate side-chains are removed by appropriate chemical means, then mucoproteins are readily hydrolysed by trypsin or pepsin (Menguy and Masters, 1965). The anti-inflammatory drugs all reduce the carbohydrate content of gastric mucus, particularly I-fucose and hexosamine. A possible hypothesis is that the drug-modified gastric mucus is hydrolysed by refluxed bile and pancreatic juices, thus removing the normal protective mucous barrier and exposing the mucosa to endogenous acid, resulting in the production of erosions. Kowalewski, Schier, and Koheil (1970) have studied the response of canine gastric mucosa to histamine after experimental impairment of the mucous barrier. They removed the mucous barrier by instilling 2 N saline into fundic pouches. Histamine infusion then produced maximal acid peptic activity in a gastric mucosa which was not protected by the normal mucous barrier. Numerous acute mucosal lesions resulted.

Can the efficiency of the Billroth-I partial gastrectomy in controlling haemorrhage be explained by this hypothesis? The poor results obtained by the Polya gastrectomy may be due to the fact that tryptic digestion of mucoprotein by refluxed bile and pancreatic juices continues in the gastric remnant postoperatively. In addition, because of the nature of the Polya anastomosis the normal mechanism for the inhibition of acid production is lost. Sokolov (1904) noted that acid in either the antrum or the duodenum caused inhibition of further acid production. With the Polya gastrectomy the antrum is removed and the duodenum is by-passed.

Du Plessis (1960, 1962) and Lawson (1964) have studied regurgitant gastritis in detail. Reflux of the duodenal contents into the stomach under experimental conditions produces a chronic gastritis. Changes in the mucosa are maximal when both bile and pancreatic juices are refluxed, and least with pancreatic juices alone (Lawson, 1964). Lawson (1964) also studied reflux following both the Polya anastomosis and the Billroth-I procedure. Microscopical changes of gastritis were limited to a 2-cm. area from the anastomosis in the Billroth-I type of partial gastrectomy. The stomach proximal to this area was entirely normal. By comparison the changes following the Polya anastomosis extended over halfway up the gastric remnant. Lawson (1964) confirmed that these changes were due to reflux into the gastric remnant and were not due to operative trauma by use of the Roux gastrectomy. From this work we may conclude that pancreaticobiliary reflux into the gastric remnant is less after the Billroth-I operation than after the Polya anastomosis.

In addition, it is a clinical observation that the Billroth-I gastrectomy is often slower to drain postoperatively than the Polya procedure. We believe that pancreaticobiliary secretions do not enter the gastric remnant for 48–72 hours postoperatively following the Billroth-I gastrectomy. This allows residual erosions to heal, and in the absence of further enzymatic mucoproteolysis the protective mucous barrier is re-established. It would also seem logical to assume that once the stimulus that originally altered the glycoprotein fraction is removed the mucus would return to normal.

The case against vagotomy and drainage is less clear. All such series which have been considered in this discussion, however, were associated with a high rate of continuing haemorrhage and therefore mortality. We have been unable to find any comparable work on reflux following vagotomy and drainage to that on the Polya and Billroth-I gastrectomies. Biliary reflux is said to occur more frequently with a gastro-enterostomy than with a pyloroplasty, and gastritis is frequently seen endoscopically after both operations. Normally, antral acidification results in an increase in mucous secretion and an increase in its carbohydrate content. This is abolished by vagotomy. Emas and Grossman (1967), in studies on dogs, have shown that there is no change in maximal acid output in response to gastrin after vagotomy and drainage. The presence of gastrin-induced acid plus the inability following vagotomy to increase mucous production may explain the high rate of continuing haemorrhage from erosive gastritis with this operation. The role of biliary reflux in these cases needs further investigation.

Acknowledgements.—The authors wish to acknowledge the help of Mr. Norman C. Tanner, who supplied many of the cases presented in this series, Mr. J. C. Nicholls and Mr. P. Carleton for helpful criticisms, and Miss Anne Reffold for typing the manuscript.

THE REVERSIBILITY OF POSTGASTRECTOMY ALKALINE REFLUX GASTRITIS BY A ROUX-EN-Y LOOP

BY H. H. LAWSON

DEPARTMENT OF SURGERY, UNIVERSITY OF THE WITWATERSRAND AND BARAGWANATH HOSPITAL, JOHANNESBURG, SOUTH AFRICA

SUMMARY

Partial gastrectomies were carried out in 6 dogs. All developed stomal gastritis. Prevention of reflux by a Roux-en-Y loop allowed the mucosa to return to histological normality. These findings support the use of this procedure for the condition of postgastrectomy reflux gastritis in human subjects, and explain the need for a vagotomy at the same operation.

CHRONIC gastritis has been shown to be present in the majority of stomachs after partial gastrectomy (Palmer, 1954). Subsequently, du Plessis (1962) described a clinical syndrome which he attributed to gastritis caused by unregulated reflux of bile and pancreatic juice into the stomach through the new stoma. The same author reported good results in human subjects with postgastrectomy alkaline gastritis when bile and pancreatic juice were excluded from the stomach by a Roux-en-Y loop. Van Heerden, Priestley, Farrour, and Phillips (1969) also recorded good results in human subjects after the same procedure.

Although the clinical evidence suggests that gastritis is reversible when reflux is prevented, there appears to be no recorded experimental work that has examined this hypothesis. For this reason the present investigation was undertaken.

MATERIALS AND METHODS

A Polya partial gastrectomy was carried out in 6 unselected mongrel dogs. As far as could be judged, the whole antrum was removed and a control biopsy was taken from the cut end of the stomach.

At a variable time after the partial gastrectomy a second operation was performed on the same animal. A 5-cm. incision was made through the anterior wall of the stomach and a biopsy was taken from both the anterior and posterior walls of the gastrojejunal junction. The gastrectomy wound was closed and the proximal or afferent loop was disconnected from the stomach. The site of the disconnexion was closed and the proximal loop containing bile and pancreatic juice was anastomosed to the side of the jejunum at least 60 cm. from the duodenojejunal junction in order to be sure that reflux did not occur. No vagotomy was added.

Table I.—THE TIMING OF THE PROCEDURES

DOG NO.	DURATION OF PARTIAL GASTRECTOMY	DURATION OF ROUX-EN-Y LOOP
1	6 months	6 months
2	6 months	1 year
3	6 months	2 years
4	1 year	2 years
5	2 years	6 months
6	2 years	6 months

When the dog was subsequently killed, the gastric remnant was opened along the greater curvature and rolls of mucosa were prepared for histology as described by Stein (1937). It was then possible to observe in the same animal the normal stomach, the stomach after gastrectomy, and the postgastrectomy stomach after a Roux-en-Y loop.

Table I summarizes the timing of these procedures.

RESULTS

The results were remarkably constant in the 6 animals.

In all cases the control biopsy from the cut end of the gastric remnant showed fundic tissue, indicating that the whole antrum had been removed. The

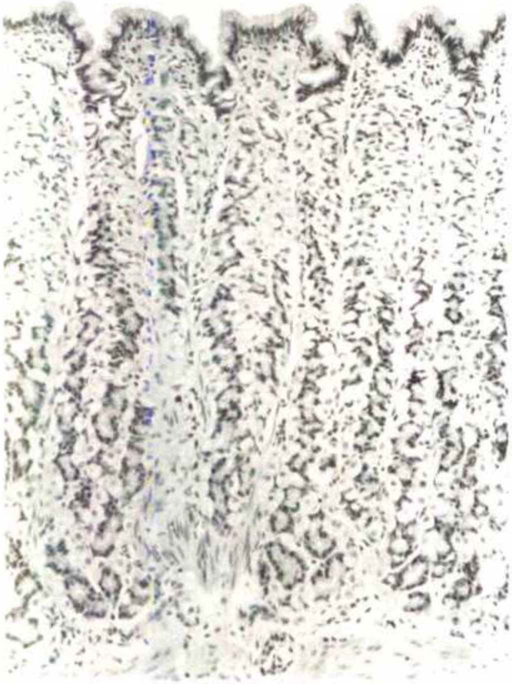

FIG. 1.—Normal fundic mucosa. Note the shallow foveolae and the wide layer of chief and parietal cells. (× 150.)

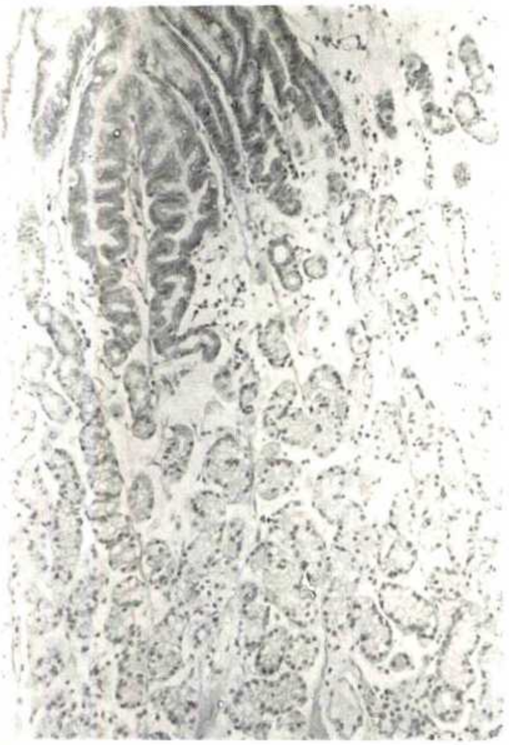

FIG. 2.—The 'corkscrew' appearance of chronic gastritis with deep foveolae and loss of chief and parietal cells. (× 150.)

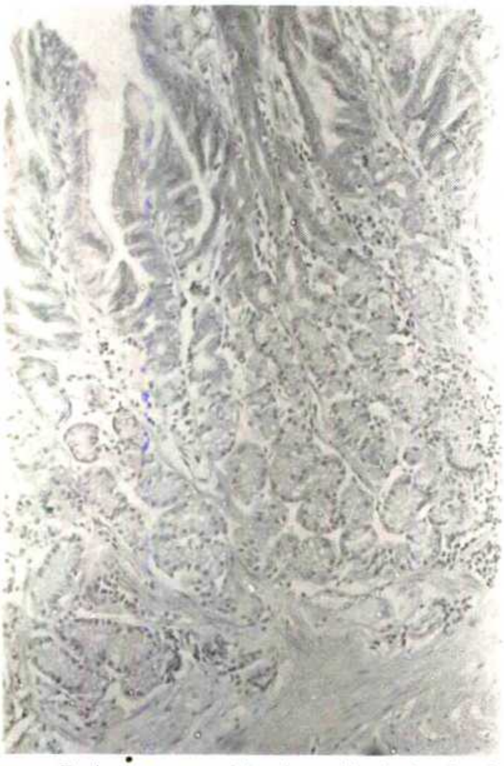

FIG. 3.—Further appearance of chronic gastritis. An intrafoveolar papilla can be seen. (× 150.)

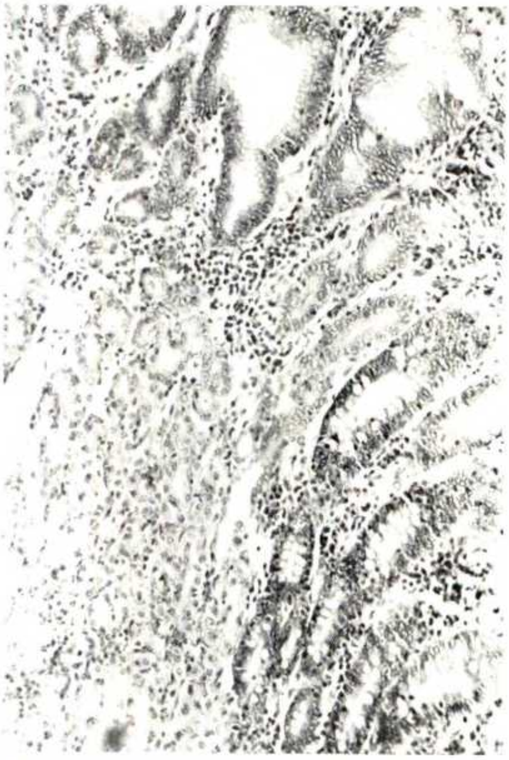

FIG. 4.—The stomal mucosa after a Roux-en-Y loop. The normal jejunum can be identified by the goblet cells. The adjacent normal fundus has chief and parietal cells. (× 150.)

appearance of the normal fundus is shown in *Fig.* 1, nd has been well described elsewhere (Palmer, 954). The points of special significance are the foveolar depth, which is only one-sixth of the total width of the mucosa, the orderly layers of parietal cells near the lumen with chief cells on the lamina muscularis mucosa, and the normal mitotic activity.

In all cases the mucosa after gastrectomy showed severe gastritis. No obvious difference was seen either in the type of gastritis or in the extent of gastritis relative to the duration of the gastrectomy. n all cases the gastritis extended throughout the length of the biopsy specimen, although there were healthy areas between the areas of gastritis.

The changes seen are illustrated in *Figs.* 2 and 3. In *Fig.* 2 there is the typical 'corkscrew' appearance of the foveolae owing to elongation downwards towards the lamina muscularis mucosa. The foveolar depth is therefore considerably increased with a corresponding decrease in the numbers of chief and parietal cells. *Fig.* 3 illustrates another characteristic feature of gastritis, where a papilla of surface epithelium may be seen in the depth of a foveola. There was a marked increase in the mitotic activity, as has been previously described in this type of gastritis Lawson, 1964).

When the animals were sacrificed after reflux had been prevented by a Roux-en-Y loop, the mucosa at the gastrojejunal junction had returned to histological normality in all 6 dogs. This is shown in *Fig.* 4, where jejunal mucosa can be identified by the large number of goblet cells in the surface epithelium, and adjacent fundic mucosa can be recognized by the parietal cells. In the fundus the depth of the foveolae was normal, and the corkscrew appearance had disappeared. The mitotic activity was normal.

DISCUSSION

In the present investigation gastric mucosa which was shown to be normal histologically became grossly abnormal after a Polya gastrectomy. When reflux was prevented by a Roux-en-Y loop the mucosa returned to histological normality. The deduction from this observation is that refluxing alkaline juice is a factor in the production of gastritis, and this is supported by other experimental evidence which has shown that bile and pancreatic juice cause chronic gastritis in the dog (Lawson, 1964; Menguy and Max, 1970).

Gastritis has been shown to be present in 50 per cent of postgastrectomy patients (Palmer, 1954) and in many normal human subjects (Hebbel, 1949). Both these observations could be explained by unregulated reflux of duodenal contents.

The mechanism by which bile acts is probably through interference with the permeability of surface mucin so that H^+ ions leave the stomach and diffuse into the mucosa, which is then damaged (Davenport, 1968; Geal, Phillips, and Summerskill, 1970).

In the series of dogs reported here it was not possible to relate the duration of the gastrectomy to the extent of the gastritis, as biopsies were limited to the area of the stoma. The full extent of the gastritis could only be assessed by the examination of the whole stomach. However, the type of gastritis appeared to be the same regardless of the duration of the gastrectomy. It seems that protection from reflux for 6 months is sufficient to reverse gastritis, which may have been present for up to 2 years. It is possible that a shorter period of protection from reflux may also be effective. Within the limitation of this experiment it may also be said that even if gastritis is present for 2 years it is worth while preventing reflux as a return to histological normality does occur.

Lambley (1962) described anastomotic ulceration following the Roux-en-Y loop procedure. Because of the reappearance of chief and parietal cells after this operation it is likely that acid secretion will increase. Therefore a vagotomy would be an essential part of the procedure in human subjects (du Plessis, 1962).

Acknowledgements.—The author thanks Professor du Plessis for his continuing support and constructive criticism. All experimental procedures were carried out in the Michael and Janie Miller Experimental Laboratory, Department of Surgery, Witwatersrand University. The histology was prepared by Mr. L. Triegaard, and the photomicrographs by Mr. E. Wesselo.

This work was supported by Medical Research Council Grant M14/71/51 and a grant from the Round Table Association of South Africa.

THE LESION OF THE SECOND CANCER OF THE LARGE BOWEL

By R. J. HEALD and H. E. LOCKHART-MUMMERY
ST. MARK'S HOSPITAL, LONDON

SUMMARY

A survey is presented of the clinical experience at St. Mark's Hospital with 83 patients suffering from metachronous cancer of the large intestine. It was found that there was a much improved chance of cure in those who were attending the follow-up clinic at the time of the occurrence of their second growth. The reasons for this and the implications in cancer prophylaxis are discussed.

It is now well known that primary cancers of the large intestine may be multiple (Ginzburg and Dreiling, 1955; Moertel, Bargen, and Docherty, 1958; Bussey, Wallace, and Morson, 1967). If two or more are present at the same time they are described as 'synchronous'. If the second cancer develops later, usually after the first has been cured by surgery, then the term 'metachronous' is generally applied to it. The records of St. Mark's Hospital contain details of 4884 survivors from operations for cancer of the colon or rectum between the years 1928 and 1970. Of these, 83 patients (1·6 per cent) had had operations for second or metachronous cancers. This paper is a clinical study of the presentation, pathology, and management of these second or subsequent growths.

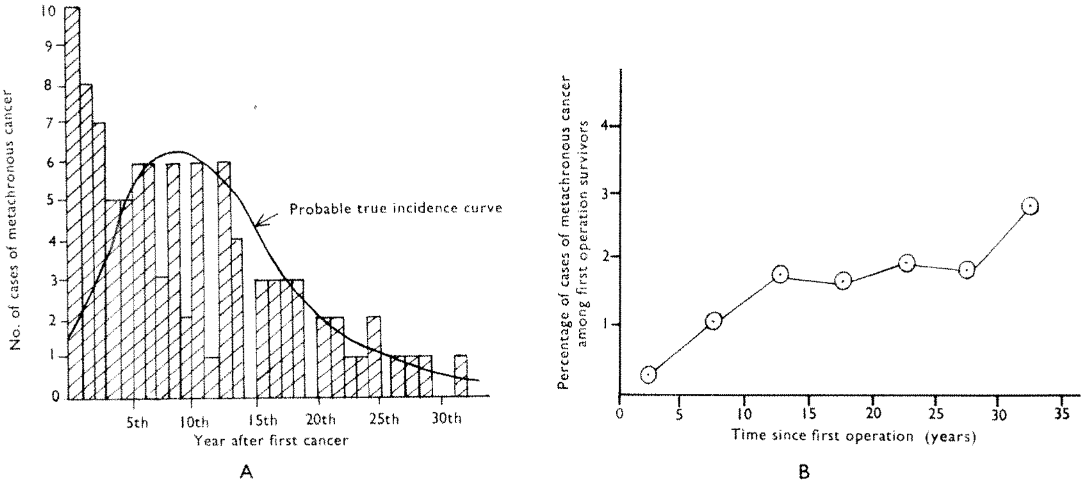

FIG. 1.—A, Incidence of metachronous cancers. B, Incidence of metachronous cancers as a percentage of patients who were alive and at risk.

Since their occurrence is a rare event many clinicians expect unusual cancers. Often they are viewed with inordinate gloom and are regarded as the harbingers of doom. Conversely, some authorities (Gruber, Schein, and Gliedman, 1970) have claimed that they are more benign than other cancers and that cure rates are unexpectedly high. We have therefore listed the features of these second growths to see if they differ in any way from other large-bowel cancers. We have then tried to assess how th diagnosis was made, whether it could or should hav been made earlier, and whether routine visits by th patient to the follow-up clinic had been of value Finally, we have tried to draw some conclusion which may be of value in the future management o patients with large-bowel cancers.

PATIENTS STUDIED

The patients who were studied were divided int two groups:—

Group A included 56 cases in whom both operations were performed at St. Mark's Hospital.

Group B comprised 27 cases in whom the firs growth had been operated on elsewhere.

Care has been taken to exclude patients in who cancer supervened on familial adenomatosis or o ulcerative colitis. In addition, local recurrences an implantations were excluded in the manner describe by Bussey and others (1967).

RESULTS

Timing of the Second Growth.—*Fig.* 1 A show the actual number of cases of second cancer each yea after the first operation. It seemed very likely tha the apparent high incidence of second growths in th first 2 years was artificial, and that many of thes must have been synchronous growths which ha been missed at the first operation. We looked carefully into the notes of these patients and found tha this was indeed the case. The reasons for missin these synchronous cancers are considered in detai later. However, it is probable that the true incidenc of metachronous cancer follows the corrected line o the histogram. Using this correction the averag nterval between first and second operations was just ver 11 years.

Fig. 1 B shows the incidence of subsequent cancers s a percentage of the patients at risk. The low ncidence in the first 5 years probably reflects the election of patients with a 'clean colon' by the first peration and by the exclusion of the 'missed ynchronous' cancers. The subsequent tendency for he incidence to rise may simply be the result of the creasing age of the survivors.

able I.—Association of Benign Tumours in Group A

Total No. of patients	56
No. with adenomas	29
No. with villous papilloma	6
Total No. with benign tumours (1 patient had both types)	34 (60 per cent)

Table II.—Site of Metachronous Cancers

Site	*No.*
Caecum and right colon	23
Transverse colon	9
Descending colon	7
Sigmoid colon	27
Rectum	24

Table III.—Pathological Features of Second or Subsequent Growths

Pathological Features	*Occurrence* (per cent)
Histological grade	
Low	29
Average	53
High	18
Dukes staging or degree of spread	
'A'	24
'B'	36
'C'	20
Inoperable	20

Association with Benign Tumours.—A full tatistical review of this important subject is in reparation. It is complicated by variations throughut the world in the definition of the words 'polyp' nd 'adenoma'. Applying the St. Mark's criteria it as previously been emphasized that the incidence of econd cancers is doubled in those patients whose irst operation specimen also contained adenomas. n group A (both operations at St. Mark's), where he chance of their discovery was greatest, benign umours were extremely common (*Table I*). They vere discovered at some stage (i.e., on one or other peration specimen or during follow-up) in almost wo-thirds of the patients, which is over double the ncidence in patients with one cancer and over ten imes that in the population as a whole. In 7 cases ocal carcinoma was actually shown to be present in a enign lesion.

Site.—The site of second or subsequent cancers is hown in *Table II*. This is a fairly normal pattern of istribution if one takes into consideration the fact hat the majority of first cancers had been in the ectum or sigmoid area. There is a slight preonderance of right-sided lesions but the figures are oo small to be significant.

Pathological Features.—Bussey and others 1967) showed that the stage and grade of the first rowth tended to be unusually favourable. This is robably because there are more long-term survivors rom operations for less malignant and less advanced growths. It does not imply an intrinsic tendency for multiple growths to be more benign.

The stage and grade of the second or subsequent growths are shown in *Table III*. The distribution of low, average, and high grades of malignancy is not significantly different from that found in most large series. However, the discovery of 24 per cent of the growths at stage 'A' and 36 per cent at stage 'B' is a significant improvement upon the staging usually found.

Table IV.—Stage of the Growth in Relation to Follow-up

Stage of Growth	Patients attending Follow-up Clinic (per cent)	Patients not attending Follow-up Clinic (per cent)
'A'	27	17
'B'	42	24
'C'	22	12
Inoperable	9	47
'A' and 'B' together (a good chance of cure)	70	40
'C' and inoperable (probably incurable)	30	60

Table V.—Stage of the Growth related to the Method of making the Diagnosis

'Primary' Diagnosis	Stage of Growth			
	'A'	'B'	'C'	Inoperable
No symptoms and sigmoidoscopy	9	3	—	—
Symptoms and sigmoidoscopy	10	6	2	3
Symptoms and barium enema	2	12	3	1
Signs, i.e., mass felt	1	12	9	6
Laparotomy diagnosis	0	0	1	2

The Value of Follow-up.—The figures for the stage and grade of the growths show that metachronous growths have the usual distribution of malignant potential but are found at a more favourable stage. The inference is that the second growths are being diagnosed earlier. We wondered if this improvement reflected the efforts of the follow-up clinic. We therefore divided group A into two subgroups: (1) those who were attending the follow-up clinic at the time when the second growth developed, and (2) those who had defaulted or had been discharged. The results are shown in *Table IV*. The control group is small (17 patients), but the 41 growths in the 'follow-up' group have been diagnosed at an appreciably earlier stage than is found in most series. Conversely, no less than 8 of the 17 patients who were not attending the clinic had inoperable growths, which is five times the incidence in those patients who attended a follow-up clinic.

The Method of making an Earlier Diagnosis.—*Table V* shows the way in which the diagnosis was arrived at. A small group of patients had no symptoms and the growth was detected entirely by follow-up sigmoidoscopy. The great majority, however, whether attending the clinic or not, did have symptoms which led on to investigation. These were essentially the same symptoms as those produced by any large-bowel cancer. Pain and bleeding each occurred in about half of the patients, but bowel upsets and more general symptoms were also common. In some of the patients a mass was detectable in the abdomen or on rectal examination, i.e., the diagnosis was made on physical signs. Finally, a small number defied all investigations and the diagnosis was made only by laparotomy. Clearly, in many patients the various examinations were complementary, but it was generally clear that the decision to operate depended on one critical discovery and only this is listed in *Table V* (e.g., if a mass was found and investigations confirmed its nature it is only listed in the 'mass' column). *Table VI* shows a marked deterioration in the staging when a growth produces symptoms, and a further deterioration when it has become palpable. These findings argue strongly for early sigmoidoscopy and barium enema in the diagnosis of large-bowel cancer.

Table VI.—STAGE OF THE GROWTH RELATED TO THE CLINICAL PRESENTATION

CLINICAL PRESENTATION	STAGE OF GROWTH		
	'A' (per cent)	'B' (per cent)	'C' AND INOPERABLE (per cent)
No symptoms or signs	75	25	0
Symptoms but no signs	30	45	25
Signs	4	40	56

Particular Pitfalls.—As the clinical history of the patients was studied it became apparent that growths in certain sites were especially liable to cause difficulty.

The Distal Limb after Perineal Excision.—There were 7 patients in this group. They all presented with discharge or with pain in the perineum. Diagnosis was often delayed because the distal limb was forgotten or because technical difficulties prevented the passage of the sigmoidoscope.

The Stump after Hartmann's Operation.—Two patients had growths in this site and both growths were missed for long periods, despite discharge from the stump through the anus.

Cancer of the Caecum.—This notoriously elusive diagnosis was a constantly recurring problem, with frequent failure of the barium enema to reveal the lesion. More recently the double-contrast enema has improved the radiological results, though failures do still occur.

Missed Synchronous Cancer.—On 23 occasions (in 21 patients) a second or third operation was performed within 2 years of the first. Consideration of the clinical details leads us to believe that 18 of the growths were present at the first operation but were not detected at that time. These patients have been discussed previously because they were removed from the figures to produce the 'corrected incidence' curve in *Fig.* 1. We thought it would be instructive to investigate the reasons for these synchronous lesions being missed. *Table VII* shows that in 12 of the 18 patients the relevant investigation had not been performed. In some this was because pain prevented instrumentation, but in most it was because attention was focused on the first lesion and further diagnostic activities were forgotten.

We believe that it is wrong to operate on any part of the large bowel for cancer without a full investigation of the remainder of the bowel. In particular the following individual cases underline some specia dangers.

1. *Resection of the colon without prior sigmoidoscopy* In 1 patient a total colectomy and ileorectal anastomosis for a second cancer plus polyps were performed above a third (rectal) cancer. Sigmoidoscopy had been deferred because of local pain. In another patient a transverse colectomy elsewhere was completed without detecting a second (rectosigmoid) carcinoma. No sigmoidoscopy had been performed, although the lesion was later seen and biopsied through the sigmoidoscope.

Table VII.—REASONS FOR MISSING SYNCHRONOUS CANCER IN 18 PATIENTS

Reason	*No. of Patients*
Sigmoidoscopy relevant but omitted	5
Sigmoidoscopy performed but lesion missed	1
Barium enema relevant but omitted	7
Barium enema performed but lesion missed	3
No details available	2

2. *Excision of the rectum without both a barium enema and a thorough palpation of the colon*: In 1 patient a carcinoma of the splenic flexure was missed when a sigmoid lesion was resected. In another patient a caecal cancer, the patient's third, was missed at operation for a growth in the sigmoid. The patient died of obstruction from the missed lesion 3 weeks later.

In yet another patient a recurrent growth was seen on sigmoidoscopy, but a different growth (the second primary) was removed and the recurrence was left in the upper rectum.

In none of these cases had a barium enema been performed.

3. *Failure to consider the possibility of metachronous colon cancer at laparotomy for some other pathology* In 1 female patient a carcinoma of the ovary was removed, but a second colonic cancer (at the splenic flexture) was missed.

DISCUSSION

A second cancer of the large bowel is unlikely to occur many times in the experience of any one surgeon. For this reason, with his attention focused on one lesion, he is in particular danger of missing the second growth. Our experiences with the 'missed synchronous' group emphasize the importance of a fixed routine which leaves nothing to chance. No resection of colon should ever be undertaken without an adequate preoperative sigmoidoscopy, as it is all too easy to miss a small polypoid lesion in the rectum or rectosigmoid which may be impalpable from the abdomen. Further, no resection or excision of the rectum should be done without a good double-contrast enema to demonstrate the rest of the large bowel. Even if the surgeon palpates the colon carefully at laparotomy it is all too easy to miss the presence of a small polyp or carcinoma, particularly in a fat patient; the surgeon who claims he can feel any polyp in the colon at laparotomy is deceiving himself. With good preparation and modern techniques a double-contrast enema is nearly always possible, even if the rectal growth is somewhat obstructive.

Another important feature of this series is that it contains a group of patients who were attending a follow-up clinic at the time when their second cancer developed. The histological grading of the metachronous growths is certainly no worse than other large-bowel cancers, and we have shown that the diagnosis was made at a much earlier stage in those who were attending the clinic. This is due in part to the discovery of some symptomless growths by sigmoidoscopy or barium enema—a group in which at least 90 per cent of the patients can expect to be cured by surgery. Another factor, however, which is difficult to quantify but in our view important is the early questioning of the patient about symptoms which might otherwise have been overlooked. It is one of the main aims of this paper to draw attention to the possibility of a second cancer developing, and to emphasize the value of investigating suspicious symptoms at an early stage.

We believe that all patients who have had a colonic or rectal cancer removed, particularly if there have been associated adenomas, should be followed up for life. It is difficult, however, to decide how frequently the various investigations should be performed. Regular sigmoidoscopy is mandatory, and perhaps the fibre-optic colonoscope will make a real impact in the future. It is our personal view, however, that a good radiology department can produce more comprehensive pictures of the colonic mucosa with greater certainty than the colonoscope. We believe that the purchase of good machinery for preparing the colon, if combined with enthusiastic radiological co-operation, is a better investment than the expensive colonoscope. If time is available, a double-contrast enema every 2 years combined with sigmoidoscopy every 6 months will yield a modest harvest of polyps and an occasional but consolingly curable cancer. This is perhaps an ideal which will not be widely realized, but at least both doctor and patient must be aware that any new bowel symptoms still demand investigation and cannot be shrugged off because of the previous operation.

Finally, our experience with this series suggests that our attitude to the diagnosis of cancer of the colon and rectum should change. Morson (1971) has produced evidence that the evolution of cancer of the colon and rectum is relatively slow. The fact that follow-up has proved of such value accords with this idea, and implies that growths of the large intestine are amongst the most suitable for prevention by regular clinical investigation, perhaps as a part of 'executive checks'.

Furthermore, the series has demonstrated the value of making the diagnosis before the growth has become palpable, and preferably before it has become symptomatic. It is apparent, therefore, that the knowing hand upon the abdomen and the passage of the informed rectal digit are no longer enough. Rather, the colon at risk must be patrolled with the sigmoidoscope and the double-contrast enema, and our efforts should be directed towards improving still further the quality of colon radiology.

Acknowledgements.—We are indebted to the surgeons of St. Mark's Hospital whose patients have been studied, and to Dr. B. C. Morson and Dr. H. J. R. Bussey for their assistance. The expenses of this investigation were met out of a grant from the Cancer Campaign.

HIRSCHSPRUNG'S DISEASE

A CLINICAL REVIEW

BY P. W. DAVIS AND D. B. E. FOSTER
UNITED CARDIFF HOSPITALS, LLANDOUGH, PENARTH

SUMMARY

1. Experience with 38 cases of Hirschsprung's lisease seen over a 20-year period is described.

2. Only 24 per cent of cases presented with a combination of symptoms and signs such as to suggest the correct diagnosis on clinical grounds.

3. Barium-enema examination carries a high true-positive' rate, but cases reported as negative must be viewed critically. A radiological diagnosis of diopathic megacolon should not be accepted without supplementary rectal biopsy and/or anorectal pressure studies.

4. Survival without surgery is compatible with Hirschsprung's disease, but the dangers of enterocolitis nust be acknowledged.

5. Rectosigmoidectomy, which includes resection to an area of normal innervation proximally and excision of part of the internal sphincter of the rectum distally, produces a satisfactory late functional result at an acceptable mortality-rate.

6. A colostomy prior to rectosigmoidectomy is advisable when there is a history of repeated attacks of subacute obstruction and one or more episodes of enterocolitis. A colostomy after rectosigmoidectomy is advisable in those cases which are submitted to laparotomy for intestinal obstruction in the period following operation, even when no mechanical cause for obstruction is demonstrable.

7. Patients with problems relating to coprostasis following treatment of congenital anorectal disorders

should be submitted to rectal biopsy, since a proportion of these patients reveal a deficiency of innervation of the distal large bowel which approximates to that seen in Hirschsprung's disease.

ALTHOUGH paediatric surgical practice has come to be concentrated in special centres, and this evolution in the pattern of treatment will continue, there will remain regions in which this branch of surgery is undertaken by general surgeons with a special interest in paediatric surgical problems. In this context we have thought it useful to assess our experience with Hirschsprung's disease over the past 20 years to enable comparison with experience in other centres and, since different types of operation have been proposed in recent years, to evaluate the need for changing our operative technique.

FIG. 1.—Harald Hirschsprung (1830–1916), Professor of Paediatrics, Copenhagen.

Harald Hirschsprung (*Fig.* 1), Professor of Paediatrics, Copenhagen, first published a description of the disease which bears his name in 1888. He reported 2 children aged 11 months and 7 months respectively, giving a full clinical history of each patient to the time of death and describing in detail the post-mortem macroscopic appearance of the dilated colon. However, Tittel (1901) was the first person to draw attention to the absence of ganglion cells in the narrow distal segment of the bowel.

In Hirschsprung's disease the infant or child commonly presents with symptoms and signs of large-bowel obstruction. This obstruction is fu
tional and is associated with an absence of gangli
cells between the muscle coats and between the in
muscle layer and the mucosa. Large irregular ner
fibres are seen in the same area. There is a transitio
zone showing a tendency to a more normal pattern
innervation before normally innervated bowel
reached. The process may be confined to the m
distal part of the rectum where it necessarily invol
the internal sphincter mechanism. However, t
aganglionosis may spread far proximally and invol
small bowel. No good evidence of 'skip' lesi
exists.

A simple explanation of the disease may be t
since the parasympathetic component of bo
innervation is lacking, a functional state of sympathe
overactivity, or muscle spasm, exists and hence th
is a functional obstruction. In the past both sym
thetic blockade and lumbar sympathectomy have be
used and abandoned because of poor results.

Gannon, Noblet, and Burnstock (1969) investigat
by a fluorescent technique the adrenergic innervati
of normal and aganglionic regions of bowel fr
patients with Hirschsprung's disease. In nor
bowel the adrenergic nerves end around intramu
ganglion cells. In aganglionic bowel the adrener
nerves form dense varicose plexuses in both muscula
externa and muscularis mucosae. Gannon and oth
(1969) suggested that the cause of megacolon
Hirschsprung's disease is a lack of nervous pathwa
controlling the *intrinsic* reflexes which is proba
congenital in origin. In a normal person, filling t
rectal ampulla beyond a critical pressure results
internal sphincter relaxation. The response in
patient with Hirschsprung's disease is a further rise
internal sphincter contraction (Howard, 1969). T
response to some extent explains the functional cau
of coprostasis in these patients, and it can be used al
as the basis of a test which aids the different
diagnosis of megacolon.

For the present some form of surgical treatme
remains necessary for the infant or child with acute
recurrent intestinal obstruction caused by Hirsc
sprung's disease. Sir Frederick Treves published
report in 1898 of a rectosigmoidectomy performed
a 6-year-old girl with Hirschsprung's disease.
laid emphasis on the narrow distal segment and i
probable origin as a congenital defect. The patie
was treated by rectosigmoidectomy and was left with
colo-anal anastomosis. She was reported on 59 yea
later by Daintree Johnson, Davis, and Evans (195
At that time she led an active life with two bow
actions daily and satisfactory voluntary contr
Surgical treatment was established on a firm bas
with the publication of the work of Swenson and B
(1948), who described a technique of rectosi
moidectomy which was evolved initially on a laborato
and subsequently on a clinical basis. Swenson h
continued to make contributions to the technique
this operation, particularly in emphasizing t
necessity for low-oblique section of the rectum
include the posterior half of the internal sphinct
mechanism (Swenson and Donnellan, 1969). In
effort to avoid the difficulties related to pelv
dissection and anastomotic problems in infants, and
retain rectal sensation, alternative techniques ha
been devised, most of them based on the retrorect

pull-through technique of Duhamel (1960) and the endorectal pull-through technique of Soave (1964).

In the United Cardiff Hospitals the procedure of choice has been rectosigmoidectomy, and the results will show that there is no compelling reason to change this. One still awaits for convincing evidence that the alternative methods produce better results. It is worth noting that Swenson and Donnellan (1969) have now followed up patients for up to 20 years and claim good results in more than 95 per cent of cases; this includes not only faecal continence and rectal sensation but also normal bladder and ejaculatory function.

Table I.—NUMBERS, SEX, AND MORTALITY OF PATIENTS WITH HIRSCHSPRUNG'S DISEASE

Positive rectal findings	16	42
Diagnostic combination	9	24
Total No. of patients	38	100

MATERIALS AND METHODS

A review of cases seen in the United Cardiff Hospitals in the 20 years from 1950 to 1969 is presented. Some cases have been discarded because of the absence of post-mortem histological proof of Hirschsprung's disease, though one cannot always be sure that post-mortem material has included the anorectal region. On the other hand, if a case has behaved in every way, clinically and radiologically, as Hirschsprung's disease it has been included although a post-mortem examination has not been obtained. Thirty-eight cases of Hirschsprung's disease have been traced and their sex and mortality are indicated in *Table I*.

Symptoms and Signs (*Table II*).—With regard to clinical diagnosis the most common *single* feature was abdominal distension (35 out of 38 cases), but just over half of the patients had a background of vomiting combined either with abdominal distension or with an abnormal bowel habit, the latter varying from absolute constipation to intermittent constipation or occasional watery stools. Less than half had noteworthy rectal findings, varying from a definite stricture to a so-called 'tight' sphincter, and in some instances the sudden expulsion of meconium or faeces on withdrawal of the finger. Only one-quarter of the 38 patients had a combination of symptoms and signs which strongly suggested a diagnosis of Hirschsprung's disease on clinical grounds.

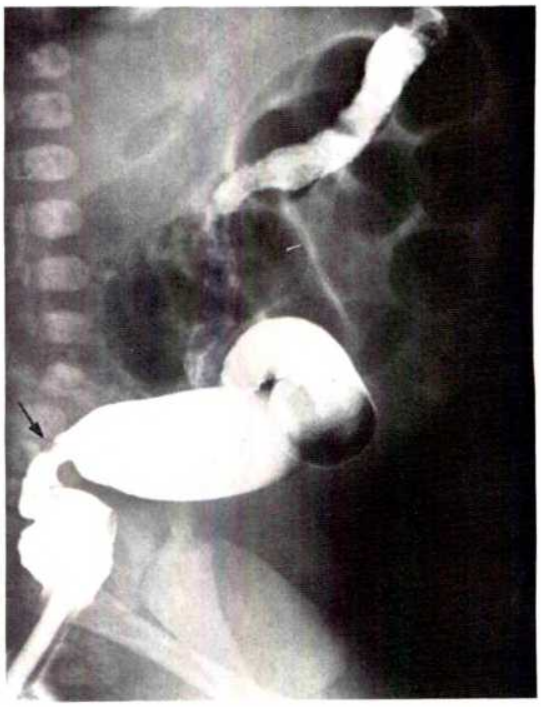

FIG. 2.—Barium enema (lateral view) of a neonate showing dilatation of the sigmoid colon proximal to the narrow segment, which is clearly seen at the rectosigmoid junction.

Radiology (*Fig. 2*).—Plain films of the abdomen are not helpful in the specific diagnosis of Hirschsprung's disease, but a barium enema is essential, and a 24–48-hour post-evacuation film is considered to be particularly useful in demonstrating the characteristic retention. Twenty-eight patients with subsequent histological proof of Hirschsprung's disease had barium-enema examinations. The results were categorized in the usual way and the findings summarized. In 22 patients (77 per cent) the diagnosis of Hirschsprung's disease was offered and this was proved to be correct. However, the passage of time or previous surgery involving the bowel may be associated with an erroneous radiological interpretation. Thus, 1 patient with a 'true positive' had had a rectosigmoidectomy performed elsewhere, and when admitted 3 years later for revision rectosigmoidectomy owing to a residual aganglionic segment, the barium enema was reported as showing idiopathic megacolon. A second patient, radiologically a 'true positive' at $3\frac{1}{2}$ years of age, which was proved by rectal biopsy, had a repeat barium enema 6 years later and this was reported as showing idiopathic megacolon.

The 6 'false negatives' were all proved subsequently to be Hirschsprung's disease. Two patients, both 3 years of age, were diagnosed as having idiopathic megacolon. One died 9 years later with enterocolitis, and the other died after rectosigmoidectomy, either from enterocolitis or from the effects of pelvic sepsis. One 6-year-old infant and one 11-day-old infant had long-segment Hirschsprung's disease, in 1 case extending high up the descending colon, and in the other extending up into the ileum. The barium

P, 25, 351

enemas of both these patients were reported as normal. One 2-day-old infant and one 5-day-infant had repeated enemas for up to 2 years before a diagnostic picture could be demonstrated.

From our experience with radiology in the diagnosis of Hirschsprung's disease the following conclusions can be drawn:—

1. A negative barium enema in a neonate cannot be taken to exclude Hirschsprung's disease and repeated examinations are justified.
2. A negative barium enema will not exclude a long-segment Hirschsprung's disease.
3. In 4 out of 28 patients (14 per cent) a radiological diagnosis of idiopathic megacolon has been offered at some time. Such a diagnosis cannot be accepted without a rectal biopsy.

Table III.—Treatment of 38 Patients with Hirschsprung's Disease

Treatment	*No. of Patients*
Conservative	6
Colostomy	6
Definitive surgery	26
Total	38

Table IV.—Details of Colostomy in 20 Patients

Procedure	No. performed	No. died	Average Age	Percentage Mortality
Emergency (neonates)	12	4	8 days	33
Emergency (infants)	7*	2	10 wk.	29
Elective	1	—	12 yr. 7 mth.	—
Total	20	6	30 days†	30

* Including 1 ileostomy for long-segment disease.

† Excluding the child of 12 years and 7 months.

Bowel Biopsy.—Nine formal rectal biopsies were performed without complications. One showed a 'false negative' because it was taken from the distal to the anorectal junction. Six bowel biopsies were performed in conjunction with laparotomy for diagnosis and colostomy. There was 1 'false negative'. No death was attributable to either of these methods of biopsy.

Outcome in 38 Patients (*Table III*).—Six of the 38 patients have been treated conservatively, either by choice or necessity, 6 were treated by a colostomy in the first place but did not survive long enough for further action, and 26 patients underwent elective surgery with or without a prior colostomy.

Conservative Treatment.—Six patients 'settled' on a conservative régime based on simple measures including rectal wash-outs and bowel stimulants. Subsequently 1 patient has been lost to follow-up. Two patients have died. The first, diagnosed as having Hirschsprung's disease at 3 weeks of age, was treated conservatively and died at 6 months as a result of advanced large-bowel obstruction and a bleeding diathesis associated with intravenous sulphadiazine. The second child was diagnosed as having idiopathic megacolon at 3 years of age and died at 12 years, having been admitted to hospital in peripheral circulatory failure, associated with enterocolitis. A post-mortem examination confirmed the diagnosis of Hirschsprung's disease.

Of the 3 survivors who were followed up, the first remains well at 8 years, following diagnosis at 7 days of age, and has recently been discharged from hospita surveillance. The second is 9 years old, and 4 years after diagnosis maintains normal bowel actions with laxatives, though suffering occasional episodes o pain and distension. The third is 10 years old, and 6 years after diagnosis, though well developed, gets occasional episodes of abdominal distension and fou diarrhoea. A recent barium enema was said to show idiopathic megacolon although a rectal biopsy 6 years ago established the diagnosis of Hirschsprung's disease. All these children must be considered at risk from enterocolitis.

Colostomy.—Six infants had a colostomy per- formed because of intestinal obstruction. In 5 this was carried out in conjunction with laparotomy to exclude an associated intestinal anomaly, although in no case was this found. The fact that these 6 infant did not survive beyond this stage of treatment must be seen in perspective since 20 colostomies have been performed as the first line of surgical treatment in thi series (*Table IV*). There is a high morbidity-rat associated with colostomy in the newly born infant relating to wound dehiscence, prolapse of colonic mucosa, stenosis of the colostomy opening, and bleeding from the bowel surface. Nineteen neonate and infants had an emergency colostomy performed the average age at the time of operation being 30 day (range, 2 days to 17 weeks). Of the 6 patients who died 2 died from complications directly referable to surgery—1 developed a small-bowel fistula and th other suffered a wound dehiscence. The remaining deaths were from a combination of associated diseas or gross congenital disorders. The overall mortality rate in relation to the total number of colostomie performed was 30 per cent.

Table V.—Details of Definitive Surgery for Hirschsprung's Disease

No. of Patients	Type of Operation	No. of Deaths	Percentage Mortality
25	Rectosigmoidectomy	1	4
25	All types	2	8

Definitive Surgery (*Table V*).—Twenty-six patients underwent definitive surgery for Hirsch sprung's disease. One patient has been excluded from further consideration because following colostomy h underwent definitive surgery elsewhere. Recto sigmoidectomy, following the Swenson technique, ha been the procedure of choice, and 26 such operation have been performed in this centre on 25 patients with 1 death, giving a mortality-rate of 4 per cent. This figure includes 2 rectosigmoidectomies performed in 1 patient. The one death in this series occurred month after rectosigmoidectomy and after normal bowel actions had commenced. Whether this death occurred from enterocolitis or from the effects o pelvic sepsis is not clear. A second child, who had been left with a colostomy following a poor result after rectosigmoidectomy performed 5 years previously died following a Soave procedure. This gives mortality-rate of 8 per cent for definitive surgery fo all types of procedures.

The youngest patient operated on was 4 months old and the oldest 13 years and 4 months. When there is an element of choice in timing definitive surgery it is our practice to undertake rectosigmoidectomy at about 7 months when the child has grown beyond the neonatal period and has established a good feeding pattern. At this time there are no behaviour problems, and infectious diseases, skin sepsis, and upper respiratory-tract infections which complicate or delay major surgery are not obtrusive (*Fig.* 3).

Morbidity.—In assessing the results of major elective surgery in infants and children a consideration of the complications is most important. As a group of patients they are not easy to handle or to assess and active intervention is sooner resorted to in the early days after operation in the hope of avoiding a situation which might become irremediable.

Taking the problems occurring in the period following operation ('early') together with those arising some time following discharge from hospital ('late'), we have found that 13 out of 25 patients had some complication. Of these 13 patients, 2 who suffered 'early' complications also suffered 'late' complications. The overall morbidity-rate was 52 per cent (*Table VI*).

Table VI.—THE MORBIDITY IN 25 PATIENTS

COMPLICATION	TIME OF OCCURRENCE	
	Early	Late
Intestinal obstruction	4	6*
Stenosis	3	—
Enterocolitis	2	—

* Includes 2 patients who also had early complications.

Table VII.—LATE RESULTS OF RECTOSIGMOIDECTOMY IN 25 PATIENTS

CATEGORY	NO. OF PATIENTS	PERCENTAGE
Good	12	48
Intermediate	5	20
Poor	3	12
Died	1	4
Lost	4	16
Total	25	100

1. *Early.*—Four patients required laparotomy for postoperative intestinal obstruction, including 1 patient who suffered a volvulus which was corrected surgically. Two of these patients showed no obvious cause for obstruction at laparotomy but both required subsequent hospitalization for subacute intestinal obstruction, 1 on three occasions. In all instances the problem resolved with conservative treatment. A third patient had no obvious cause for obstruction at the time of laparotomy but subsequently developed a rectovaginal fistula.

Three patients developed 'stenosis' in the region of the anastomosis. In 2 instances this stenosis has been attributed to anastomotic stricture; 1 patient was submitted to revision surgery and the other awaits further surgery. The third patient had a stenosis which was due to a residual aganglionic or transitional segment and this was excised at a second rectosigmoidectomy.

Two patients developed evidence of enterocolitis following operation. One responded to treatment following isolation of a pathogenic *Escherichia coli* organism. The second patient had a similar organism isolated prior to operation but not subsequently. This patient died, but whether from the effects of enterocolitis or from pelvic sepsis is not clear.

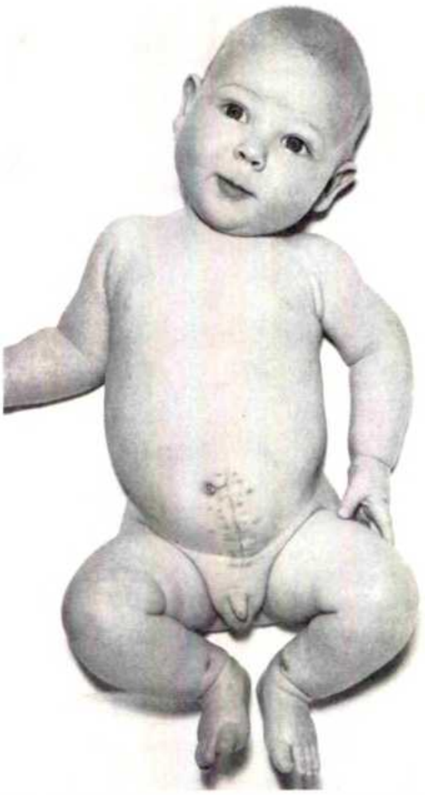

FIG. 3.—M. T., 10 days following rectosigmoidectomy at 4 months.

2. *Late.*—The late morbidity has been manifested in all instances as episodes of subacute intestinal obstruction which always responded to conservative measures. Two of these patients, who had had a laparotomy performed in the 'early' phase when no cause for obstruction was found, have required multiple admissions, and although neither has been readmitted to hospital for as long as 3 years in 1 instance the presence of a residual aganglionic segment has been proved histologically. A third patient who presents approximately every 6 months with subacute obstructive symptoms, which resolve without the need for hospitalization, has been shown to have a residual aganglionic segment.

Late Results of Rectosigmoidectomy (*Table VII*).—Follow-up data are available for 21 out of 25 patients (83 per cent). Assessment has been made between 1 and 15 years following operation, with a mean follow-up time of 6·3 years. The follow-up has been carried out by means of personal interviews, examinations of recent hospital patient notes, and postal inquiry via the patients' general practitioners and parents. Three categories of result have been defined:—

1. *Good*: No further treatment required.
2. *Intermediate*: Episodic abdominal pain and distension with constipation and/or diarrhoea. The patient may have required single or multiple hospital admissions for observation or conservative treatment. The patient may in time move into either of the other two categories, 1 or 3.
3. *Poor*: The patient will require further major surgery.

Good (12 patients).—All patients have normal bowel actions with no obstructive episodes or incontinence. They lead normal healthy lives.

Intermediate (5 patients).—Two patients, who have had multiple hospital readmissions for subacute obstructive episodes, have required no further treatment for the past 3 years. Two other patients require out-patient surveillance for intermittent abdominal distension associated with constipation. One patient is fit and well but suffers bowel incontinence once daily.

Poor (3 patients).—Two patients developed anastomotic stenosis requiring revision surgery. One awaits surgery, and the other had a Soave procedure 5 years after rectosigmoidectomy. The third patient had a functional stricture treated by a second rectosigmoidectomy.

Died (1 patient).—Death in this patient, which occurred about 4 weeks following rectosigmoidectomy, was from the effects either of enterocolitis or of pelvic sepsis. A post-mortem examination was not obtained.

Lost (4 patients).—One patient was fit with normal bowel function at the time of discharge from hospital. A second patient was seen 6 months following discharge from hospital and was free of complaints at that time. There was no information on the 2 other patients whom it was not possible to trace.

Revision Surgery.—Following definitive surgery a second operation is made necessary by any operative technique which allows development of a mechanical stricture at the site of anastomosis. Revision surgery may also be necessary when a functional stricture becomes evident. This may be due to abnormal bowel being left in the colon immediately proximal to the anastomosis, a situation avoided by the use of frozen-section control. The abnormal bowel may show the typical features of aganglionosis with abnormal large nerve-trunks, or there may be a number of immature ganglion cells without abnormal nerve-trunks, representing an approximation to the normal pattern of innervation and often referred to as the 'transitional zone'. A similar functional problem will occur if distal resection of the large bowel is made cephalad to the anorectal junction rather than in that region. The histological features of the bowel distal to the line of anastomosis will be those typical of Hirschsprung's disease, i.e., complete aganglionosis with abnormal nerve-trunks.

Three patients in this series have required revision surgery. One patient had a rectosigmoidectomy performed elsewhere and 3 years later (aged 4 years) required a second rectosigmoidectomy when the presence of residual aganglionic bowel was proved histologically. Six months following discharge from the hospital she was free from complaints. The second patient developed a stricture following rectosigmoidectomy. This responded to dilatation, although function was not satisfactory. The patient made a good recovery following a second rectosigmoidectomy 6 months later, and the histological features suggested the problem was related to a residual transitional zone. This patient was well with normal bowel function 6 weeks after operation, but was lost to subsequent follow-up. The third patient, aged 18 months, developed anastomotic stenosis following rectosigmoidectomy and remained with a colostomy until revision surgery 5 years later. This patient died from pelvic sepsis following a Soave procedure (*Table V*).

Colostomy in Relation to Rectosigmoidectomy (*Table VIII*).—Thirteen patients had a colostomy in place at the time of rectosigmoidectomy.

Table VIII.—COLOSTOMY IN RELATION TO RECTOSIGMOIDECTOMY

PROCEDURE	NO. OF PATIENTS	COMPLICATIONS	NO. OF DEATHS
Prior colostomy	13*	4†	0
No colostomy	12	3	1
Total	25	7	1

* Includes 1 ileostomy for long-segment disease.

† One patient had his colostomy resected during rectosigmoidectomy.

Excluding 1 patient who was over 12 years old at the time of definitive surgery and exceptional in this respect, the mean age for this group at the time of rectosigmoidectomy was 10·5 months (range, 5 to 18 months). Following rectosigmoidectomy, which included resection of the colostomy, 1 patient required laparotomy for 'obstruction'; no cause for this was found and a colostomy was not re-established. The child recovered but developed episodes of abdominal distension with diarrhoea which eventually settled down. A second patient required revision surgery for a stricture which was probably functional in so far as the bowel resected at the second operation showed the features of incomplete innervation, i.e., a transitional zone. Another patient awaits revision surgery for a stricture of surgical origin. A fourth patient had a rectosigmoidectomy performed at 18 months after a neonatal period complicated by gross pelvis sepsis and multiple fistula formation *prior* to establishment of a colostomy. Recovery from the rectosigmoidectomy was smooth although associated with stenosis which required revision surgery at 5 years.

Twelve patients did not have a colostomy established prior to rectosigmoidectomy, which was performed at a mean age of 18 months (range, 4 months to 4·5 years). Two subsequently required laparotomy for intestinal 'obstruction', though no definite cause for this was established at operation. One had a colostomy performed and afterwards recovered satisfactorily. The other did not have a colostomy performed and subsequently developed a rectovaginal fistula. A third patient died from either enterocolitis or pelvic sepsis before a colostomy could be established.

Leaving aside the infant for whom colostomy is essential for the relief of acute large-bowel obstruction, it would seem reasonable to state that a colostomy should be performed before rectosigmoidectomy where repeated episodes of subacute large-bowel obstruction or any single episode of enterocolitis are a feature of the history. This is best performed as a proximal transverse colostomy so that it does not have to be dismantled, as does a left iliac colostomy, during the course of rectosigmoidectomy. This might not be applicable to the occasional case of long-segment disease. Prior to rectosigmoidectomy the anorectal canal should be dilated at regular intervals to avoid the tendency to functional narrowing of the bowel owing to the absence of faecal passage and the intrinsic nature of the deficiency in the innervation of the bowel. Such dilatations will then render anastomosis in this region somewhat easier and help to avoid a stricture of surgical origin. The colostomy can be closed with safety about 3 weeks after rectosigmoidectomy and after digital examination of the anastomosis. In the absence of a colostomy and following rectosigmoidectomy, if indications should arise for exploration of the abdomen on the supposition of obstruction, for which no obvious cause can be found at laparotomy, it is probably wise to perform a proximal colostomy, since both pelvic sepsis and enterocolitis can present in this way and much will have been gained by diverting the faecal stream.

DISCUSSION

The diagnosis of Hirschsprung's disease can be made sufficiently early in life to hold out good prospects of cure. If intestinal obstruction is not so far advanced as to warrant immediate laparotomy and colostomy a barium enema is particularly helpful in establishing a diagnosis. This is best followed at a suitable point in time by rectal biopsy, particularly if the radiology is inconclusive or suggests idiopathic megacolon in an older child. With regard to adjuvant methods of diagnosis we have no experience at this time of anorectal pressure studies (Lawson and Nixon, 1967), but we believe that these will help greatly, particularly in helping to sort out the older child with chronic constipation and in salvaging those with Hirschsprung's disease which has been diagnosed as idiopathic megacolon on clinical and/or radiological grounds. At present we rely on rectal biopsy alone to help us in this problem.

We believe that Swenson's technique of rectosigmoidectomy, if carefully followed, should produce acceptable results both in respect of mortality and late bowel function, and we await the production of convincing comparative data from larger centres before we intend to change our method. Certain details are worth emphasis. A colostomy is not always essential prior to elective operation, but even in the absence of specific indications the evidence suggests that in a small number of cases problems related to pelvic surgery will be avoided by the presence of a colostomy. The anorectal region should be dilated regularly prior to operation, and rectosigmoidectomy should be performed with facilities available for frozen section. Both these precautions will help to prevent an unsatisfactory result owing to either anastomotic stenosis or functional stenosis associated with a residual segment of bowel which does not show the normal pattern of innervation. In this connexion Swenson's own teaching should be followed carefully, viz., a section of the posterior circumference of the internal sphincter should be included by oblique resection of the bowel in the anorectal region, if problems related to distal hold-up of faeces are to be avoided despite an adequate clearance proximally of abnormal bowel. Faecal incontinence owing to removal of the rectum and its sensory modality has not been a feature in the late follow-up of our patients. Others have put this forward as an argument for retaining the rectum—a feature of the Duhamel and Soave procedures. We have 1 patient who had had an ileo-anal anastomosis performed at 9 months and when reviewed at 11 years had one or two bowel actions daily. He has developed normally (*Fig.* 4). This patient was the most extreme example of proximal extension of Hirschsprung's disease in our series. In 1 other case aganglionosis extended to the mid-transverse colon, while in the remainder it has involved the large bowel up to the sigmoid

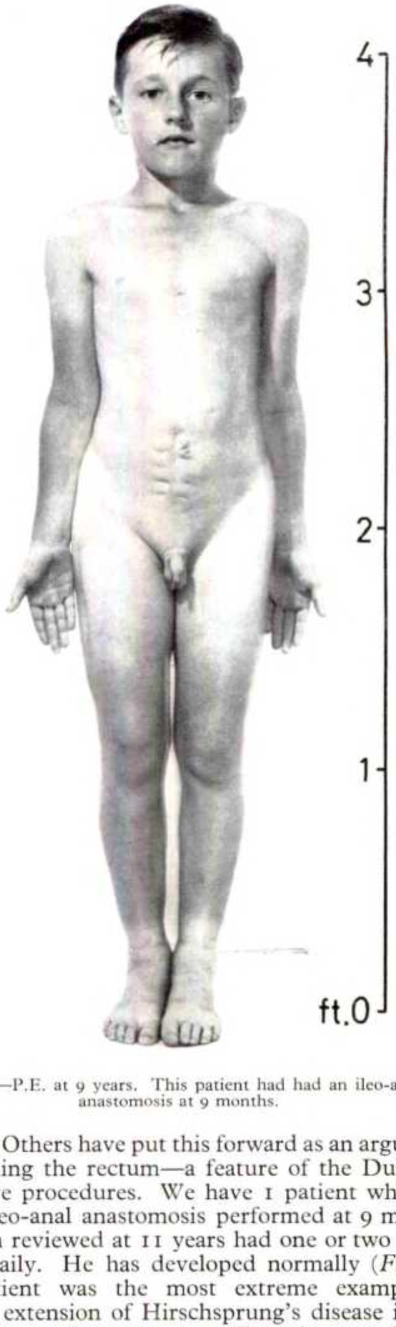

FIG. 4.—P.E. at 9 years. This patient had had an ileo-anal anastomosis at 9 months.

colon region or the lower rectum only. We have not found evidence for 'skip' lesions in any case. The age range of our patients has not demanded an inquiry into ejaculatory function at this point in time, but Swenson has found that this and bladder continence have been retained fully in his patients.

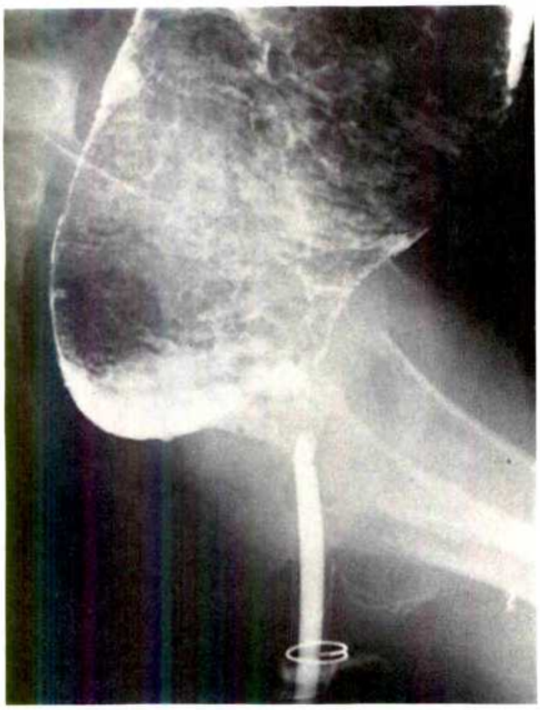

FIG. 5.—M. B. Barium enema (lateral view), 4 years after abdomino-anal pull-through for rectal agenesis, shows megacolon associated with distal functional stricture. The metal ring is on the anal skin.

We have no certain experience of hypoganglionosis, as described by Bentley (1964), but we do have 2 patients who have continued to have megacolon and coprostasis following treatment of rectal agenesis and microscopic anus (*Fig.* 5). The actual numbers with such problems in relation to the total treated for these congenital defects have not been worked out precisely, since our experience in this field is the subject of a current review. Rectal biopsy in a male 4 years after abdomino-anal pull-through for rectal agenesis showed scanty Auerbach's plexuses. The original specimen of the blind rectum showed almost complete aganglionosis with hypertrophied nerve-fibres. A 3-year-old girl, born with a microscopic anus in association with sacral agenesis, was submitted to rectal biopsy and this showed hypertrophied nerve-fibres and very scanty ganglion cells, which were small and poorly defined.

The figures given for aganglionosis occurring in association with anorectal abnormalities vary between 3·4 per cent (Kiesewetter, Sukarochana, and Sieber, 1965) and 30 per cent (Parkkulainen, Hjelt, and Sulamaa, 1960). Where distal large-bowel surgery has been performed, particularly if this has involved ligation and division of the inferior mesenteric artery, an ischaemic cause for a deficiency in innervation might be suggested (Ehrenpreis, 1965; Nixon, 1966). However, where surgery has been confined to such a minor operation as a 'cut-back' procedure there would seem to be evidence of a developmental deficiency in innervation. In functional terms both these conditions behave like Hirschsprung's disease. Their problems are complicated by potential deficiencies in the internal and external sphincter mechanisms, but in either case resection of the abnormally innervated bowel to a point where innervation is normal would seem an essential part of their treatment. Apart from simple observations of the external sphincter mechanism by digital examination, anorectal pressure studies combined with electromyometry will represent an advance in predicting the functional outcome of major surgery in such cases.

Acknowledgements.—We would like to take this opportunity to thank our paediatric colleagues, and the pathologists and radiologists, for their close co-operation in the management of these patients. In particular, we express our appreciation of the nursing staff for their skill in looking after these infants and children.

PYLORUS-PRESERVING GASTRECTOMY IN THE TREATMENT OF DUODENAL ULCER

By T. P. J. HENNESSY,* D. G. WEIR, and D. D'AURIA

THE DEPARTMENTS OF SURGERY AND MEDICINE, TRINITY COLLEGE, DUBLIN, AND THE FEDERATED DUBLIN VOLUNTARY HOSPITALS

SUMMARY

Twenty patients with duodenal ulcer have been treated by a pylorus-preserving gastrectomy. A functioning pyloric sphincter was maintained by retaining a 2-cm. cuff of antrum and carrying out a Billroth-I type of resection proximally. Basal acid output was reduced by 52·4 per cent and maximal acid output by 65 per cent. Gastric emptying time was prolonged, without producing stasis. A provocative test for the presence of dumping produced symptoms in only 1 patient following this operation in comparison with a high incidence of symptoms in patients who had had a Polya gastrectomy or vagotomy and drainage.

The results suggest that the procedure may be of value in the treatment of chronic duodenal ulcer.

The relative merits of partial gastrectomy and vagotomy and drainage in the treatment of duodenal ulcer have been assessed by controlled trials (Cox, 1968; Goligher, 1970). These trials have shown that there is no significant difference between the results of either operation. Although the great majority of patients do well following these conventional procedures, a small number exhibit undesirable sequelae such as dumping, bilious vomiting, diarrhoea, anaemia, and weight-loss. There is evidence to suggest that these side-effects are due, at least in part, to rapid gastric emptying (George, Connell, and Kennedy, 1968; Colmer, Davies, Owen, and Shields, 1969).

In 1967 Maki, Shiratori, Hatafuku, and Sugawara described a procedure which combined gastric resection with the preservation of a functioning pyloric sphincter. By means of manometric and fluoroscopic studies on dogs (Maki and others, 1967) they had found that transection of the stomach 1·5–2 cm. proximal to the pylorus left a functioning pyloric sphincter with normal gastric emptying. A clinical trial of the procedure was carried out on 50 patients, 30 of whom had gastric ulcers while the remainder had adenomatous polyps or other benign gastric lesions. Gastric emptying was found to be normal after operation, none of the patients developed dumping symptoms, and there was a satisfactory reduction in gastric acidity.

In 1969 Goodale, Tsung, Prevost, Edlich, and Wangensteen investigated the possibility of applying the Maki procedure to the treatment of duodenal ulcer. They obtained a 56 per cent reduction in acid secretion from Heidenhain pouches in dogs and complete protection against the stomal ulceration normally produced by the interposition of a loop of terminal ileum in the first part of the duodenum.

This communication reports the preliminary results of a clinical trial of the Maki procedure in 20 patients with duodenal ulcer.

MATERIALS AND METHODS

Patients.—The 20 patients in the trial had the diagnosis of duodenal ulcer made clinically and radiologically. Confirmation of the diagnosis was made at operation in each case. Patients with pyloric stenosis were excluded, but otherwise the series was consecutive. There were 16 male and 4 female patients. Their ages ranged between 20 and 60 years.

Procedure.—The abdomen is opened through a midline epigastric incision and the diagnosis of duodenal ulcer is confirmed. Mobilization of the distal two-thirds of the stomach is carried out in the usual way, with the exception of the distal 2 cm. where the lesser and greater omenta are carefully preserved. The antrum is then transected 2 cm. proximal to the pyloric ring. No clamps are applied distal to the line of transection, and bleeding points are picked up with fine forceps and ligated. The proximal line of transection is oblique and aims at removing approximately two-thirds of the stomach. The proximal cut end of the stomach is closed in two layers for a sufficient length to form a new lesser curvature and to leave a stoma suitable in size for anastomosis to the preserved antrum. This anastomosis is constructed with a continuous catgut suture to the mucosa and a seromuscular layer of interrupted unabsorbable sutures.

Investigations.—

Gastric Secretion.—Gastric acid secretion was measured pre- and postoperatively, using the augmented histamine test of Kay (1953).

Gastric Emptying.—Gastric emptying was measured by serial radiographs following the ingestion of a mixture of barium and gruel in which 100 g. of barium were added to 150 ml. of gruel (Maki and others, 1967). Gastric emptying times were compared with emptying times following partial gastrectomy, and vagotomy and drainage.

Dumping.—The presence of dumping postoperatively was assessed by giving the fasting patient 75 g. of glucose in 300 ml. of water to drink. The patient was then observed for signs of dumping, such as palpitation, weakness, sweating, and dizziness. In addition to these subjective findings, the patient's pulse and blood-pressure were checked at 10-minute intervals. A rise of 10 points in pulse-rate accompanied by a fall in blood-pressure of 10 points was taken as evidence of dumping.

Gastroscopy.—Five patients were submitted to postoperative gastroscopy, using the Olympus E.F.T.

---

* Present address: Department of Surgery, University College, Cork, and St. Finbarr's Hospital, Cork.

fibre-optic gastroscope, and the movements of the pylorus were observed.

RESULTS

Clinical.—There was no mortality in this series. Postoperative progress was uneventful in all cases. Patients had nasogastric suction discontinued within 48 hours and had resumed a normal diet within 10 days. At present (from 3 to 9 months postoperatively) all patients are free of symptoms, except for 1 female patient who complains of a feeling of fullness and occasional vomiting.

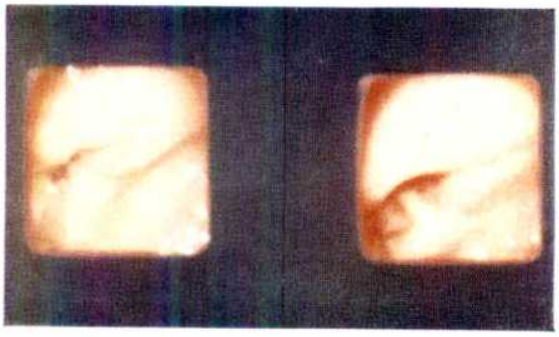

FIG. 1.—Contractions of the pylorus following Maki gastrectomy.

Table I.—BASAL ACID SECRETION (B.S.) BEFORE AND AFTER MAKI GASTRECTOMY

CASE No.	PREOPERATIVE B.S. (mEq.)	POSTOPERATIVE B.S. (mEq.)	REDUCTION IN B.S.	
			mEq.	Per cent
1	4·7	0·2	4·5	95·7
2	8·0	7·7	0·3	2·2
3	2·2	1·4	0·8	36·3
4	1·1	0·2	0·9	82·0

18	2·5	0·6	1·9	76·2
19	3·2	1·4	1·8	56·3
20	0·6	3·7	—	—
Mean	3·4	1·6	1·8	52·4

Mean percentage reduction in B.S. = 52·4 ± 35·6 per cent.

Gastric Secretion.—The mean postoperative reduction in basal acid secretion was 52·4 ± 35·6 per cent (*Table I*). Reduction in maximal acid output, as observed by Kay's augmented histamine test, was 65 ± 18·1 per cent (*Table II*).

Gastric Emptying.—*Table III* shows the emptying rates following the Maki procedure, Polya gastrectomy, and vagotomy and drainage. Only 1 patient in the Maki series emptied in less than 60 minutes. Seven out of 10 patients who had had a Polya gastrectomy emptied in 60 minutes or less. Emptying times following vagotomy and drainage were variable. In 2 of the patients with vagotomy and pyloroplasty who had emptying times of between 150 and 180 minutes there was still some barium mixture in the stomach at 240 minutes. All the patients with a Maki gastrectomy were completely empty at 240 minutes.

Table III.—PATTERN OF GASTRIC EMPTYING

OPERATION	TIME		
	30–60 min.	50–120 min.	150–180 min.
Maki	1	6	13
Polya	7	3	0
Vagotomy and P.G.E.	2	2	2
Vagotomy and pyloroplasty	1	2	3

Table IV.—DUMPING SYMPTOMS

NO. OF PATIENTS	OPERATION	SWEATING	WEAKNESS	DIZZINESS	PALPITATION	TACHYCARDIA AND HYPOTENSION	TOTAL NO. OF PATIENTS WITH DUMPING
20	Maki	1	1	1	0	1	1
10	Polya	5	3	5	5	6	6
6	Vagotomy and P.G.E.	1	2	3	2	2	3
6	Vagotomy and pyloroplasty	2	2	2	1	2	3

Dumping.—*Table IV* gives the results of the provocative test for dumping. One patient had symptoms of dumping following pylorus-preserving gastrectomy. Six of the 10 patients who had had a Polya gastrectomy showed evidence of dumping, as did 3 out of 6 patients with vagotomy and pyloroplasty.

Gastroscopy.—The pylorus was visualized postoperatively in 5 patients. In 3, rhythmic contractions of the sphincter were seen (*Fig.* 1). In 2, no sphincter movements were observed.

DISCUSSION

The first criterion of any new surgical treatment for peptic ulceration is that it must prevent the development of recurrent ulceration. The follow-up of this series is too short as yet to say whether this complication will occur. The retention of antral mucosa which is inherent in the preservation of the pylorus raises the possibility that recurrent ulceration could occur. However, a high level of gastrin production from the antral mucosa will be produced if either the acid stream is diverted away from the antral mucosa or gastric retention occurs. In the pylorus-preserving gastrectomy both of these possibilities are avoided. Furthermore, the reduction in gastric acidity provided by this operation is comparable with the reported figures following truncal and selective vagotomy (Jepson, Lari, and Johnston, 1968; Mason, Giles, Graham, Clark, and Goligher, 1968; Dignan, 1970), which have been shown to prevent recurrent ulceration.

The main advantage of the pylorus-preserving gastrectomy lies in its avoidance of the postcibal complications of other gastric operations. By maintaining the reservoir function of the stomach and a normal rate of stomach emptying, dumping symptoms are almost completely avoided. This may be contrasted with the high incidence of such symptoms which occur in association with the rapid rate of gastric emptying following a Polya gastrectomy, and with the variable rates of gastric emptying following vagotomy and drainage operations, which may on occasion be associated with gastric stasis.

The pathway by which the pylorus remains innervated is not known. In highly selective vagotomy (Johnston and Wilkinson, 1970) the nerves of Latarjet passing to the distal antrum are preserved. These nerves are necessarily divided in pylorus-preserving gastrectomy. Maki has suggested that vagal fibres accompany the right gastric artery to the pylorus. The absence of stasis following selective vagotomy without drainage (Burge, McLean, Stedeford, Pinn, and Hollanders, 1969) supports this view.

PERIMUSCULAR EXCISION OF THE RECTUM FOR CROHN'S DISEASE AND ULCERATIVE COLITIS

A CONSERVATION TECHNIQUE

By E. C. G. LEE and B. L. DOWLING
NUFFIELD DEPARTMENT OF SURGERY, RADCLIFFE INFIRMARY, OXFORD

Summary

The incidence of abnormalities of micturition and sexual function after removal of the rectum is discussed. It is thought that surgical damage to the autonomic nerves in the pelvis is the main cause of disability in young patients with benign disease. The various modifications of the standard abdominoperineal dissection of the rectum which have been introduced to prevent injury during the operation are described. None has proved entirely successful.

A new technique of rectal dissection, in which two surgeons concentrate on opposite sides of the bowel and carry out the dissection under direct vision in a bloodless field, is described. The results of its use in 24 patients are recorded.

Disorders of micturition and loss of sexual function frequently follow surgical removal of the rectum, especially when the standard abdominoperineal excision is employed to treat a carcinoma (Cooling, 1958; Ceulemans, 1968; Smith and Ballantyne, 1968). As many as one-third of patients may be rendered impotent (Goligher, 1951). Others lose the ability to ejaculate semen (Goligher, de Dombal, Watts, and Watkinson, 1968). Temporary retention of urine is not uncommon, but normal function usually returns by the end of the second week (Smith and Ballantyne, 1968). A small number of patients find it difficult to pass urine satisfactorily for months or years after the operation. Rarely, total incontinence may occur. Complications of this severity may be acceptable when an attempt is being made to eliminate malignant disease. Recently, however, loss of function has been shown to occur in a significant number of patients who have had the rectum excised for ulcerative colitis or Crohn's disease (Stahlgren and Ferguson, 1959). Impotence is often temporary, but in as many as 17 per cent of these patients it may be permanent (May, 1966; Watts, de Dombal, and Goligher, 1966). The patient's age also plays a part. Goligher (1967) found that 6 of 8 patients over the age of 50 were totally impotent although the most careful dissection had been carried out. Only 1 of 33 patients below this age suffered permanent damage. Other authors report similar findings (May, 1966; Daly, 1968).

There are probably numerous causes for the loss of function. These include the psychological problems and general depression of health which may follow major surgery in an elderly patient. It is possible that alteration of the normal pressures in the pelvis resulting from the loss of tissue and muscle may account for some of the disorders of micturition, but the most important single factor in the production of abnormalities of function of the bladder and sex organs is the damage to the autonomic nerves which results from the surgical dissection. This is particularly true of the young patients who are found to have a loss of function after panproctocolectomy.

ANATOMY

Below the peritoneal reflection the rectum is surrounded by fatty tissue. Waldeyer's fascia is a thickened sheet in the retrorectal fat which forms a sling around the rectum and anchors the anorectal junction to the pelvis (Wilson, 1967). This 'suspensory ligament' must be separated from the rectal wall when it is being mobilized (Gabriel, 1963). Within it the autonomic nerves of the pelvis ramify (Ashley and Anson, 1946).

The parasympathetic outflow in the pelvis unites to form a large nerve on each side which runs downwards and forwards until it branches lateral to the rectum (Mitchell, 1953). These nervi erigentes are often clearly visible at operation when the presacral fat is explored. The inferior sympathetic ganglia lie in the same region but are not as easily seen. Branches of both sets of nerves form a plexus in the fat of the side-wall of the rectum before passing forwards to supply the other pelvic structures. This inferior hypogastric plexus is partly fixed to the wall of the rectum by the nerves which supply it. Most attempts to prevent injury have been directed at preserving the nervi erigentes which mediate penile erection and ejaculation as well as effecting bladder contraction. Ejaculation was previously thought to be a function of the sympathetic nervous system (Learmonth, 1931). Both systems play important but controversial roles in the function of pelvic organs (Whitelaw and Smithwick, 1951). Whatever their functions, the peripheral fibres of both cannot be separated during an operative dissection of the rectal attachments.

In order to prevent damage to these nerves various modifications of the standard abdominoperineal dissection have been described. The most important of these are low ligation of the inferior mesenteric vessels (Daly, 1968), careful dissection of the lateral and posterior ligaments (Stahlgren and Ferguson, 1959; May, 1966), retention of the levator ani muscles (Daly, 1968), and preservation of the nervi erigentes in the presacral fat (Watson, 1951; Goligher and others, 1968).

It has been our experience that it is difficult not to enter the presacral pad of fat during the customary manual dissection of the posterior rectal space, however much care is taken. Further, it is even more difficult to prevent damage to the hypogastric plexus of nerves in the lateral perirectal tissue when the rectum is being pulled up and down alternately by the two surgeons, each intent on a concentric dissection. It therefore seemed important to evolve a technique using sharp dissection under direct vision in order to keep as close to the wall of the bowel as possible.

We have devised a technique for synchronous abdominoperineal mobilization of the rectum in this perimuscular plane, using two manœuvres not previously described in this context. A solution of noradrenaline, 1 in 200,000, is injected into the perirectal fat to separate the tissues and to reduce bleeding during the dissection. In order to reduce manipulation and to stay as close to the wall of the bowel as possible the abdominal surgeon concentrates on the posterior plane and the perineal dissector on the anterior one. Lateral dissection is not carried out until these two spaces have been opened and it is then performed under direct vision.

DETAILS OF THE OPERATIVE TECHNIQUE

The standard modified lithotomy position is employed using Lloyd-Davies leg supports, with the operating table angled at a 15–20° head-down tilt. Epidural anaesthesia is an additional help to reduce the bleeding. The operation is described here in the female pelvis because its extra width allows easier visualization, but the technique does not differ significantly in the male.

Pelvic Dissection from Above.—The surgeon operating at the upper end concentrates on the posterior part of the dissection (*Fig.* 1). During panproctocolectomy this stage is reached after the sigmoid colon has been mobilized. An incision is made in the peritoneum covering the mesentery on either side of the sigmoid colon about 1–2 cm. from its wall. The vessels are then divided as close to the bowel as possible, proceeding distally from a point well above the pelvic brim. The ureters may be demonstrated as the peritoneum of the pelvic floor is being approached. By remaining close to the wall of the bowel a low ligation of the terminal branches of the inferior mesenteric vessels is carried out. As the rectum becomes mobilized it can be dislocated forwards until the presacral pad of fat lying below the iliac vessels comes into view. The lateral peritoneum may then be incised close to the bowel wall. Point A in *Fig.* 1 illustrates the start of the posterior plane of dissection just outside the muscle wall of the rectum. By combining the injection of noradrenaline and saline and by using scissors dissection, this perimuscular plane is followed downwards into the pelvis. It is possible to reach as far as the distal sacrum or coccyx under direct vision. Blood-vessels may be ligated if large, or coagulated with a diathermy. No extensive lateral dissection is undertaken at this stage.

Perineal Dissection.—Whilst the abdominal dissector is separating the rectum from the presacral pad of fat (*Fig.* 2, point A) the perineal surgeon concentrates on the mobilization of the anterior part of the rectal wall. An incision is made around the anus after it has been doubly ligated. Sufficient skin should be removed to allow the edges to come together without pitting. The incision is deepened through the external sphincter muscles by cutting with diathermy. These muscles may be removed, but it is possible to retain them. A solution of noradrenaline (1 in 200,000) is injected into the tissues and the tissues are cut until the plane just outside the anterior muscular wall of the rectum is reached (*Fig.* 2). The wall of the rectum (*Fig.* 3, RW) is separated from the vagina without difficulty, using the solution to distend the intervening tissues.

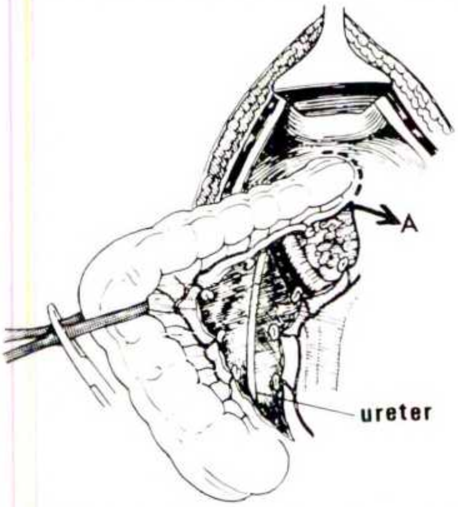

FIG. 1.—Pelvic dissection seen from above. Point A marks the start of the plane between the back of the rectum and the presacral pad of fat.

This sharp dissection in the perimuscular space is continued anteriorly until the peritoneum of the pouch of Douglas becomes visible (*Fig.* 3, P). Using the technique described it is a relatively bloodless procedure. At this stage the posterior plane can be completed by pulling the rectum forwards and dividing the tissues with the scissors after distending with noradrenaline. The colon will now have been freed anteriorly and posteriorly, leaving the lateral attachments.

Lateral Dissection.—Most of the lateral dissection is probably best carried out from above, once again distending the tissues with noradrenaline solution. However, it is surprising how much of the dissection can safely be carried out from below. The haemorrhoidal vessels are ligated close to the rectal wall. When the entire rectum has been freed and the small bowel divided in the abdomen, the colon can be delivered through the perineal wound to prevent soiling of the peritoneal cavity. In a fat patient, or when the pelvis is long and narrow, it has occasionally been found easier to cover the anus with a glove and to pass it into the pelvis so that lateral dissection can be completed under vision from above without pulling excessively on the bowel.

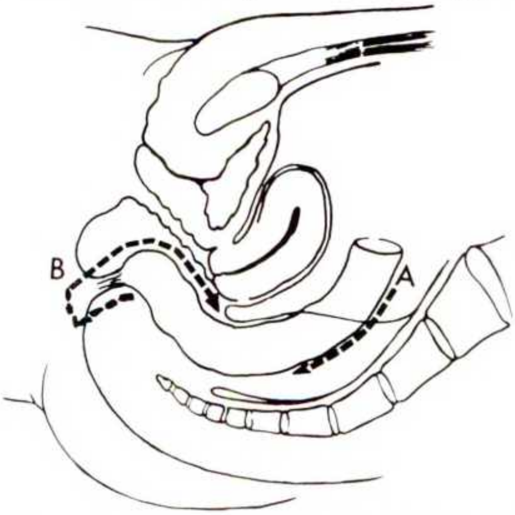

FIG. 2.—Lateral view of the female pelvis. The abdominal dissector concentrates on the retrorectal plane (A) and the perineal dissector on the anterior plane (B).

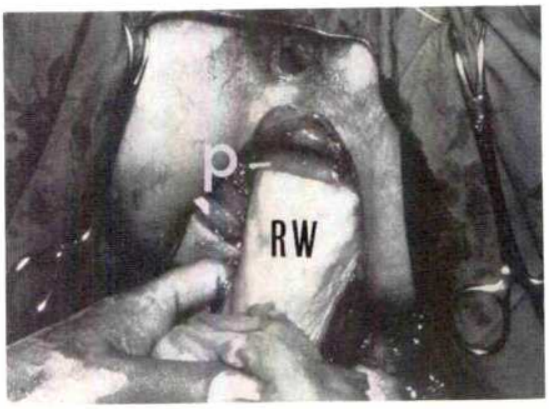

FIG. 3.—Photograph of the perineal dissection, showing the anterior wall of the rectum (RW) having been separated off the vaginal wall until the peritoneum of the pouch of Douglas (P) comes into view.

Closure.—Using this technique the rectum can be removed with little damage to the surrounding pelvic structures. The pelvic peritoneum is closed from above with a layer of fat beneath it, and the levator ani muscles are approximated with interrupted catgut sutures. The fat of the intact ischiorectal fossae can be seen bulging towards each other and they can be approximated with a few interrupted catgut sutures. The tissue spaces of the pelvis below the peritoneum are drained with a central catheter to which low-pressure suction is applied. The skin is closed with interrupted sutures.

DISCUSSION

Most surgeons agree that an attempt should be made to conserve as many of the pelvic structures as possible when operating for benign disease. The various modifications of the standard technique of rectal excision have been described above. Goligher has experimented with a perineal dissection in which the levator ani and sphincter muscles are retained and the dissection is continued by dividing the muscle coat 'all round to enter the plane of the pelvic dissection reached from above' (Goligher, 1967). However, he and others have abandoned the technique in favour of a formal perineal dissection because postoperative convalescence was prolonged in these patients owing to inadequate drainage through the intact sphincters (Lahey, 1952). We have tried a similar dissection in the submucous plane but stopped using the manœuvre after finding that it was seldom possible to avoid opening the lumen of the bowel.

We have employed the technique of perimuscular excision to remove the rectum in 18 patients with ulcerative colitis and in 6 with Crohn's disease who were treated by panproctocolectomy. None of the patients died and no case suffered an extended convalescence due to pelvic infection. The main problem encountered has been the persistence of a sinus in the perineal wound. Five of the 24 patients still retain small sinuses up to 6 months after surgery, and a number of other cases have had delayed healing of the perineal wound. However, the incidence of this complication after the dissection described above is similar to that recorded in the literature by Jalan, Smith, Ruckley, Falconer, Small, and Prescott (1969). A haematoma occurred in 1 patient and minor sepsis of the perineal wound in 5 others. The operation is not technically difficult and has been carried out successfully in a 6-year-old boy with ulcerative colitis.

None of the patients suffered permanent abnormalities of bladder function. In all the patients, indwelling catheters were retained for the first few postoperative days. Two developed infected cystitis. Three others complained of frequency of micturition during the first few weeks. One woman was unable to pass urine when the catheter was removed and it had to be replaced for a further 24 hours. No stress incontinence or total incontinence has been encountered. Of the 11 adult males, all have reported normal erections and 9 have described normal ejaculations.

Contra-indications to Adrenaline or Noradrenaline.—Certain patients are particularly sensitive to the adrenal medullary hormones. Adrenaline may cause abnormalities of cardiac contraction in patients receiving halothane as an anaesthetic (Rosen and Roe, 1963; Katz and Katz, 1966). Hypertensive patients, and in particular those taking drugs which block adrenergic nerves or propanalol, may be hypersensitive to the action of adrenaline and noradrenaline (Meulheims and Entrup, 1964; Smith and Corbascio, 1970). In these it may be possible to use saline alone to distend the perirectal fat during the dissection. In normal individuals it is safe to inject 1 mg. of the hormone over a short period. We have not used more than 60 ml. of the solution during any operation, which corresponds to only one-third of this dose.

CONCLUSION

We have described a technique of dissection which allows the surgeon to remain in a precise plane just outside the muscular wall of the rectum. It prevents damage to the pelvic nerves and does not add to the difficulty or duration of the operation.

The results in the cases described are encouraging. There have been no drawbacks and, in particular, the risk of pelvic infection and sinus formation does not appear to have been enhanced.

Acknowledgements.—We should like to thank Dr. S. C. Truelove, of the Nuffield Department of Clinical Medicine, for all the help that he and his team have given with these cases and in the preparation of this article.

Now ICI bring to surgical scrubs the proven advantages of Hibitane in

TRADE MARK

hibiscrub

Antibacterial Activity

From the bacteriological point of view the demand is for a surgical scrub which combines maximum antibacterial activity with pronounced residual effect.

'Hibiscrub' fulfills these requirements. It is not only rapidly effective against both gram positive and gram negative organisms but also exhibits good residual activity – a major advance in the development of surgical scrubs.

Hand Care

The effect of prolonged usage on the hands of surgical staff is a critical factor in the acceptability of any surgical scrub. Sensitivity reactions, excessive detergency etc., can lead to the abandonment of certain scrub regimes.

'Hibiscrub' is positively pleasant to use – nurses using it regularly have reported on the excellent condition of their hands.

VESICO-URETERIC REFLUX FOLLOWING RENAL TRANSPLANTATION[*]

By R. V. S. YADAV,[†] W. JOHNSON, P. J. MORRIS, P. SPRAGUE, D. YOFFA, and V. C. MARSHALL[‡]

DEPARTMENT OF SURGICAL METABOLISM AND INTERIM RENAL UNIT, ROYAL MELBOURNE HOSPITAL

SUMMARY

Twenty-eight patients who had received a renal transplant have been studied in order to determine the incidence and significance of vesico-ureteric reflux in association with urinary infection.

The ureters had been anastomosed either by uretero-ureteric or ureterovesical techniques without an anti-reflux procedure.

Ten of the 28 patients had reflux into the transplant and 4 had reflux into a non-functioning ureteric stump. Reflux was significantly more frequent in the ureterovesical group.

Marked reflux in patients with recurrent urinary infections was associated with renal damage. Marked reflux in uninfected patients or mild reflux in patients with recurrent urinary infections was not associated with renal damage.

VESICO-URETERIC reflux has received considerable attention in the general field of urinary-tract infections but little in relation to urinary infections after renal transplantation. There are several reports describing various urinary complications after renal transplantation, such as urinary fistula, ureteric obstruction, and ischaemic necrosis of the ureter, but there is only passing reference to vesico-ureteric reflux in these reports (Starzl, 1964; Prout, Hume, Lee, and Williams, 1967; Murray, Wilson, Tinley, Merril, Cooper, Birtch, Carpenter, Hager, Dammin, and Harrison, 1968; Martin, Mimms, Kaufman, and Goodwin, 1969).

This study of patients with cadaveric renal transplants was undertaken in order to determine the incidence of vesico-ureteric reflux following different techniques of ureteric anastomosis and the relationship of reflux to infection and to renal function. Urinary infection is often a serious problem after transplantation not only because of its possible role in producing septicaemia but also with regard to its effect on renal function.

MATERIALS AND METHODS

Twenty-eight patients with functioning cadaveric renal transplants were studied at periods ranging from 8 to 60 months following transplantation.

There were 17 males and 11 females whose ages ranged between 17 and 50 years.

The type of ureteric anastomosis is shown in *Table I*. Patients receiving grafts several years ago often had either an end-to-end or an end-to-side uretero-ureteric anastomosis. In later grafts ureterovesical anastomosis was usually performed. The ureterovesical anastomosis was performed by a direct anastomosis from outside the bladder into the lateral aspect of the bladder dome, with or without a short intramural tunnel.

Table I.—TYPE OF URETERIC ANASTOMOSIS

Type of Anastomosis	*No. of Patients*
Ureterovesical	17
Uretero-ureteric	
End to end	4
End to side	7
Total	28

Assessment of Reflux.—Voiding cysto-urethrography was carried out, with extreme care being taken to avoid introducing infection. A urethral catheter was passed into the bladder and the urine obtained was cultured. Sodium iodide solution, 12·5 per cent, in neomycin, 2 per cent, was used as contrast material. A preliminary film was taken, the patient was screened, and exposures were made after the bladder had been filled with contrast, and during and after voiding.

Reflux was considered marked if it occurred freely into the ureter and pelvicaliceal system, but mild if it was transient, only occurring during voiding and not reaching the pelvicaliceal system.

Midstream specimens of urine were obtained 1 week after the cysto-urethrogram. Only 1 patient had a colony count of more than 10,000 organisms per ml. which was a result of catheterization. Following a 2-week course of chemotherapy the urine culture was sterile and has remained so.

Assessment of Infection.—Cultures of midstream urine (or of specimens from retention catheters in the postoperative period) were obtained daily immediately after transplantation and then subsequently at each follow-up visit. Counts of more than 100,000 colonies per ml. were regarded as indicating infection. In a small number of cultures, counts between 10,000 and 100,000 were reported, and in deciding their significance the cultures obtained immediately before and after were taken into account.

At least two episodes of infection had occurred in the preceding 8 months in all patients who were classed as being infected. Infections occurring in the immediate post-operative period have been excluded.

Assessment of Renal Function.—Serum creatinine has been the most reliable test of renal function

[*] Presented at the joint Annual Meeting of the Royal Australasian College of Surgeons and the Surgical Research Society of Australasia at Brisbane, Australia, on 18 May, 1970.

[†] Present address: Assistant Professor of Surgery, M.P.S. Medical College, Jamnagar, Gujarat, India.

[‡] Address for reprints: Dr. V. C. Marshall, Director, Surgical Metabolism, Department of Surgery, University of Melbourne, Victoria, 3052, Australia.

in our experience. A serum creatinine of less than 1·8 mg. per cent has been regarded as indicating good function and a value of more than 1·8 mg. per cent as indicating poor function.

RESULTS

Vesico-ureteric reflux was demonstrated in 13 of the 28 patients (*Table II*). Three had reflux into a non-functioning ureteric stump (*Fig.* 1). Nine refluxed up the ureter to the transplanted kidney (*Fig.* 2). One patient refluxed into both ureteric stumps as well as up the ureter to the transplanted kidney (*Fig.* 3).

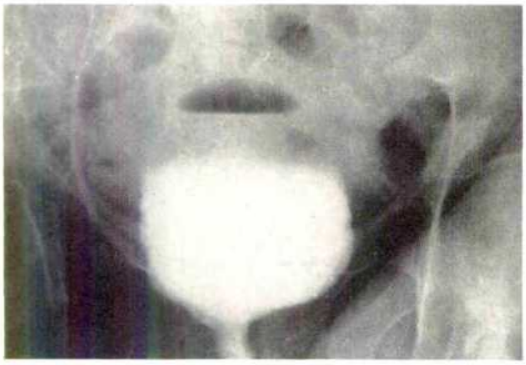

FIG. 1.—Reflux into a non-functioning ureteric stump.

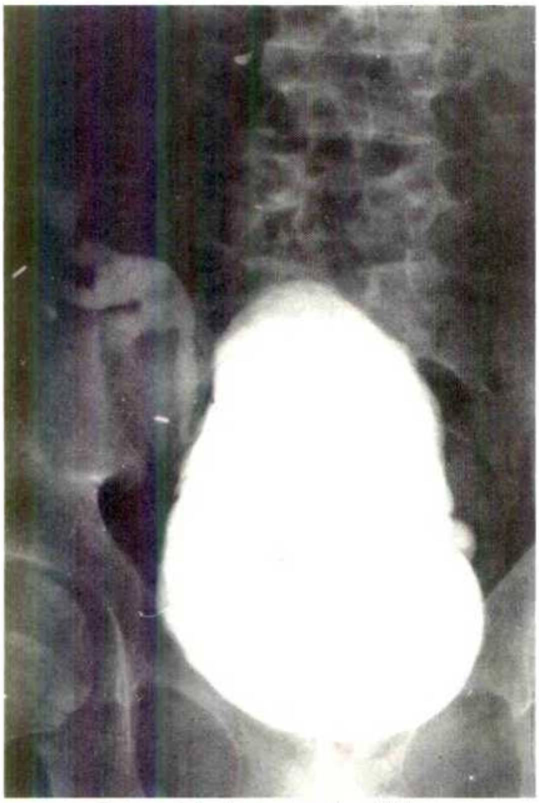

FIG. 2.—Reflux into a transplanted kidney.

As shown in *Table III* the incidence of reflux into the transplanted kidney was much higher after ureterovesical implantation than following uretero-ureteric anastomosis.

Thirteen of the 28 patients had had at least two urinary-tract infections in the 8 months before investigation. Reflux was more frequent in these patients than in those without infection (*Table IV*).

Total	28	10

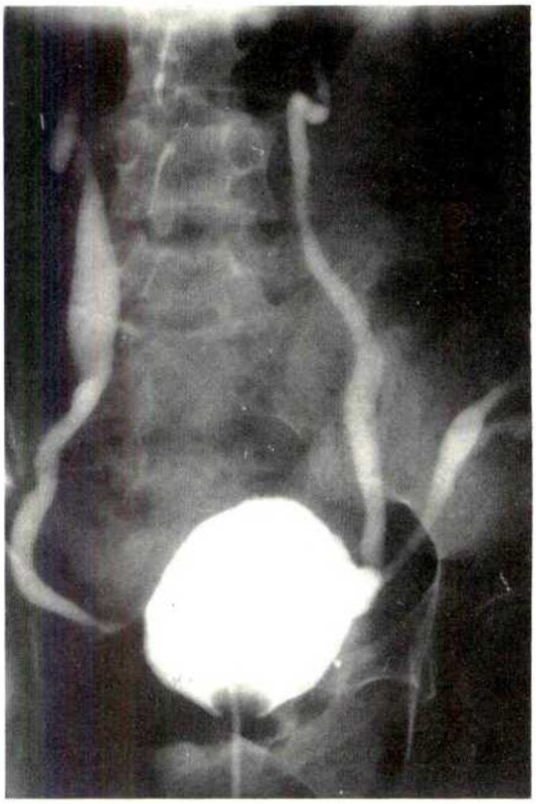

FIG. 3.—Reflux into both non-functioning ureteric stumps and to the transplanted kidney.

In considering the effect of reflux on the transplanted kidney the patients have been grouped according to the degree of reflux and the presence of infection (*Table V*). It can be seen that marked reflux of sterile urine occurred in 3 patients with normal renal function. Mild reflux associated with infection occurred in 2 patients who have normal renal function. In all 4 patients with the combination of marked reflux and urinary infection a depression of renal function has occurred. In 2 of the 4 the deterioration has been gradual. In the other 2 the depression of renal function varies with episodes of infection; in 1 the renal function between attacks remains normal but the other patient has suffered a gradual deterioration in function.

Table VI.—URINARY INFECTIONS IN RELATION TO SEX

SEX	TOTAL NO. OF PATIENTS	NO. OF PATIENTS WITH INFECTION
Female	11	7
Male	17	6
Total	28	13

Two of the 3 patients, who have reflux into a ureteric stump only, have normal renal function. The remaining patient has had severe pulmonary and gastro-intestinal complications with gradual deterioration of renal function, which appears to be more related to periods of hypertension and the use of several potentially nephrotoxic drugs than to urinary infection alone.

DISCUSSION

The high incidence of reflux in patients with renal transplants is not surprising since the most common form of ureteric anastomosis, ureterovesical implantation, was carried out without any special anti-reflux technique. Of the 17 patients implanted in this fashion, 9 showed reflux.

One out of the 11 patients who were anastomosed by the uretero-ureteric technique had reflux into a ureter. It seems likely that this orifice was abnormal prior to transplantation.

Any reflux occurring in a patient after transplantation must be considered undesirable, but it is not easy to decide exactly how undesirable. Reflux may be compatible with normal renal function, even if marked, provided that the urine is sterile, as was seen in 3 patients. Even in the presence of recurring infection, mild reflux has not caused a detectable change in renal function. However, the 4 patients who had a combination of recurring infection with marked reflux all have evidence of renal damage. It was not possible from these studies to determine whether reflux was causative in producing recurrent infection, but it is clear that persisting urinary infection and reflux are often associated, and if both are marked, deterioration of renal function may occur.

SUMMARY

The results of surgery in a group of 7 patients with lymphangioma circumscriptum are presented. Lymphangiography was carried out in 5 of these patients and in 1 further patient who was not submitted to surgery.

Lymphangiography of the affected limb revealed normal subcutaneous lymphatic vessels and normal filling of nodes in the regional node areas. No direct connexion between the lymphangioma and the subcutaneous lymphatics or regional lymph-nodes was demonstrated.

Lymphography helps to show the extent of the underlying pathology before operation. It is also helpful in showing the relation of the lesion to the main lymph pathways of the area so that they may be preserved during operation.

Surgical treatment for patients with lymphangioma should only be undertaken if a definite cosmetic improvement can be assured. Even with discrete lesions regional excision has to be wide in extent owing to the marked tendency to subcutaneous extension of the abnormality. With these conditions satisfied the results of surgery should be good. With more extensive lesions partial excision of the most troublesome areas in one or more stages may give considerable benefit.

LYMPHANGIOMA circumscriptum is a variety of lymphangioma in which a local eruption of persistent thin-walled translucent vesicles appears in groups or patches on the skin. The first report in the literature was probably that of Fox and Fox (1879), and by 1893 Francis was able to review 28 cases, setting out the main clinical and pathological features of the condition. Since that time there have been numerous isolated case reports, some of which have recorded the recurrence of lymphangioma circumscriptum following surgery. We have, however, been unable to find any report of a series of patients who were treated surgically and were submitted to follow-up examination.

The present paper reports the results of surgery in 7 patients with lymphangioma circumscriptum, 5 of whom were investigated by lymphangiography prior to surgery. One further case was investigated by lymphangiography but was not submitted to operation.

MATERIALS AND METHODS

The main indications for investigation and consequent surgery in our patients were as follows:—

1. *Cosmetic Reasons.*—All the patients were troubled by the appearance of the lesion. On occasion, in the case of a child, it was the mother who was worried and who sought advice. This factor alone was not an absolute indication for surgery, which depended in each individual case on surgical judgement as to whether the scar would be more acceptable than the lesion.
2. *Troublesome and Recurrent Leakage of Lymph and Blood.*—This was occasionally a major symptom and often developed from a relatively localized area of the lymphangioma.
3. *Recurrent Infection of the Lymphangioma.*—Should infection occur in a lymphangioma, recurrent attacks of inflammation often develop, necessitating excision of the lesion.

Lymphography Technique.—The technique of lymphography was essentially the same as that described by Kinmonth (1954) with regard to direct intralymphatic injection of subcutaneous lymphatic trunks. Patent blue violet (10 per cent aqueous solution) was injected into the distal area of the limb under investigation. After massage of the limb a proximal incision, usually on the dorsum of the hand or foot, revealed a blue-coloured lymphatic trunk. This was then cleaned of surrounding fat and cannulated with a No. 30 needle swaged to polythene tubing. Ultra-fluid lipiodol, in quantities that have previously been recommended (Guiney, Gough, and Kinmonth, 1964), was then injected and radiographs were taken during the procedure. Further films of the limb and lymph-node areas were taken 24 and 48 hours later. In 3 patients, slow infusion of ultra-fluid lipiodol was made directly into one of the vesicles of the lymphangioma. Progress of the contrast material was followed with radiographs at intervals up to 5 days following the procedure.

Surgical Techniques for Excision of the Lymphangioma.—Occasionally the skin lesion appeared well defined and was easily encompassed by a one-stage surgical excision. Because of the known tendency for abnormal and dilated lymphatic spaces to be more extensive in the dermis and subcutaneous tissue than the visible skin lesion might suggest, the area of the excision was always generous. The lines of the excision were arranged so that they

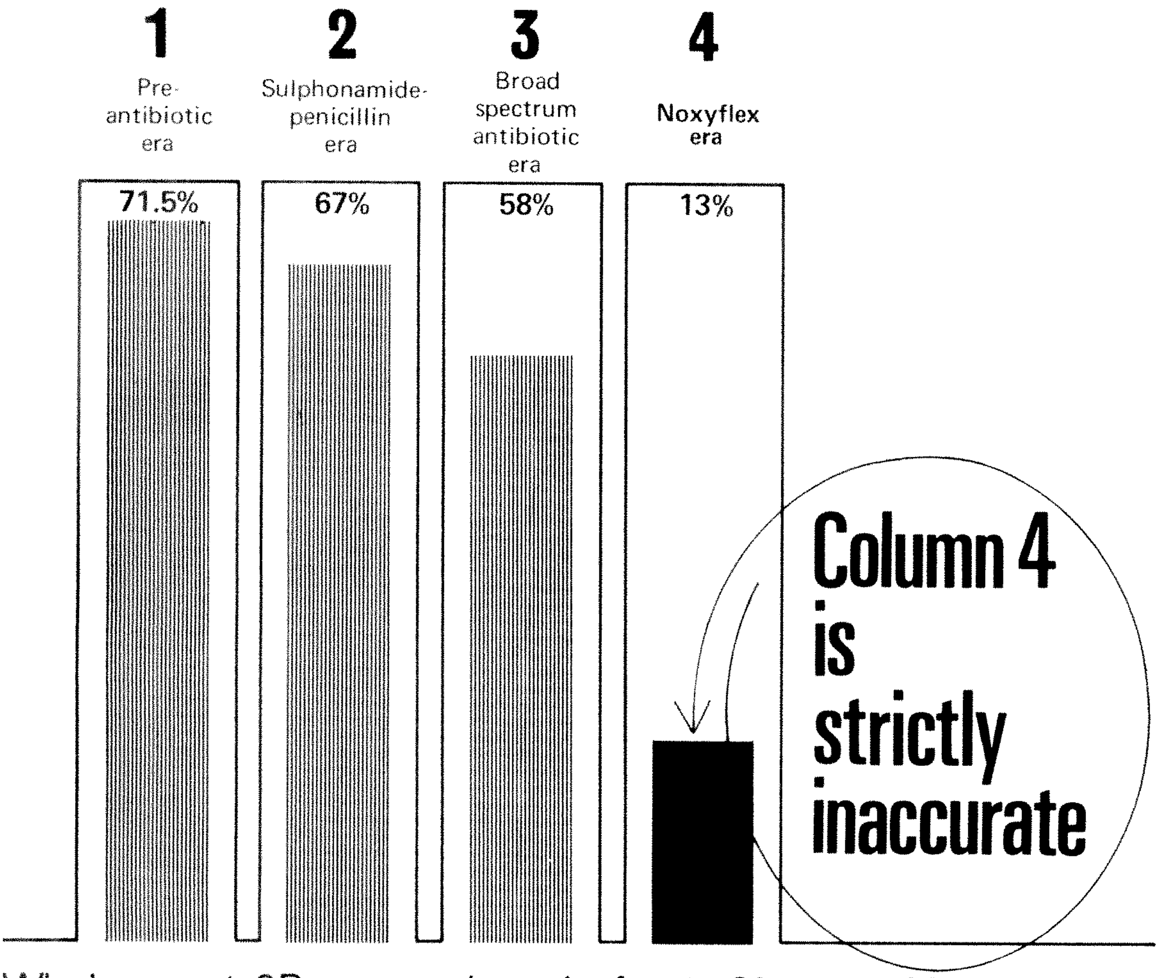
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

When bacterial contamination of the peritoneum is diagnosed or suspected: Noxyflex

CLEAR THE FLOOR!

HANAULUX SATELLITE ceiling mounted auxiliary lamp

Specially designed for mounting on the ceiling fitting of Sierex Boston or Stockholm operating theatre lamps, the Satellite auxiliary lamp leaves the floor clear of fittings and trailing cables. It can be adjusted independent of the main lamp to provide complete and efficient lighting for every type of surgery.

Two models are available:

The Universal gives a single spot of high intensity light for augmenting the main lighting.

The Hamburg provides a completely separate area of lighting where two teams are operating simultaneously, as in heart surgery.

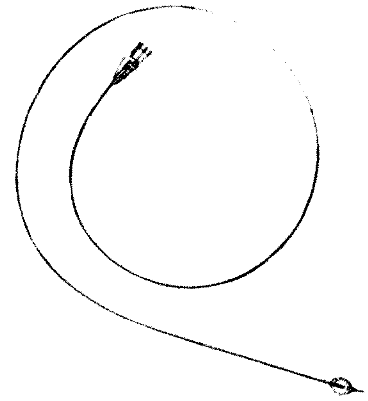
FOGARTY CATHETERS FOR ACUTE VASCULAR OCCLUSION

FOR: Venous Thrombectomy
Occlusion/Emergency Tamponade
Arterial Embolectomy
Dilation/Creation of Atrial Septal Defects in Infants
Double Lumen Balloon Catheter/Creation of Atrial Septal Defects in Infants
Biliary Balloon Probe/Exploration and Removal of Debris and Stones
Irrigation
Rugged Universal Hub Fits All Luer-Lok Type Syringes



BALLOON CATHETER CONCEPT

Each catheter has a specially constructed balloon at the distal tip (except Irrigation Catheter). In thrombectomy and embolectomy, when the catheter is introduced into a vein or artery, the instrument follows the path of least resistance and the tip threads itself past the thrombus or plaque. The balloon is then inflated with sterile fluid and the catheter withdrawn, bringing the clot with it. As an emergency tamponade, for dilation, or as a biliary probe, the balloon is similarly inflated.

GENERAL DESIGN FEATURES

1. Tips on the various types are specially designed for the particular procedure; all are soft and atraumatic.
2. Controlled symmetrical balloon geometry.
3. Secure balloon attachment by epoxied suture.
4. Length marked catheter bodies.

ALL FOGARTY CATHETERS ARE SUPPLIED STERILE

DICONAL TABLETS

for relief of severe pain when morphine injection would normally be given

DICONAL* is indicated in conditions where potent analgesics such as morphine would normally be used.

DICONAL Tablets contain dipipanone, which has a morphine-like action. The inclusion of the anti-nauseant and anti-emetic cyclizine enables the drug to be given by mouth.

Each tablet contains Dipipanone Hydrochloride, BP, 10 mg and Cyclizine Hydrochloride, BP, 30 mg. DICONAL is subject to the DDA.

Full information is available on request.

followed the accepted skin crease lines or Langer's lines, and all subcutaneous tissue down to the deep fascia was excised.

More often patients presented with an extensive lesion and it was obvious that any operation to remove the lesion in its entirety would have to be performed in stages. The full implications of treatment were carefully explained to the patient before any surgery was carried out. In a number of cases no attempt was made to excise the lesion completely but the most troublesome area was excised in one or more stages.

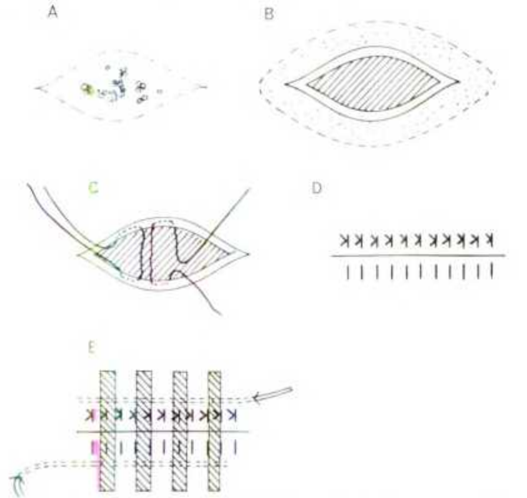

FIG. 1.—A, Elliptical excision of lymphangioma circumscriptum. B, The skin and subcutaneous tissue are excised. The surrounding skin and subcutaneous tissue are undercut equivalent to the transverse diameter of the wound. C, The wound edges are approximated with buried dermal horizontal mattress sutures of 00 catgut. D, The wound margins are further approximated with interrupted vertical mattress sutures of 000 nylon. E, Redivac drains are inserted. The wound is further strengthened with Steristrip dressings.

The details of the surgical technique used are shown in *Fig.* 1. Complete healing of the wound was required before a further stage could be considered, and if it was found necessary 3–6 months were allowed to elapse before the next stage was done.

Assessment of Results.—The assessment of results was based on our own observations at follow-up, together with close questioning of the patient or relative for their impression of the cosmetic appearance. In each case the original indications for operation were reviewed and the results of surgery were assessed in relation to these. Results were classified as 'good' if there was marked improvement, 'satisfactory' if there was only moderate improvement, and 'bad' if there was no improvement or the condition was worse than before surgery.

In addition to being seen in the follow-up clinic, the 6 patients who were treated surgically were sent a questionnaire in May, 1970, requesting answers to the following questions:—

Have any new vesicles appeared since your operation?

How do the scar(s) appear now?

Are they reasonably good, or thickened and unsightly?

Do you feel the operation was worth while in terms of the results produced by it?

Do you think the appearance is better now than it was before the operation was carried out?

Knowing what you do now about the results of surgery, would you have agreed to undergo the operation or would you have preferred the condition left as it was?

All the patients answered and returned the questionnaire. On the basis of these replies the patients' overall views of the results of treatment were also classified as 'good', 'satisfactory', or 'bad'.

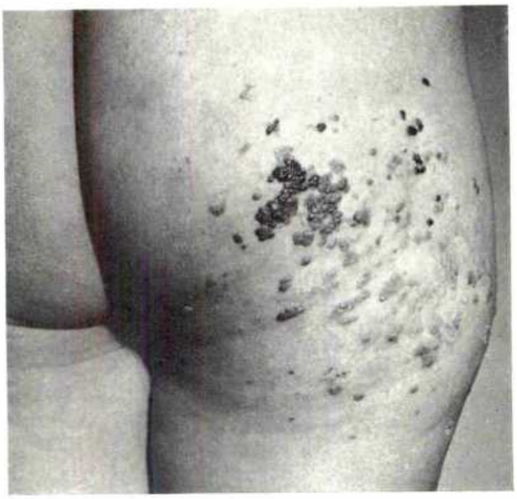

FIG. 2.—Lymphangioma circumscriptum on the buttock before surgery.

CASE REPORTS

Case 1.—Female, aged 25 years. This patient was referred to St. Thomas's Hospital in 1968 with a widespread area of lymphangioma circumscriptum on the right buttock and upper thigh which had first appeared at the age of 14 years (*Fig.* 2). Some slight thickening within the subcutaneous tissue of the buttock could be felt. Occasional bleeding and lymph leakage from the vesicles had occurred in the previous 2 or 3 years and on various occasions they had been treated with diathermy at another hospital. Bilateral pedal lymphangiograms were carried out in 1968 and showed normal subcutaneous lymphatics draining to the inguinal and pelvic lymph-nodes, which also appeared normal (*Fig.* 3). Contrast medium was injected into two vesicles on the right buttock. Some filling of lymphatic spaces deep to the injection site was shown but the contrast medium did not spread from this site (*Fig.* 4). No communication with the lymphatics of the limb or with the regional lymph-nodes was shown. Films taken 2 and 5 days after the original injection of the vesicles showed the contrast medium still present in the subcutaneous lymphatic spaces in the buttock with no evidence of any proximal drainage. The only possibility of removing the lesion was by staged surgery and this was embarked upon. An elliptical area of skin was removed from the buttock in 1968 which included underlying fatty tissue to a depth of 4 cm. This produced a good result and the scar healed well. In February, 1969, a further ellipse of skin (20 × 8 cm.) with most of the remaining vesicles was removed from the buttock (*Fig.* 5). When last seen in March, 1970, there were a few scattered vesicles over the right buttock, but the scars were neat and the patient was pleased with the cosmetic results of surgery and did not wish a third-stage operation.

Case 2.—Female, aged 10 years. At the age of 4 years this girl had developed an area of lymphangioma circumscriptum, 5 × 5 cm., on the upper and inner part of the right thigh. In 1968 she was referred to St. Thomas's Hospital, and bipedal lymphangiography was carried out which showed normal subcutaneous lymphatics in both lower limbs and filling of the inguinal and iliac lymph-nodes. A cannula was passed into a lymphangiomatous vesicle in the area of lymphangioma circumscriptum and 0·75 ml. of ultra-fluid lipiodol was injected. No connexion could be demonstrated between the lymphangioma and subcutaneous lymphatics, and the contrast medium injected into the lymphangiomatous site had not changed its position 4 days later. In June, 1968, an ellipse of skin was removed which included most of the lymphangioma. A few peripheral vesicles were left surrounding the scar. In October, 1969, it was noted that the scar was rather hypertrophic, but this has since flattened. At the present time there is some diffuse swelling in the area beneath the scar and there are five or six vesicles on the skin surface.

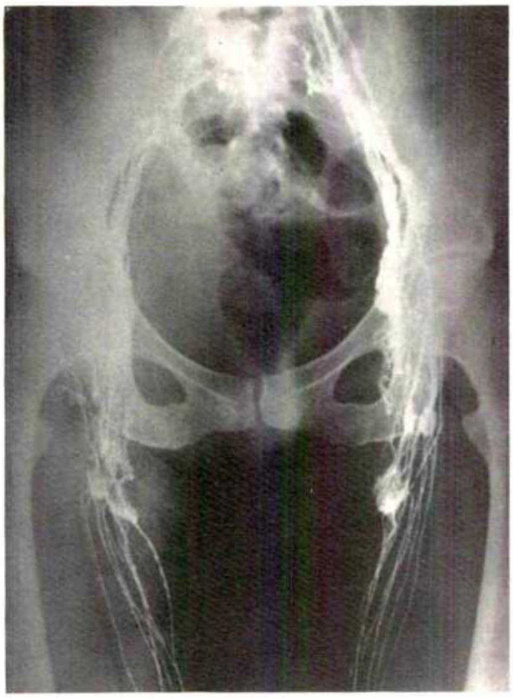

FIG. 3.—Lymphangiogram showing normal subcutaneous lymphatics and pelvic lymph-nodes.

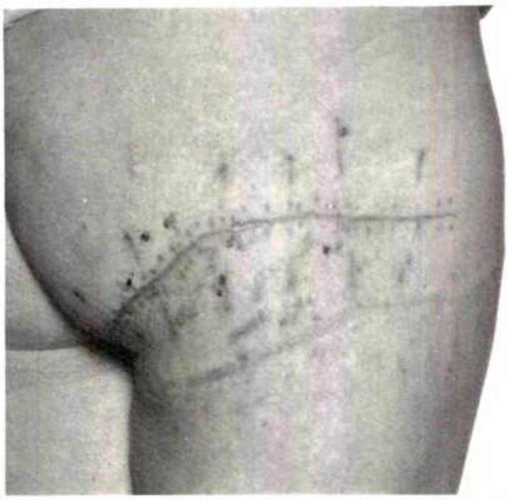

FIG. 5.—The appearance of the buttock after two-stage removal of lymphangioma circumscriptum. A third stage would have removed the area between the scars and left the patient with one scar.

Case 3.—Male, aged 11 years. This patient was first seen at St. Thomas's Hospital in 1968 with an area of lymphangioma circumscriptum on the back of the right shoulder which had appeared 6 years previously. In June, 1968, a right brachial lymphangiogram was carried out. Subcutaneous lymphatics of the area of the lymphangioma circumscriptum were cannulated and 0·5 ml. of ultra-fluid lipiodol was infused. The contrast medium remained in the area of the lymphangioma circumscriptum. No communication between this lesion and the draining lymphatics could be seen. In July, 1968, the whole of the area of lymphangioma circumscriptum was excised together with the underlying subcutaneous fat. The patient made a good postoperative recovery and when last seen there had been no recurrence of the lymphangioma.

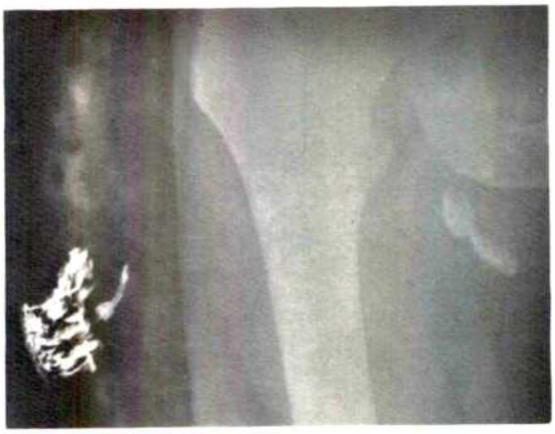

FIG. 4.—Intravesicular lymphangiogram outlining the cystic spaces. There is no communication with the subcutaneous lymphatics.

RESULTS

Lymphography.—In 6 patients the site of the lymphangioma circumscriptum was suitable for lymphangiographic investigation. In all 6 patients the main lymphatic drainage of the affected limb appeared normal and none of the contrast medium injected into the distal subcutaneous lymphatics found its way into the lymphangioma (*Table I*). Injection of contrast medium into the vesicles of the lymphangioma circumscriptum was carried out in 3 patients. Cystic spaces in the subcutaneous tissues deep to the lymphangioma circumscriptum were outlined in these patients but delayed films taken up to 5 days later showed no movement of the contrast medium towards the regional lymph-nodes (*Table I*).

Results of Surgical Treatment.—The results of treatment and the period of follow-up are summarized in *Table II*. In 1 patient (*Case* 3), in whom the entire vesicular area and subcutaneous extension were excised in one stage, there has been no recurrence of the lesion after 2 years. This result was classified as good, although the scar is still rather thickened.

In 5 patients the lesion was too extensive in area to excise completely in one stage and partial excision of the most troublesome area was performed. One of these patients was troubled with recurrent cellulitis, apart from the cosmetic factors, and this, which was the indication for surgery, has not recurred following operation. In 4 patients a few new vesicles have appeared around the scar but there has been no major recurrence. In 1 patient a new subcutaneous swelling has developed beneath the scar. In 1 patient with an extensive lesion on the buttock, partial excision was performed in two stages with a good result.

In only 1 patient was lymphatoma formation a problem in the postoperative period, although slight serous discharge from the incision for a day or two occurred in several others. Hypertrophic thickening of the scar was a marked feature initially in 3 patients, but in each case has subsequently flattened, leaving a scar which is flat but rather broad and unsightly.

Table I.—SITES OF LESION AND RESULTS OF LYMPHANGIOGRAPHIC INVESTIGATION

SUBJECT	AGE AT ONSET	SITE OF LYMPHANGIOMA CIRCUMSCRIPTUM	SUBCUTANEOUS LYMPHANGIOGRAM	INTRAVESICULAR LYMPHANGIOGRAM
Case 1, female, aged 25 yr.	14 yr.	Right buttock and upper thigh. 25 × 15 cm.	Normal bipedal lymphangiogram	No drainage of contrast material up to 5 days
Case 2, female, aged 10 yr.	4 yr.	Upper and inner right thigh. 5 × 5 cm.	Normal bipedal lymphangiogram	No drainage of contrast material up to 4 days
Case 3, male, aged 11 yr.	5 yr.	Back of right shoulder. 7 × 7 cm.	Normal right brachial lymphangiogram	No drainage of contrast material
Case 4, female, aged 18 yr.	6 yr.	Back of left shoulder with underlying swelling. 7 × 5 cm.	Not performed	Not performed
Case 5, female, aged 18 yr.	Birth	Right upper arm with underlying cystic mass. Some extension to axilla and chest wall. 12 × 7 cm.	Not performed	Not performed
Case 6, female, aged 14 yr.	10 wk.	Left breast, axilla, and upper arm. Underlying swelling in the region of the left breast and upper arm. Extensive	Normal left brachial lymphangiogram	Not performed
Case 7, male, aged 27 yr.	8 wk.	Left axilla and upper arm. Underlying swelling. 8 × 9 cm.	Normal left brachial lymphangiogram	Not performed
Case 8, female, aged 16 yr.	Soon after birth	Flexor aspect of the left forearm with underlying swelling. 2 × 1½ cm. Further swelling at left epicondyle	Normal left upper limb lymphangiogram	Not performed

Table II.—ASSESSMENT OF RESULTS OF SURGERY

SUBJECT	INDICATION FOR SURGERY	SURGICAL TREATMENT	ASSESSMENT OF RESULT		COMMENT	LENGTH OF FOLLOW-UP
			Medical Assessment	Patient Assessment		
Case 1, female, aged 25 yr.	(1) Cosmetic (2) Leakage	Excision of most of lesion in two stages	Cosmetic—good Leakage—good	Good	Scars good. A few vesicles still present	1 yr.
Case 2, female, aged 10 yr.	Cosmetic	Most of lesion excised in one stage	Satisfactory	Satisfactory	Scar hypertrophic at first—now flat. Some new swelling under scar	1½ yr.
Case 3, male, aged 11 yr.	Cosmetic	Entire lesion excised	Good	Satisfactory	No recurrence. Scar hypertrophic	2 yr.
Case 4, female, aged 18 yr.	Cosmetic	Excision of most of lesion and subcutaneous swelling. Postoperative radiotherapy to scar	Satisfactory	Good	Scar hypertrophic at first—now flat	1½ yr.
Case 5, female, aged 18 yr.	(1) Leakage (2) Cosmetic	Excision of most troublesome area with underlying cystic mass	Leakage—good Cosmetic—good	Good	Scar thickened. Some new vesicles since operation	6 mth.
Case 6, female, aged 14 yr.	(1) Infection (2) Cosmetic	Partial excision of lesion and underlying mass from left axilla and chest in 1963. Further excision in 1967	Infection—good Cosmetic—satisfactory	Satisfactory	Scars good. Still getting new vesicles	3 yr.
Case 7, male, aged 27 yr.	(1) Leakage (2) Cosmetic	Excision of most of troublesome area	Leakage—good Cosmetic—good	Good	Scars good. No new vesicles	2½ yr.

All the patients felt that surgery had been worth while and were, in general, pleased with the results. We were rather more reserved in our appreciation of the results in view of the occasional unsightly appearance of a hypertrophic scar. However, even when the scar was relatively unsightly, the patient often preferred it to the appearance of the lymphangioma: 'I would rather have the scar than a mass of blisters over my back as people tend to think you have a disease of some kind.'

DISCUSSION

Wegner (1877) originally classified lymphangiomata into simple, cavernous, and cystic forms, and this is commonly accepted. Watson and McCarthy (1940) added two other types, cellular or hypertrophic lymphangioma and diffuse lymphangioma, to this classification. Peachey, Lim, and Whimster (1970) have reviewed 65 cases of lymphangioma involving skin or mucous membrane and have classified these into two main groups.

'Localized' lymphangioma circumscriptum is small, usually less than 1 cm.^{2} in area, and is histologically distinct in that the abnormal lymphatic spaces are confined to the dermis. These lesions often have blood-containing vesicles and can be mistaken for haemangiomata. Excision of these 'localized' lesions is simple and recurrence is unlikely since all the abnormal lymphatic tissue is easily removed.

In the 'classic' type of lymphangioma circumscriptum, with which the present paper is concerned, the appearances are different. Scattered or grouped lymph-containing vesicles occur over an area of skin which may be extensive. Indeed, it may be argued that the adjective 'circumscriptum' is inaccurate as a description of the 'classic' type. One of the authors (J. B. K.) has suggested that the name 'lymphangioma diffusum' would give a truer description of these lesions. Haemorrhage within some of the vesicles is common and variable in degree so that vesicles may have a pink or red coloration. Coagulation of the blood may produce a purple or black appearance. In long-standing cases vesicles may be situated at the top of small papules or there may be a superimposed warty hyperkeratosis.

In many cases several patches of involvement are present within one general area, and although they can occur in any area of the skin they are most frequently found over the proximal parts of the limbs and the adjacent limb girdles. Lesions in the region of the upper arm, axilla, and adjacent chest wall, including the pectoral and scapular regions, are particularly common. Lesions of this type are often present at birth or appear soon afterwards but some occur for the first time in childhood or later. Careful examination often shows some diffuse thickening or swelling in the subcutaneous tissue beneath an area of lymphangioma circumscriptum, denoting a subcutaneous lymphangiomatous element, and in occasional cases the patient gives a history of a diffuse or cystic swelling preceding the appearance of vesicles on the skin surface. In a small group of patients there may be more widespread subcutaneous swelling or generalized enlargement of perhaps an arm or leg.

Histology of the excision specimens in these 'classic' lesions is characteristic. Grouped, cystic lymphatic spaces are present in the papillary layer of the dermis. Dilated lymphatic spaces can be traced deeply into the subcutaneous tissue, where they may involve a larger area than the vesicles on the skin surface would suggest. In cases with obvious subcutaneous swelling, cystic spaces in the subcutis may have a structure similar to that seen in cavernous lymphangioma.

Reports of lymphangiographic investigation in cases of lymphangioma circumscriptum are extremely rare. Russell and Pridie (1967) reported a man aged 18 years who had had an operation for removal of a 'lipoma' of the right hip at 18 months. At the age of 16 years a 'cavernous multilocular haemangioma' had been dissected away from the subcutaneous tissue in the upper thigh, and lesions of lymphangioma circumscriptum had subsequently developed in the region of the right hip. A right pedal lymphangiogram showed contrast medium to flow to the inguinal region where a large collection of contrast material appeared. There was a paucity of lymph-vessels above this, but a large widened vessel was seen coursing more laterally than normal and further collections of contrast material appeared above and medial to the area of non-filling. It was uncertain whether the abnormality shown was due to the lymphangioma or to the previous surgery. Intravesicular lymphangiography was not performed.

In each of 6 patients investigated by lymphangiography in the present series the subcutaneous lymphatics of the affected limb were normal. Contrast medium injected into the vesicles in 3 cases outlined cystic spaces in the subcutaneous tissue deep to the lymphangioma but showed no movement towards the regional lymph-nodes, suggesting that these lymphangiomata have little or no connexion with the normal lymphatic drainage.

In our experience it is often difficult to excise completely the whole of the lymphangioma, which is more extensive in the subcutaneous tissue than the appearance of the vesicular lesions on the skin surface would suggest. If a wide and deep excision of the lesion with removal of all abnormal tissue is possible the chances of permanent cure are good. In some cases simple excision may be carried out in a one-stage operation, while in others complete excision may be possible in two or more stages. Several o our patients with relatively extensive lesions were pleased with the results of a limited surgical excision of the most troublesome area of the lymphangioma Most of the lesions could be excised completely in two or more stages. The tendency to produce hypertrophic and unsightly scars after surgery for lymphangioma has been noted previously by Watson and McCarthy (1940). This has not been a marked feature in our series of patients.

Although all of our patients feel at present that surgery has been worth while we are well aware that the length of follow-up is as yet relatively short. Only observation over a prolonged period of time will show whether the benefits of surgery are maintained

Acknowledgements.—Our thanks are due to Dr H. J. Wallace and those other dermatologists who so kindly referred their patients to us. We are also grateful to Mr. T. W. Brandon of the photographic department of St. Thomas's Hospital for the medical illustrations.

THE BOERHAAVE SYNDROME

(SPONTANEOUS RUPTURE OF THE OESOPHAGUS)

By JOSEPH CALLAGHAN

ATTENDING SURGEON, WINNESHIEK COUNTY MEMORIAL HOSPITAL, DECORAH, IOWA

Summary

Two cases of spontaneous rupture of the oesophagus are presented. Thoracotomy and surgical closure of the perforations resulted in satisfactory outcome in both instances. It is believed that the second case is the only recorded case in which haematemesis from a bleeding duodenal ulcer was the precipitating factor, and also it is believed that he is the oldest survivor to be reported. The literature, aetiology, and treatment of this interesting disease are discussed.

Late one evening in 1724 a Dutch surgeon named Hermann Boerhaave (Derbes and Mitchell, 1955) was summoned to see Baron Von Wassenaer, Grand Admiral of the Dutch fleet. This gentleman had over-indulged at the dinner table and had taken some olive oil as an emetic. During the subsequent retching and vomiting he suddenly developed severe pain in his chest and declared that he would surely die. At autopsy, Boerhaave discovered the olive oil and a portion of roast duck in the Admiral's pleural cavity which had entered through a tear in the distal oesophagus. Spontaneous rupture of the non-diseased oesophagus is a rare occurrence, but one which is invariably fatal unless promptly recognized and adequately treated.

CASE REPORTS

Case 1.—A 60-year-old white male was admitted to Winneshiek County Memorial Hospital, Decorah, Iowa, in January, 1966, with severe epigastric and low anterior chest pain. Six hours previously he had awakened with a headache for which he had taken two aspirin tablets. He had become nauseated, had retched violently, and had vomited about 100 ml. of gastric contents. Direct and specific questioning revealed that he had then immediately experienced severe lower chest and high epigastric pain. This pain radiated into his left supraclavicular region and it was aggravated by breathing, coughing, and swallowing.

Examination shortly after admission to the hospital and 6 hours subsequent to the onset of his illness revealed a very ill man, propped up in bed, with shallow, rapid respirations, and peripheral cyanosis. His blood-pressure was 126/80, and his pulse was 100 per minute. Clinical examination of the heart and lungs was unrevealing. Abdominal examination showed marked, generalized, board-like rigidity. Abdominal tenderness was conspicuous by its absence—only minimal inconstant tenderness being present high in the epigastrium. The bowel-sounds were hypo-active. The rest of the physical examination was essentially negative.

The history was suggestive of spontaneous rupture of the oesophagus, but the much more common entities of myocardial infarction and perforated peptic ulcer had to be eliminated, if possible. An electrocardiogram was interpreted as being normal. An upright chest radiograph, together with flat and decubitus radiographs of the abdomen, failed to reveal any evidence of free air. Lipiodol oesophagrams were then carried out in the supine and left lateral positions but these did not show any leakage from the oesophagus. In spite of this the original diagnosis of probable spontaneous rupture of the oesophagus was maintained, chiefly on the basis of the classic clinical history and the rapid progressive deterioration of the patient's general condition over a short period of time. The patient was taken to the operating room 2 hours after admission and 8 hours after the onset of his illness.

The mediastinal oesophagus was approached through a left posterolateral thoracotomy incision between the seventh and eighth ribs. There was no free fluid in the pleural cavity, but upon opening the distal mediastinal pleura a foul odour was noted, and the peri-oesophageal tissues were oedematous and inflamed. A 2-cm. longitudinal, full-thickness tear was located on the left posterolateral aspect of the oesophagus, approximately 5 cm. above the diaphragm. A nasogastric tube was passed into the stomach under direct vision. The edges of the laceration were débrided and closed in layers with interrupted 000 chromic catgut sutures. The posterior leaf of the mediastinum pleura was tacked over the repair, but the rest of the inferior mediastinum was left open for drainage purposes. The chest was closed, leaving a large chest tube which was connected to an under-water seal.

Postoperatively, the patient was very ill for several days, with recurrent fever spikes to 39·6° C. and marked toxic psychosis. The nasogastric tube was removed on the fourth postoperative day and oral feeding was started. The chest tube drained significant amounts of purulent fluid until the tenth day when the drainage ceased and the tube was removed. The patient's hospital stay was prolonged by two loculated empyematous pockets which responded to repeated thoracenteses. The patient was discharged 5 weeks after operation, having lost 135 kg. in weight.

Three months after discharge he had returned to full employment. A radiograph of his chest was normal, except for minimal pleural thickening, and he had regained his weight-loss.

Case 2.—This patient was an 80-year-old retired farmer with a reputation in his community for being a prodigious beer drinker. He was admitted to hospital in February, 1968, with haematemesis, severe abdominal pain, and incipient shock. He was quite confused and a very poor historian, but questioning revealed that 4 hours prior to admission he had felt weak and had vomited several hundred ml. of dark blood. He had drunk several bottles of beer and several glasses of whisky, but had still continued to have haematemesis. Direct and specific questioning revealed that during the course of one bout of vomiting he had suddenly developed severe upper abdominal pain.

The patient was examined shortly after admission to hospital, and at that time he was propped up in bed and was quite dyspnoeic. His skin was cool and clammy and he was obviously very ill, with a rapid weak pulse of 110 per minute. His blood-pressure was 96/70. At that time, the patient's severe pain was localized mainly in the epigastric region. Bowel-sounds were hypo-active and there was generalized abdominal rigidity, which was more marked in the upper abdomen. Again, as in *Case* 1, tenderness was conspicuous by its absence. There was no subcutaneous emphysema and the heart sounds were clear and distinct. The lungs were clear to percussion and auscultation. Swallowing of saliva did not aggravate the pain, although coughing and deep breathing did.

During the course of this physical examination he vomited 200 ml. of bright red blood which smelt strongly of alcohol. He was still definite in relating the onset of his abdominal pain to a previous bout of haematemesis. A series of radiographs for free air had been ordered previously by his family physician but they had been negative. An electrocardiogram was done, but this was also normal. Blood was being cross-matched for the patient and vigorous replacement of fluids and electrolytes under central venous pressure monitoring was being done when the patient was taken to the operating room 1½ hours after admission and 6 hours after the onset of his illness. The preoperative diagnosis was probable bleeding peptic ulcer with resultant post-emetic spontaneous rupture of the oesophagus.

The abdomen was opened through an upper-right paramedian incision for the purpose of locating and stopping the source of bleeding and also because an abdominal source for the patient's severe abdominal pain and rigidity was possible. Gastroduodenotomy disclosed a hyperaemic ulcer, 1 cm. wide, on the posterior wall of the duodenum, with a readily discernible vessel in the centre of the ulcer bed which was not bleeding at that time. The vessel was oversewn with a heavy silk figure-of-eight suture. The stomach was emptied of several hundred ml. of old blood and clots, and the gastroduodenotomy was closed by a single-layered silk, Weinberg-style, Heineke-Mikulicz pyloroplasty. Exploration of the entire abdominal cavity for further pathology was negative. Curiosity led to a careful scrutiny of the oesophagogastric junction and the overlying peritoneum. There was absolutely no evidence of inflammation or oedema or other signs of distal mediastinal pathology visible from within the abdomen. A gastrostomy with a No. 18 Foley catheter was performed and the abdomen was closed in the usual fashion—the concomitant vagotomy being done through the chest. The patient was turned into a left midlateral position and the chest was opened through the bed of the seventh rib. About 200 ml. of a turbid coloured fluid were present in the pleural cavity. The distal mediastinal pleura appeared oedematous but was grossly intact. On opening the pleura a large amount of necrotic tissue and several beans presented. A longitudinal laceration, 2 cm. long, through all layers was present in the posterolateral aspect of the distal oesophagus, 4 cm. above the diaphragm. A nasogastric tube was passed into the stomach under direct vision and the edges of the laceration were débrided and closed in layers with 000 chromic catgut. A bilateral truncal vagotomy was done. The anterior leaflet of the mediastinum was left open for drainage purposes. The chest was closed in the usual fashion with under-water seal drainage. The patient had a comparatively smooth postoperative course, apart from a postoperative psychosis which cleared up before his discharge on the eighteenth postoperative day. He has since remained well.

DISCUSSION

This disease is not a common one and has only recently been described in some of the better surgical textbooks. Derbes and Mitchell comprehensively reviewed the subject in 1956 and reported 157 cases collected from the world literature. Three years later Dorsey, Hohf, and Lynn (1959) reported the first spontaneous rupture of the oesophagus in a neonate, and since that time there have been 3 further cases in neonates (Wiseman, Celano, and Hester, 1959; Hochberg and Parlamis, 1961; Le Brigand, Bordes, and David, 1961). Single cases of oesophageal rupture in adults were reported by Mahon and Robision in 1960 and by Ross in 1961. The preoperative diagnosis in both of these cases was perforated peptic ulcer. The case reported by Ross (1961) was found to have a rupture of the middle third of the oesophagus at autopsy. There have been only 3 other reported cases of spontaneous middle-third perforation and 1 case of cervical oesophageal rupture (McKeown, 1965). Briggs, Hamel, and Schulkins reported 8 cases in 1961, 1 of which was diagnosed correctly on admission. Three fatal cases were reported by Bruno, Grier, and Ober in 1963. In reviewing all of their cases of perforation of the oesophagus from all causes (instrumental, anastomotic leak, etc.), Foster, Jolly, and Sawyers (1965) found 5 cases of spontaneous rupture. An excellent collective review on the subject was published by Tesler and Eisenberg in 1963. In 1968 Thal reported 6 cases which were treated by his fundic patch valvuloplasty operation, with 5 cures. In 1969 Wychulis, Fontana, and Payne, from the Mayo Clinic, published their experience with instrumental and non-instrumental perforations of the oesophagus. They presented 4 cases of post-emetic rupture occurring in non-diseased organs, with a survival rate of 50 per cent. In the same study they presented 4 other post-emetic perforations associated with oesophagitis or stricture. There were no survivors in this latter group, all of whom were operated on more than 24 hours after the onset of their illness. In 1969 Berne, Shader, and Doty reported 5 cases with 5 cures. Of interest and much significance is the fact that all of these cases were treated successfully by an abdominal approach, which is discussed later in this paper. Apparently, this disease is being recognized more frequently in recent years, and therefore the results from earlier treatment are improving.

Aetiology.—The common physiological denominator in nearly all cases is an explosive act of vomiting or violent retching, often occurring after a large meal. A few cases have been reported where vomiting did not occur, but these cases were associated with acts which increased intra-abdominal pressure: childbirth (Kennard, 1950), straining at defaecation (Beal, 1959), and a convulsive seizure (Klein and Grossman, 1943). Two cases have been reported which followed forceful swallowing (Conte, 1966). No other known case has been reported where massive upper gastro-intestinal haemorrhage was the precipitating factor, as occurred in the second patient presented here, and incidentally it is also believed that he is the oldest survivor reported. Mackler (1952), on the basis of extensive experimental work on fresh cadaveric oesophagi, believes that rupture is due to a sudden violent increase in intra-abdominal pressure with explosive expulsion of a large amount of gastric contents into a fully relaxed oesophagus, the tear occurring where this massive distension is initially sustained—the distal oesophagus. It may also be significant that the distal oesophagus lacks the buttressing quality afforded the proximal and mid-oesophagus by such comparatively unyielding structures as the trachea, aortic arch, descending aorta, left bronchus, pericardium, and various autonomic nerve plexuses. However, in 95 per cent of cases the tear characteristically occurs in the left postero-lateral aspect of the distal oesophagus. At present there is no suitable explanation for this particular site of predilection. The tear is nearly always longitudinal in nature, measuring 2-4 cm., and located 3-6 cm. above the diaphragm. The longitudinal nature of the tear is explained by Derbes and Mitchell (1956) by mathematical analysis, using the principle of free body diagrams which show that hydrodynamic factors incident to increased internal pressure compel the oesophagus to tear in a vertical plane.

Signs and Symptoms.—The classic symptomatology consists of sudden, severe, low anterior chest or epigastric pain, precipitated by a violent act of vomiting or retching. The pain is unremittingly excruciating and may radiate into the neck, arms, or back. Dyspnoea, cyanosis, and orthopnoea develop rapidly, and peripheral vascular collapse may soon appear. Swallowing often aggravates the pain, and if the swallowing is followed shortly thereafter by a bout of coughing, it may safely be assumed that the mediastinal pleura has ruptured and that the oesophageal tear communicates with the pleural cavity. It should be remembered that any act which increases intra-abdominal pressure, even forceful swallowing, may be the precipitating factor.

Physical examination usually reveals a critically ill patient, most often a male—males outnumber females by 5 to 1. The patient is usually sitting up in bed in a crouched forward position. Varying degrees of dyspnoea and cyanosis are often present. Subcutaneous emphysema is frequently present over the chest wall and classically in the suprasternal notch. Evidence of hydro- or pneumothorax may be present on clinical examination. The abdomen is often rigid with varying degrees of epigastric or generalized abdominal tenderness. Radiographic examination of the chest is helpful if it shows free mediastinal air or hydro- or pneumothorax. Lipiodol or gastrografin swallow is diagnostic if the contrast material is shown to leak into the mediastinum or pleural cavity. Oesophagoscopy has been used successfully on several occasions (Carter and Hinshaw, 1965).

Differential Diagnosis.—Many acute surgical and medical catastrophes may partly mimic and be mistaken for spontaneous rupture of the oesophagus. The most common misdiagnosis is a perforated ulcer. This is followed by myocardial infarction, dissecting aneurysm of the aorta, spontaneous pneumothorax, acute cholecystitis, pancreatitis, pulmonary embolism, incarcerated or strangulated diaphragmatic hernia, etc. Some of the diagnostic aids already alluded to may be of great value, but a suspicious awareness of the condition is of equal or greater importance in reaching a correct diagnosis.

Treatment.—There is universal agreement among writers on the subject that surgical repair should be performed as soon as possible. The first successful surgical repair was performed by Barrett (1947).

A few isolated cases of recovery have been reported following closed-chest drainage. In their review of 157 cases collected from the world literature Derbes and Mitchell (1956) found that 55 cases had been treated surgically, with a mortality rate of 36 per cent. They were also able to document in a most dramatic fashion the fate of 71 of the remaining cases which had been treated by non-surgical methods. Of these 71 medically treated cases, 25 per cent died within 12 hours, 75 per cent were dead within 36 hours, while the remainder were all dead within 7 days.

As has previously been mentioned, the best results are obtained when the diagnosis is made early in the course of the disease and surgical repair is performed promptly. Frequently, however, the perforation may have occurred many hours or days before the correct diagnosis is made, and in the past the mortality in this group has been very high. These critically ill patients, when subjected to thoracotomy, present a very perplexing problem to the surgeon. The distal oesophagus is extremely inflamed and oedematous and is surrounded by a suppurative mediastinitis. After the necessary débridement of the necrotic edges of the laceration, these inflamed and swollen oesophageal tissues do not readily retain sutures placed for closure of the defect, and breakdown of the repair is a frequent unfortunate outcome.

In recent years Thal (1968) has applied his fundic patch valvuloplasty operation to these late post-emetic perforations, ranging from 18 to 36 hours in duration, and has reported excellent results in 5 out of 6 cases. This operation, which is more frequently used for distal oesophageal acid peptic stricture, achalasia, and hiatus hernia, with some modification in these latter cases, consists essentially of the following steps: a thoracic approach, generous division of the diaphragm through the central tendon, and free mobilization of the upper stomach by division of the vasa brevia. The fundus of the stomach is then readily brought up into the chest and the necrotic edges of the old perforation are widely débrided. The fundus of the stomach is then placed over the oesophageal defect and sutured to the edges of the defect which are free of any tension. This fundic patch later becomes lined with squamous epithelium. A functioning, competent oesophagogastric valve is then obtained by a second layer of sutures approximating the remainder of the fundus to the right and left posterolateral aspects of the oesophagus which, in fact, invaginates the distal oesophagus into the fundus. At the end of the procedure the stomach embraces at least two-thirds of the circumference of the oesophagus over a length never less than 5 cm. Woodward (1968) has modified this procedure by wrapping the fundus around the complete circumference of the oesophagus after the insertion of the fundic patch.

Whatever the eventual place accorded fundic patch valvuloplasty in the treatment of oesophageal acid peptic stricture, achalasia, and hiatus hernia, it has unquestionably proved its merit in managing those cases of spontaneous post-emetic perforation of the oesophagus in which the diagnosis and treatment are long delayed. In the past the surgical approach to the oesophagus in these cases was through a thoracotomy incision. However, nearly all of these lacerations occur in the distal oesophagus and since experience with transabdominal vagotomy for peptic ulcer has demonstrated that the distal oesophagus can be very adequately exposed and mobilized through an upper abdominal incision, this seemed a logical surgical approach to Berne and others (1969). In 1969 Berne and others presented 5 cases in which the rupture was proved radiographically to exist in the distal oesophagus. All cases were operated on by an upper abdominal midline incision, and the distal oesophagus was mobilized by performing a bilateral truncal vagotomy. In all cases a circumoesophageal gastric fundoplication was used to buttress the repair. In addition, a gastric drainage procedure and gastrostomy was done. The operative site was drained transabdominally by soft rubber or sump drains, and closed-tube thoracostomy drainage was used as indicated. A satisfactory outcome was obtained in all 5 cases.

In 1965 Sanderson reported an interesting case who recovered from an obscure, almost fatal illness which had been precipitated by nausea and vomiting. Three months later the patient underwent a thoracotomy for decortication of visceral and parietal pleura because of marked pleural thickening. Pathological examination of the submitted specimens showed vegetable fibres within multiple granulomas. In retrospect, this is probably the only patient who recovered from a spontaneous rupture of the oesophagus without surgical aid.

In recent years there have been very encouraging results obtained by the conservative management of upper oesophageal perforation caused by endoscopy. Mengoli and Klassen (1965) reported 18 such cases who were treated conservatively, with only 1 death. Shapiro (1965) has accumulated a series of 24 cases who were treated conservatively, without a single fatality. In 1969 Wychulis and others (1969) presented 24 cases of instrumental cervical oesophageal perforation. All of these recovered with conservative treatment, which included cervical mediastinotomy with drainage in 17 cases. Instrumental perforations occur during the course of an endoscopic examination on an empty stomach, and are sometimes suspected or recognized at the time that they occur. The most common location for endoscopic perforation is the cervical oesophagus, where local tenderness, subcutaneous emphysema, pain, and fever often appear early and attract the attention of the alert endoscopist. Treatment, which usually includes surgical drainage, is started early in most cases, with excellent results. On the other hand, spontaneous rupture of the oesophagus occurs explosively on a full stomach with consequently greater spillage and contamination of the mediastinum; moreover, the diagnosis and treatment of spontaneous rupture are often delayed for many hours. It is very unlikely that the results from conservative treatment, even with the help of modern therapy, would match those obtained by surgical closure of the perforation.

Now, to simplify treatment of pseudomonas:

Pyopen infusion

Four years of clinical use have established the effectiveness of Pyopen in pseudomonas infections. In published papers Pyopen's clinical cure rate is 72% even though the majority of the 1100 patients treated had severe underlying diseases.

The best results have been achieved with a dosage of 20-30 G I.V. daily. Pyopen infusion makes this dosage easier to administer by providing Pyopen in ready-to-use infusion bottles, with diluent and transfer needles for the easier preparation of infusion solutions.

Pyopen is, of course, a penicillin, and as such, safe for prolonged treatment even in renal impairment.

If you would like any further information, our Medical Department will be pleased to help.

Pyopen

Adult Dosage: 20-30 G I.V. daily.
Contra-indication: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins.

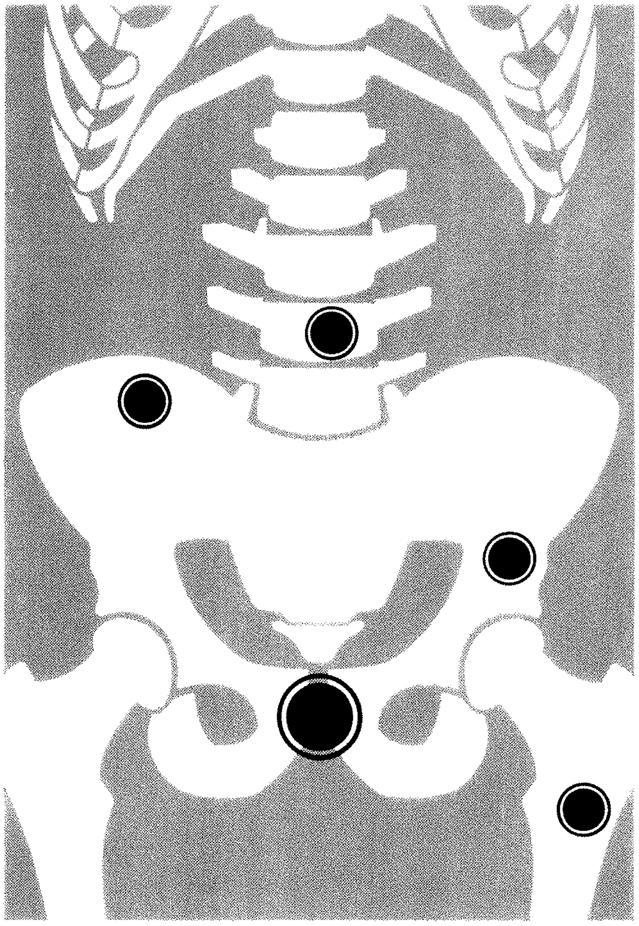
Pyopen* (carbenicillin sodium B.P.) is a British product originated by

Beecham Research Laboratories
Brentford, England. *regd.

Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



Response is rapid. **Honvan** is a practical alternativ to surgery in acute urinary retention caused by prostatic carcinoma.

Gastric tolerance o **Honvan** is good and side effects comparatively rare

Honvan is available for both intravenous and oral administratio

a selective cytotoxic action – in prostatic carcinoma

THE EFFECTS OF CALCULI ON URETERAL FUNCTION

By J. A. ROSS and P. EDMOND

THE DEPARTMENTS OF UROLOGY AND CLINICAL SURGERY, UNIVERSITY OF EDINBURGH,
AND THE ROYAL INFIRMARY AND EASTERN GENERAL HOSPITAL, EDINBURGH

SUMMARY

The dynamic action of the renal pelvis and ureter has been studied in 50 patients with ureteral colic due to calculi.

Calculi in the renal tract, passing down and obstructing the ureter, profoundly disturb the normal intraluminar pressure and peristaltic activity. Initially, there is a rise in pressure above the obstruction with increased peristaltic activity, which is later followed by a marked depression of this activity.

Fatigue from prolonged stretching of the ureteral muscle and the lack of normal stimulus owing to diminished secretion of urine are considered to be the most likely explanation for this loss of activity.

Urgent relief of the obstruction is the logical treatment, and the policy of forcing fluids in the presence of an obstructed ureter may be questioned. The relief of pressure with retrograde catheterization at an earlier stage than is the current practice should be considered.

MOST patients with colic resulting from calculous disease of the upper urinary tract are treated empirically and they pass the calculus spontaneously. When symptoms or stones persist retrograde catheterization may be performed in order to provide both information and treatment.

Ureteral colic has gross effects on the physiological action of the kidney and its outflow tract (Ross, McNair, Isaac, Thomson, and High, 1962; French and Robb, 1963; Smith, 1966). In 87 patients with renal colic associated with calculi, intravenous pyelography during the attack showed delayed or impaired function with nephrogenic effects in 82 instances (94 per cent). Further confirmation of the rise of intrarenal pressure is the development of renal peripelvic and pyelosinus extravasation which have been reported in acute renal and ureteral colic (Harrow, 1966, 1969; Hale and Whitehouse, 1970) (*Fig.* 1).

Pressure recordings during retrograde pyelography have been used to study the dynamic activity of the ureter in various conditions (Ross, Edmond, Coull, and Simpson, 1965; Ross, Edmond, Coull, and Griffiths, 1967; Edmond, Ross, and Kirkland, 1970). This technique has now been employed in the investigations of patients with calculous disease.

MATERIALS AND METHODS

Fifty patients who had been admitted to hospital with ureteral colic were studied. Urinary infection was not a prominent feature in these patients and a significant culture was obtained in only 7 cases: *Escherichia coli* in 4, *Proteus* in 1, *Staphylococcus albus* in 1, and a mixture of *E. coli*, *Proteus*, and enterococci in 1.

The *site* of recording in relation to the position of the calculus was as shown in *Table I*.

Time Factor.—Patients were treated initially with analgesics, antispasmodics, and fluids. Retrograde ureteral catherization was carried out if the stone had not moved appreciably or if discomfort persisted.

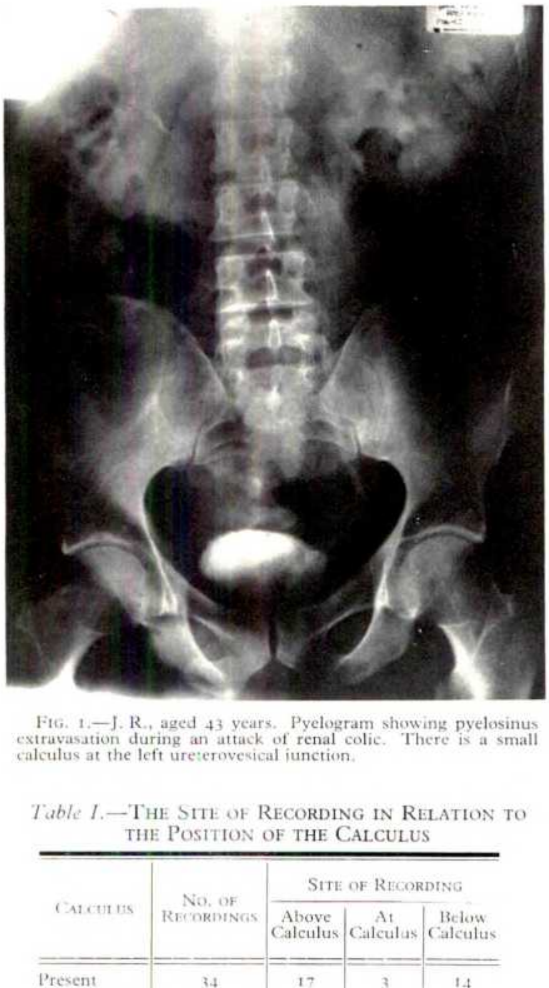

FIG. 1.—J. R., aged 43 years. Pyelogram showing pyelosinus extravasation during an attack of renal colic. There is a small calculus at the left ureterovesical junction.

Table I.—THE SITE OF RECORDING IN RELATION TO THE POSITION OF THE CALCULUS

CALCULUS	NO. OF RECORDINGS	SITE OF RECORDING		
		Above Calculus	At Calculus	Below Calculus
Present	34	17	3	14
Passed or removed	16	—	—	—

In 5 patients colic was present at the time of recording. In the others the recordings were made within 5 days of the patient's admission or within 5 days of the intravenous pyelogram showing nephrogenic effects. In 1 patient a second record was taken from the same level 2 years after the removal of a calculus.

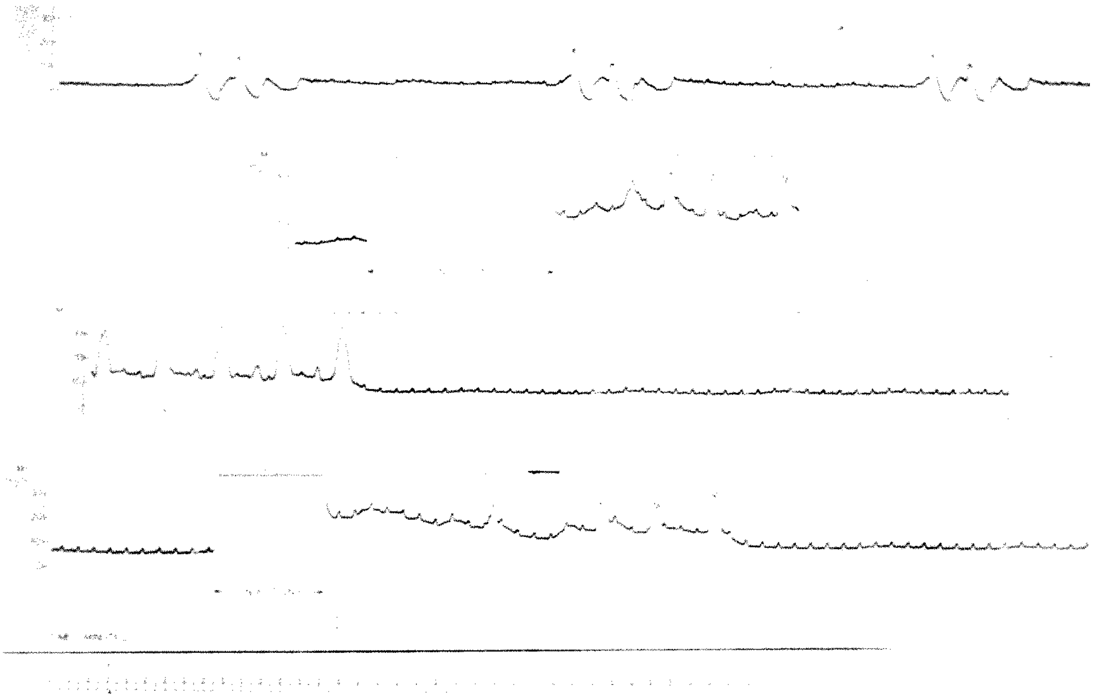

FIG. 2.—E. H., aged 32 years. Consecutive tracings showing slow infrequent contractions above a calculus which is still in situ in the lower third of the ureter. Peristalsis was stimulated by the injection of fluid (twice), which also caused a rise in basal pressure.

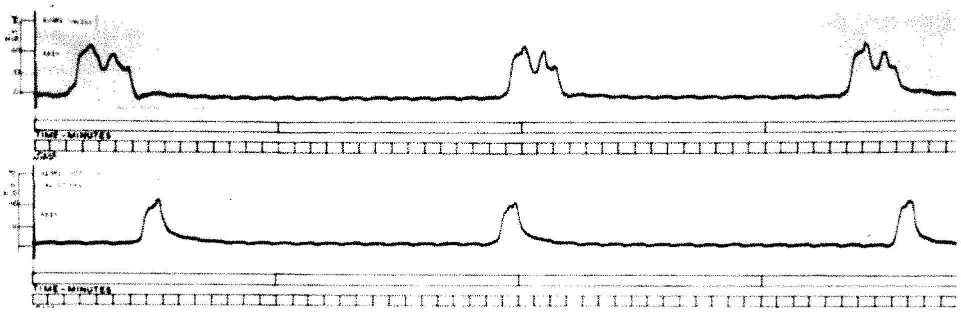

FIG. 3.—M. W., aged 56 years. This patient had had severe right renal colic 4 days before the pressure was recorded. The upper tracing was taken just below the calculus at the pelvi ureteral junction, while the lower tracing was recorded at 15 cm. from the bladder. Note the slow, rather prolonged contractions.

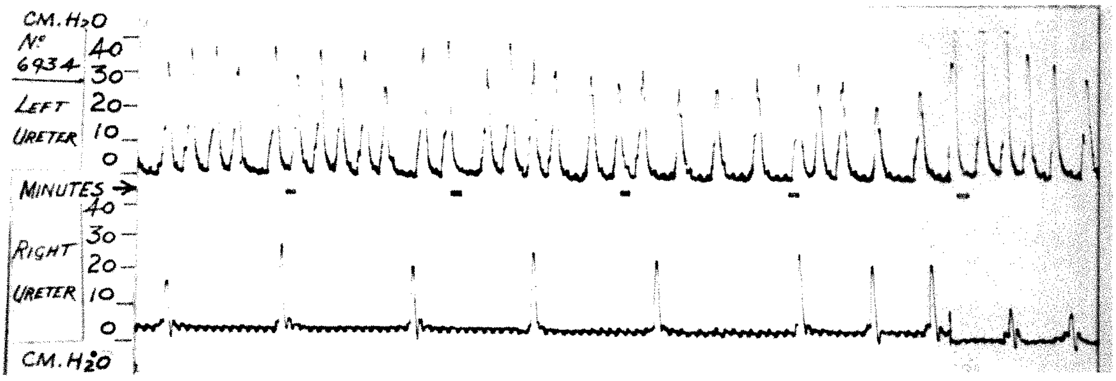

FIG. 4.—J. C., aged 59 years. Tracings made 10 days after an attack of right renal colic. Both ureters were recorded simultaneously. Note the contrast between the normal contractions of the left ureter and the much smaller and slower contractions of the right ureter.

OBSERVATIONS

The rate, amplitude, rhythm, and form of the peristaltic wave were noted and in some patients records were obtained from the unaffected side and were available for comparison.

The normal basal pressure in the ureter is about 14 cm. H_2O (Rattner, Fink, and Murphy, 1957; Ross and others, 1967), but it can readily be raised by extrinsic compression and by injection of fluid. In 5 patients where records were taken above the calculus during an attack of colic, a high basal pressure was demonstrated. Even in the absence of colic the basal pressure was invariably increased to some degree above the calculus.

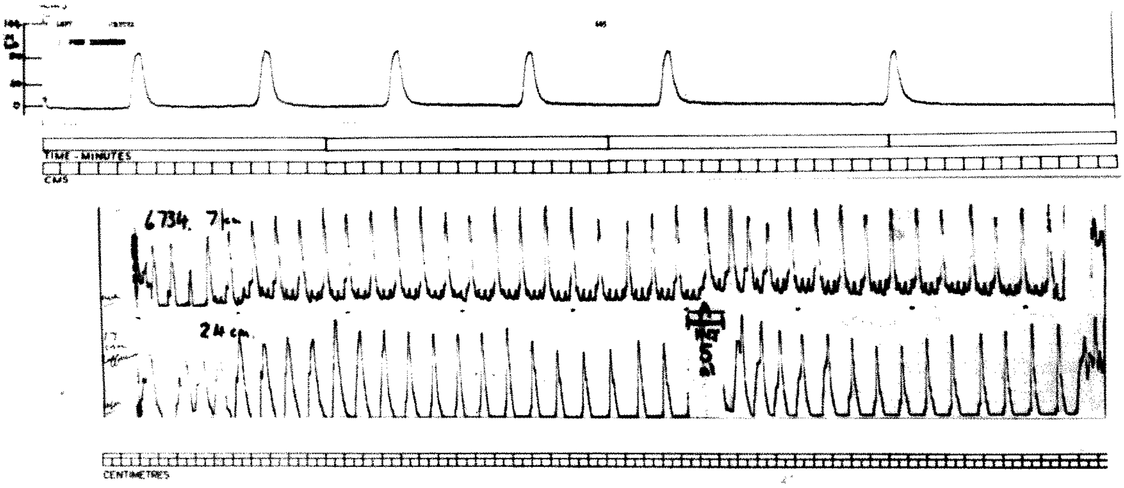

FIG. 5.—E. S., aged 27 years. The top tracing is from the left ureter at 11 cm. from the bladder, just below a calculus. Note the infrequent contractions. The calculus was subsequently removed at operation. The lower tracings are from the same patient 2 years later. Simultaneous tracings from the left ureter at 7 (middle tracing) and 24 cm. (bottom tracing) show normal activity.

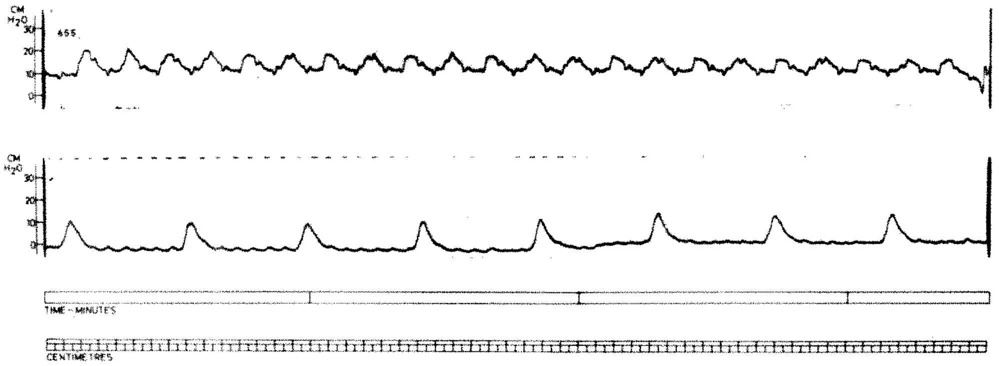

FIG. 6.—T. L., aged 38 years. A calculus was present in the left ureter. The upper tracing shows a rise in basal pressure and an increased rate of contraction but no increase in amplitude during an attack of colic. This contrasts with the normal pressure and the reduced rate of contraction in the lower tracing, for which the patient was conscious and pain-free and had unimpeded drainage down the ureter.

In obstructed ureters, when filled with radio-opaque fluid for pyelography purposes, the basal intraluminar pressure rose considerably and took much longer to return to normal than in unobstructed ureters (*Fig.* 2). Zimskind, Davis, Lewis, De Caestecker, and Berwind (1968) showed experimentally in dogs that after acute ureteral obstruction, pressure in the ureter rises sharply and remains elevated for the following 8 hours.

Reduction in the rate or amplitude, and sometimes both, of the peristaltic contractions was demonstrated in the 45 instances where pain was not a feature at the time of the examination. This finding was irrespective of the level at which the record was obtained (*Figs.* 3, 4). Several factors probably contribute to this:—

1. Infection.—This was not an important factor in the present series since in most records with marked diminution in rate and amplitude of the peristaltic waves the urine was sterile. Under experimental conditions, coliform organisms have been shown to reduce peristaltic activity (Teague and Boyarksy, 1968a, b). In long-standing infected cases it is inevitable that the associated fibrosis of the pelvic and ureteral muscle would be an important factor in diminished activity, as has been shown in other conditions (Ross, Edmond, and Kirkland, 1968).

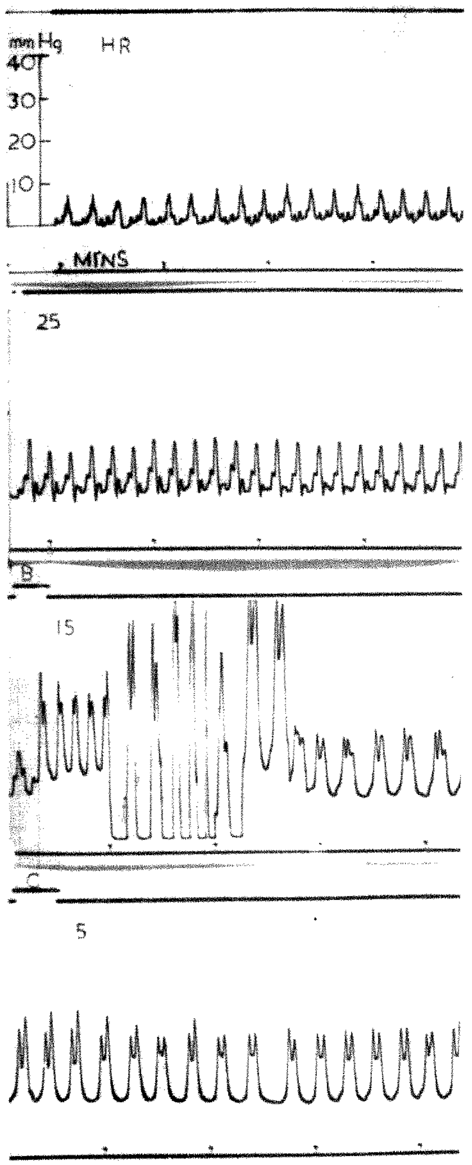

FIG. 7.—H. R., aged 23 years. A small (2-cm.) calculus was arrested at 15 cm. The pressure recordings show hyperactivity at the level of the calculus. Reading from the top to the bottom the tracings correspond to the level of the pelvis, and 25, 15, and 5 cm. from the bladder.

2. Antispasmodic Drugs.—In 6 patients who were being treated with antispasmodic drugs, records were taken from the normal side as well as from the side affected by the calculus. In each instance normal peristalsis was observed on the normal side, suggesting that the drugs did not have any appreciable physiological effect at the time of study.

3. Hypoplasia of the Pelvic and Ureteral Musculature.—Diminished ureteral activity could result from hypoplasia of the muscles. This may be a factor in a small number of patients, but a return to the normal pattern of activity after the passage of a calculus is usually observed (*Fig.* 5).

4. Fatigue of the Musculature.—The muscle of the renal outflow is active at first in the endeavour to pass the calculus. In records during colic this activity was noted (*Figs.* 6, 7), and it is often successful in ridding the ureter of its obstruction. In a personal series (J. A. R.) of 91 patients with ureteral colic (50 right-sided, 41 left-sided) only 9 required operative removal of the calculus. Records were usually taken after the colic had subsided, and the diminished activity observed may be due to temporary fatigue from overstretching of the musculature. When a ureter is distended the intraluminal pressure rises, the contractions practically cease or their effective amplitude becomes small, and they do not regain their normal amplitudes for some minutes (*Fig.* 8).

Murnaghan (1957) has demonstrated that after prolonged stretching, muscle ceases to function normally. If the outlet of the isolated ureter is completely occluded the entire musculature becomes overstretched and eventually inert under these adverse conditions. Forced diuresis, which is so often employed in the treatment of renal colic, will tend, initially, to increase the overdistension, and this in turn may decrease the effective peristaltic activity of the ureter.

5. Absent or Diminished Flow of Urine.—The changing volume of its contents is the main stimulus to ureteral activity (Lapides, 1948). When the outflow from the kidney is obstructed by a calculus the pressure within the pelvis rises, initially producing the 'nephrogenic' effect seen on the intravenous pyelograms and later even disruption of the pelvis. This initial rise in pressure is not maintained when the kidney ceases to form urine, and pressure in the pelvis becomes equal to, or higher than, the glomerular filtration level.

The reduced activity of the ureter after a calculus has passed indicates that normal function may not have returned and that the stimulus of a normal flow of urine may still be lacking. How long the ureter

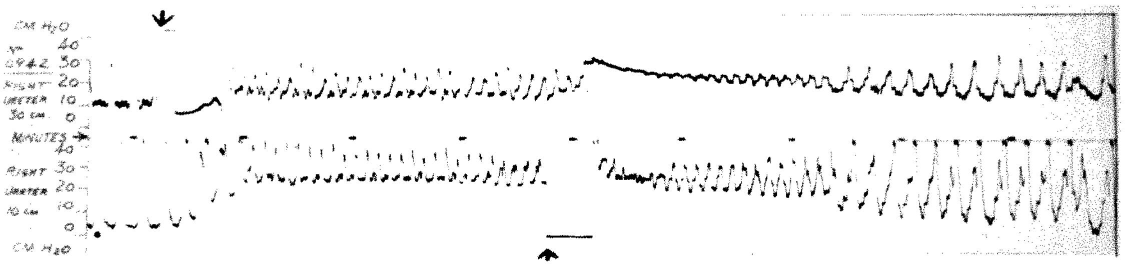

FIG. 8.—A. H., aged 50 years. Simultaneous tracings from the right ureter at 30 cm. (upper tracing) and 10 cm. (lower tracing) from the vesico-ureteral junction, showing the effect of stretching the ureteral wall by filling first at 30 cm. and then at 10 cm. (arrows).

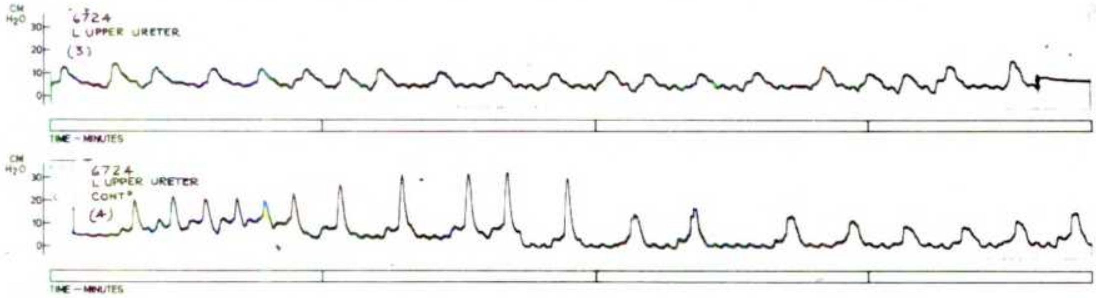

FIG. 9.—M. K., aged 31 years. A calculus was present in the left pelvis. A tracing from the left upper ureter below the calculus shows small contractions, which were stimulated to a bigger amplitude by injecting 5 ml. fluid at the beginning of the lower tracing.

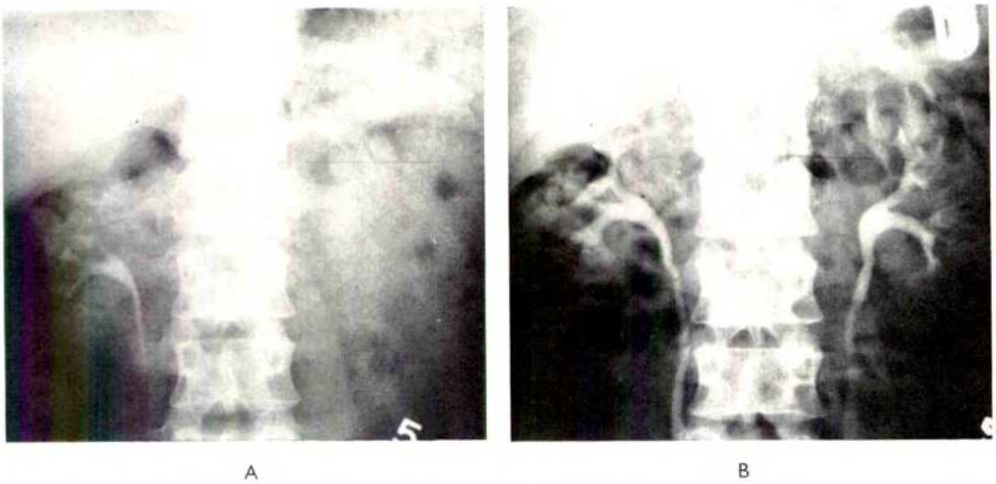

FIG. 10.—T. H., Intravenous pyelograms taken (A) during an attack of left renal colic, and (B) 6 days later, showing recovery of function after the passage of a small calculus.

takes to recover is not known, but peristalsis can be immediately reactivated below a calculus by injecting a quantity of fluid from below (*Fig.* 9). Intravenous pyelograms after the passage of a calculus often show a return to normal excretion (*Fig.* 10). Davies, Jones, Croft, and Shuttleworth (1969), in their assessment of pyeloplasty by radioactive renography, show that the parenchymal function returns to normal earlier than had been suspected, and Caine and Hermann (1970) have shown that, even after anastomosis, transmission of the peristaltic wave occurs between the twenty-third and the twenty-sixth days.

The period of delay in the return of function after the passage of a calculus must vary in individual cases, but in the early postcolic phase the absence of the normal stimulus is probably one of the main factors causing the reduced activity of the ureter which is so constantly observed.

Acknowledgements.—We wish to thank Dr. J. G. Sclater, Dr. J. Munro, and Mr. J. Cook for their co-operation in this study.

CARCINOMA OF THE DUODENUM

By JOHN S. KENEFICK

SENIOR SURGICAL REGISTRAR, ROYAL FREE HOSPITAL, LONDON

SUMMARY

Five patients with carcinoma of the second part of the duodenum, presenting with obstructive jaundice, are discussed. The diagnosis was established at operation and radical surgery was not possible in any case. Local excision of the tumour and the adjacent duodenal wall with reanastomosis of the bile-duct and pancreatic duct to the duodenum were performed. Three patients died from the disease within 1 year of operation and 2 patients are still alive 16 and 18 months after operation. The clinical features of this disease are reviewed.

PRIMARY carcinoma of the duodenum is rare. The initial symptoms are vague, and patients with this condition often present a perplexing diagnostic dilemma. The diagnosis is frequently not established until the pathological process has extended beyond the bounds of surgical redemption.

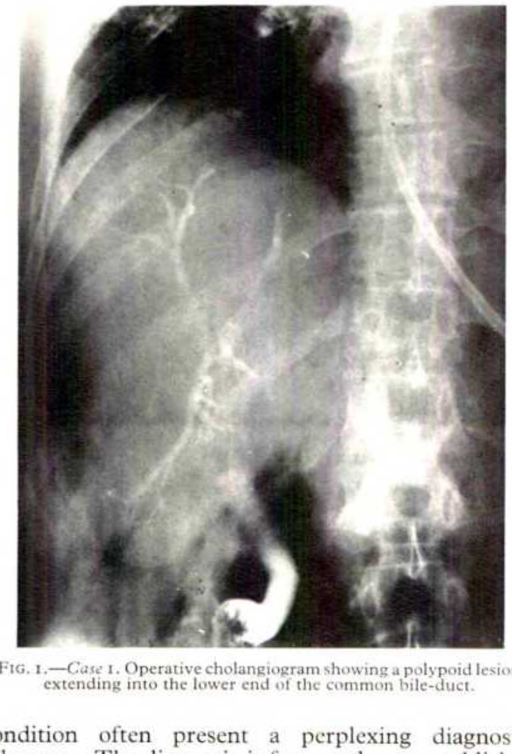

FIG. 1.—*Case* 1. Operative cholangiogram showing a polypoid lesion extending into the lower end of the common bile-duct.

The purpose of this paper is to report 5 cases of carcinoma of the duodenum presenting with obstructive jaundice and to review the disease.

CASE REPORTS

Case 1.—Mrs. E. H., a housewife aged 61 years, had had transient episodes of obstructive jaundice in 1957 and 1964. In December, 1968, she had been admitted elsewhere with a third attack of jaundice. Laparotomy had revealed non-calculous cholecystitis with one minute calculus in the common bile-duct. A dilator had passed easily into the duodenum. Cholecystectomy had been performed. A subsequent T-tube cholangiogram had shown a filling defect of the medial duodenal wall but the contrast medium had flowed freely into the duodenum.

One month later the patient was admitted to the Royal Free Hospital with recurrent obstructive jaundice. Laparotomy revealed a polypoid neoplasm of the medial duodenal wall which was shown by cholangiography to be extending into the lower end of the common bile-duct (*Fig.* 1). There were several enlarged lymph-nodes in the porta hepatis and lesser omentum. Local excision of the tumour (*Fig.* 2) and the adjacent duodenal wall were performed, and the common bile-duct and pancreatic duct were reanastomosed to the duodenum separately.

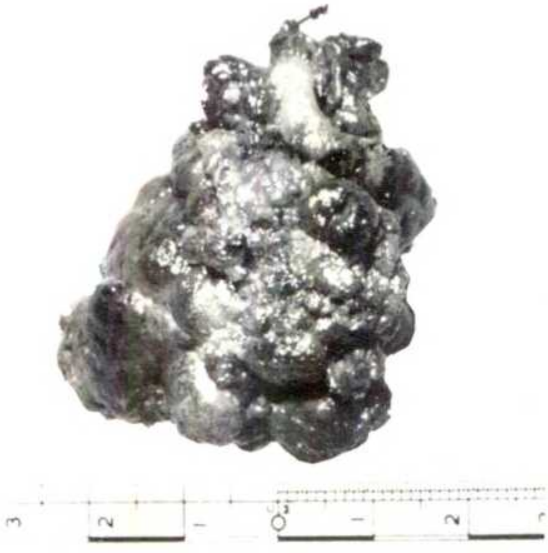

FIG. 2.—*Case* 1. Tumour excised from the duodenal wall.

Histologically, the tumour was a well-differentiated papillary columnar-cell carcinoma of the duodenum (*Fig.* 3).

The patient remains well to date.

Case 2.—Mrs. L. T., a housewife aged 53 years, had developed transient obstructive jaundice in November, 1968, after removal of a benign ovarian cyst. Jaundice had recurred 1 month later. She had complained of pruritus for 1 year and had lost 19 kg. in weight. When admitted to hospital, hepatomegaly was the only abnormal physical sign. The haemoglobin was 10·5 g. per cent, serum bilirubin 0·8 mg. per cent, and alkaline phosphatase 46 K.A. units. A cholecystogram showed no concentration of dye in the gall-bladder after a double dose of contrast. Liver biopsy showed changes suggestive of large-duct obstruction, and a liver scan showed filling defects in both lobes of the liver. Preoperative percutaneous cholangiography demonstrated a dilated biliary tree with obstruction at the lower end of the common bile-duct (*Fig.* 4).

At operation there was a pedunculated neoplasm of the medial wall of the second part of the duodenum adjacent to the ampulla of Vater. There were several secondary deposits in the liver. Local excision of the tumour and adjacent wall was performed and the common bile-duct and pancreatic duct were reanastomosed separately to the duodenum.

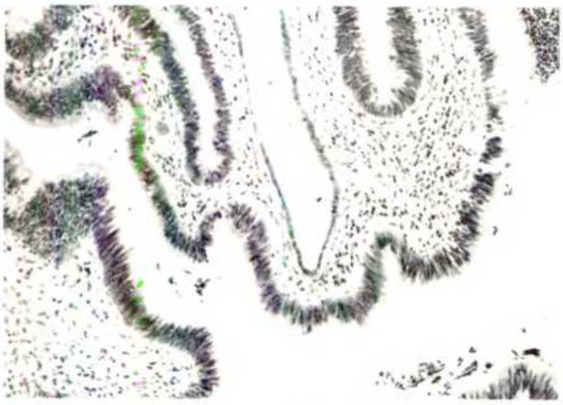

FIG. 3.—*Case* 1. Adenocarcinoma of the duodenal wall. (× 20.)

Histologically, the tumour was a papillary adenocarcinoma arising from the duodenal wall (*Fig.* 5).

When last seen in December, 1969, she felt well but had hepatomegaly.

Case 3.—Mr. H. P., aged 59 years, was known to have familial intestinal polyposis. He had had abdomino-perineal excision of a carcinoma of the rectum in 1953 and a total colectomy for carcinoma of the ascending colon in 1955. He had then remained well until 1968 when he had started to lose weight and had become jaundiced.

When admitted to the Royal Free Hospital in December, 1968, he was jaundiced and the liver was enlarged. The E.S.R. was 122 mm. per hour, serum bilirubin 3·6 mg. per cent, and alkaline phosphatase 100 K.A. units. A percutaneous liver biopsy showed the histological features of large-duct biliary obstruction, and percutaneous cholangiography showed a grossly dilated biliary tree (*Fig.* 6).

At operation there was a papillary neoplasm of the medial wall of the second part of the duodenum, infiltrating the duodenal wall and obstructing the common bile-duct and pancreatic duct. Resection was not possible and cholecystectomy, choledochojejunostomy, and gastrojejunostomy were performed.

Biopsy of the tumour showed an invasive papillary adenocarcinoma of the duodenum (*Fig.* 7).

He developed jaundice and hepatomegaly and died in October, 1969, 9 months after operation.

Case 4.—Mrs. M. H., a housewife aged 82 years, was admitted to the Royal Free Hospital in July, 1967, with a 3-week history of right hypochondrial pain and jaundice. The liver and gall-bladder were palpable. The serum bilirubin was 6·2 mg. per cent and alkaline phosphatase 123 K.A. units. An operative cholangiogram showed a dilated common bile-duct (*Fig.* 8).

Exploration revealed a sessile neoplasm of the medial wall of the second part of the duodenum, obstructing the common bile-duct and pancreatic duct. Local excision of the tumour was performed.

Histological examination showed a well-differentiated adenocarcinoma arising from the duodenal mucosa (*Fig.* 9).

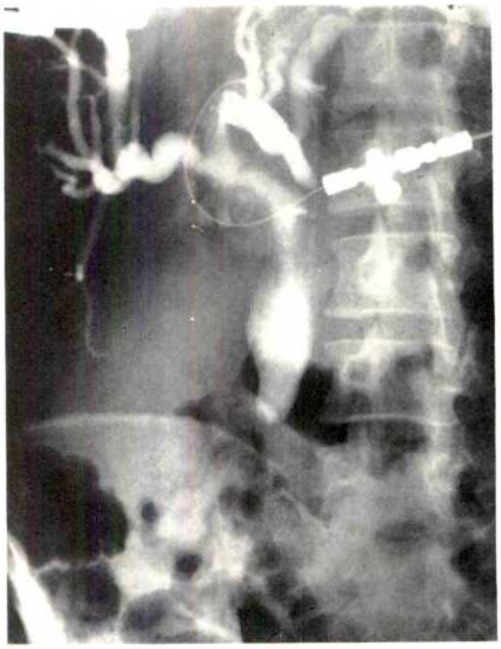

FIG. 4.—*Case* 2. Percutaneous cholangiogram showing obstruction of the lower end of the common bile-duct.

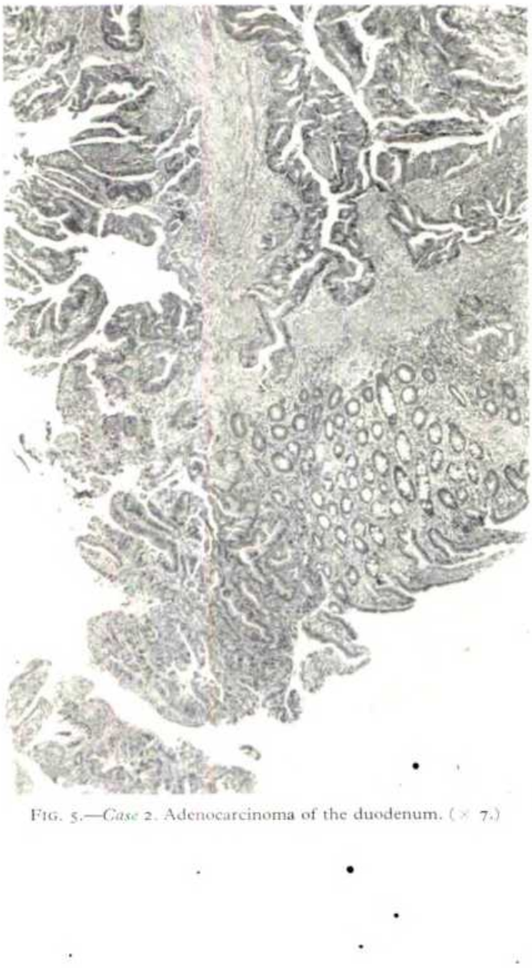

FIG. 5.—*Case* 2. Adenocarcinoma of the duodenum. (× 7.)

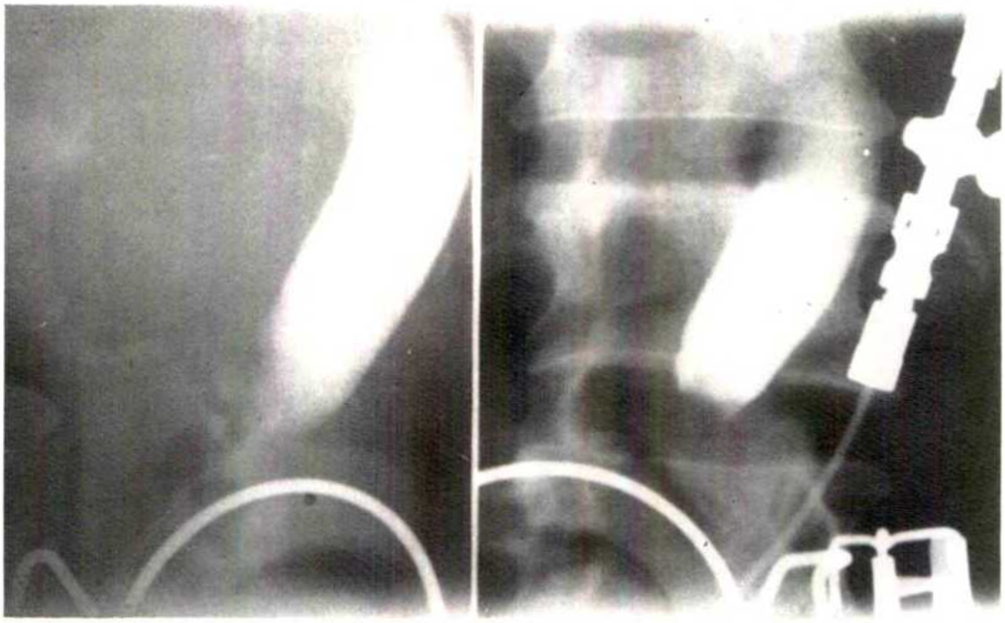

FIG. 6.—*Case* 3. Percutaneous cholangiograms showing obstruction of the lower end of the common bile-duct.

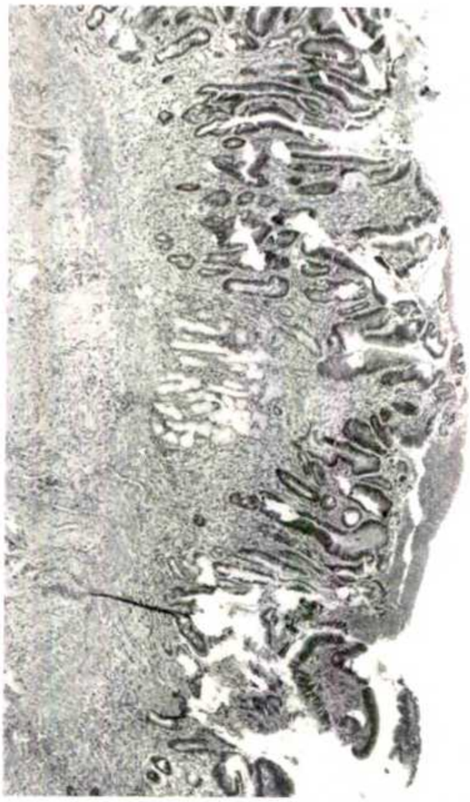

FIG. 7.—*Case* 3. Biopsy of a tumour showing an adenocarcinoma of the duodenum.

The patient remained well until August, 1968, when the jaundice recurred, and she died 12 months after operation.

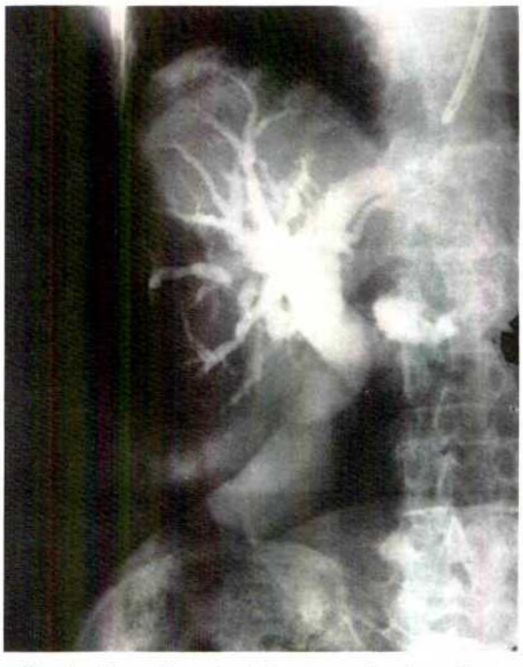

FIG. 8.—*Case* 4. Operative cholangiogram showing a dilated common bile-duct.

Case 5.—Mr. P. C., aged 64 years, was admitted to the Royal Free Hospital in July, 1967, with jaundice, epigastric pain, and weight-loss. He was deeply jaundiced and the liver was enlarged. The E.S.R. was 122 mm. per hour, serum bilirubin 12·5 mg. per cent, and alkaline phosphatase 41 K.A. units.

At operation the common bile-duct was grossly dilated. Cholangiography confirmed an obstruction at the lower end of the duct (*Fig.* 10). Exploration revealed a pedunculated neoplasm of the medial wall of the second part of the duodenum, obstructing the common bile-duct and pancreatic duct. Local excision of the tumour was performed and the common bile-duct and pancreatic duct were anastomosed separately to the duodenum.

Histologically, the tumour was a well-differentiated adenocarcinoma of the duodenal mucosa (*Fig.* 11).

In February, 1968, the patient developed jaundice, ascites, and massive hepatomegaly, and he died in March, 1968, 8 months after operation.

HISTORICAL REVIEW

Primary carcinoma of the duodenum was first described by Hamburger in 1746, but it was not until 1932 that the clinical and pathological features were correlated by Mateer and Hartmann. Resnik and Cooper (1958), in a review of the literature of 1948–56, could only find 7 cases that had survived for more than 5 years after definitive surgical treatment. They attributed the poor results, first, to the inability of the clinicians and radiologists to establish the diagnosis while the lesion was still surgically remediable, and, secondly, to the timidity of surgical treatment once the diagnosis had been established.

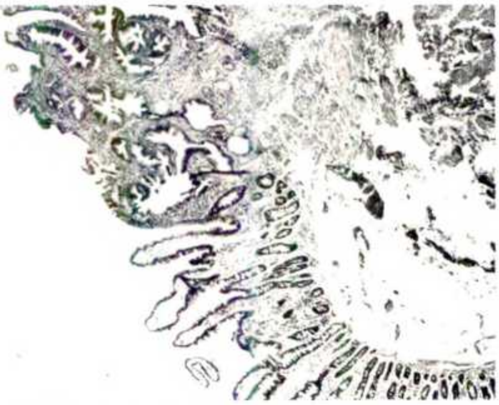

FIG. 9.—*Case* 4. Section showing the transition from normal duodenal mucosa to adenocarcinoma. (× 5.)

INCIDENCE

Primary carcinoma of the duodenum accounts for 0·03–0·05 per cent of all carcinomas (Eger, 1933; Howard, 1943; Burgerman, Baggenstross, and Cain, 1956). Three per cent of gastro-intestinal carcinomas occur in the small intestine and, of these, 45 per cent arise in the duodenum (Burgerman and others, 1956). In 1916 Jefferson stated: ‘considering the shortness of the duodenum, it is evident that inch for inch it is more liable to cancer than the rest of the small intestine’. Primary carcinoma of the duodenum is most common in the fifth and sixth decades but can occur as early as the second decade. Most series report an equal incidence in both sexes.

PATHOLOGY

In a review of 25,032 necropsies Burgerman and others (1956) found 31 cases of malignant duodenal tumours, excluding ampullary lesions. Of these, 87 per cent were adenocarcinomas and the remainder were leiomyosarcomas, lymphosarcomas, and reticulum-cell sarcomas. Thirty-five per cent were situated in the first part of the duodenum, 45 per cent in the second part, and 10 per cent in the third and fourth parts. The macroscopic appearance of duodenal carcinoma takes one of four forms: ulcerative,

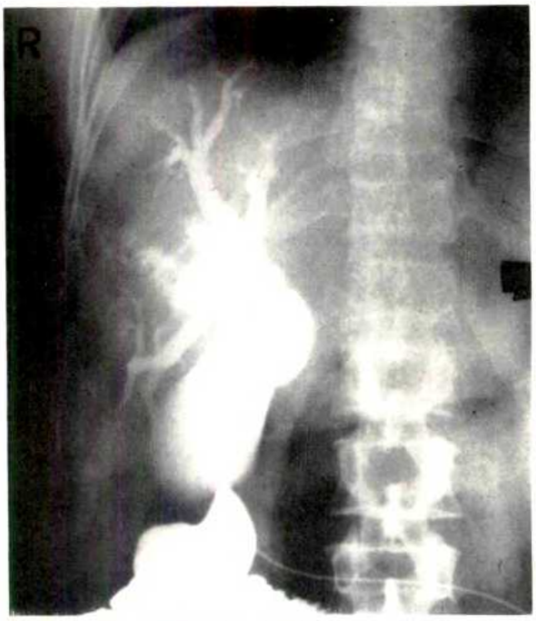

FIG. 10.—*Case* 5. Operative cholangiogram showing a grossly dilated common bile-duct.

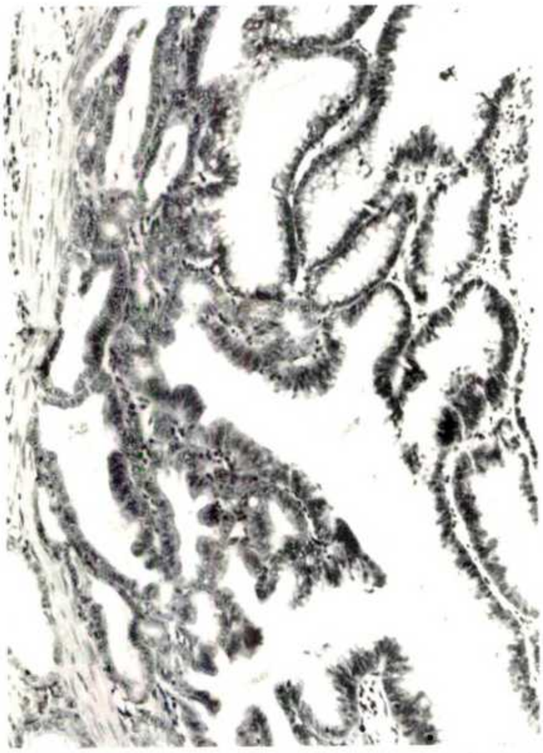

FIG. 11.—*Case* 5. Well-differentiated carcinoma of the duodenal mucosa. (× 27.)

polypoid, annular, and infiltrative, and the average diameter is 4·6 cm. Duodenal carcinomas metastasize to the regional lymph-nodes and the liver, but they may produce widespread metastases later in the course of the disease. Metastases were present in 20 of the 31 cases reported by Burgerman and others (1956). Brenner and Brown (1955), Burgerman and others (1956), and Dixon, Lichtman, Weber, and McDonald (1966) believe that periampullary lesions should be excluded unless there is conclusive proof of their origin from the duodenal mucosa, and this may be extremely difficult to establish. Lieber, Stewart, and Lund (1939) reviewed 229 periampullary lesions and accepted only 3 cases of duodenal origin. All 5 cases reported in the present series were papillary adenocarcinomas and were seen to arise from the duodenal mucosa. They assumed a polypoid form and extended into the duodenal lumen. The transition from normal to neoplastic mucosa is well seen in *Fig.* 9. All cases of periampullary carcinoma when the tissue of origin was in doubt were excluded from this series.

CLINICAL FEATURES

The average duration of symptoms before diagnosis is 10 months. Iovine and Tsangaris (1961) classified the clinical complex into four groups: (1) duodenal obstruction, (2) biliary obstruction, (3) ulceration with haemorrhage, and (4) penetration. Burgerman and others (1956), reviewing 31 cases of duodenal carcinoma, found the incidence of symptoms to be as follows: abdominal pain, 74 per cent; weight-loss, 74 per cent; vomiting, 55 per cent; haematemesis, 23 per cent; melaena, 29 per cent; jaundice, 23 per cent; abdominal mass, 19 per cent; anaemia, 55 per cent.

Abdominal pain is usually localized in the right hypochondrium and has a dull continuous aching quality. Colicky pain occurs with duodenal obstruction. Weight-loss is a constant feature, averaging 10·9 kg. over a period of 3–12 months. Hypochromic anaemia is usually associated with haematemesis and melaena, and occult blood is found in the stools in 48 per cent of cases. The incidence of jaundice in carcinoma of the duodenum—23 per cent of all cases (Burgerman and others, 1956)—is low compared with the figure of 89–100 per cent for other forms of malignancy in this area (Warren, Cattell, Blackburn, and Nora, 1962). However, jaundice is usually the presenting symptom with duodenal carcinoma situated near the ampulla of Vater, as in the 5 cases reported here.

Diagnosis is established by radiological study of the upper gastro-intestinal tract, and the important radiological features are alteration of the mucosal pattern, intraluminal filling defects (tumours larger than 1 cm. should be demonstrable), altered contour and flexibility of the duodenum, and the effects of duodenal obstruction. Radiological study of the duodenum has been enhanced by the introduction of hypotonic duodenography (Kreel and Mackintosh, 1968), and greater use of this technique should enable more frequent preoperative diagnosis.

TREATMENT

Approximately 50 per cent of cases come to surgery, and of these, 54 per cent have palliative surgery and 38 per cent have radical surgery (Berger and Koppelman, 1942). The main operative procedures employed are pancreaticoduodenectomy, segmental resection of the duodenum with or without a portion of the adjacent pancreas, and local resection of the tumour.

Local resection of the tumour is the operation of choice in lesions that are locally malignant and that have not invaded the pedicle or adjacent duodenal wall. This is particularly suitable in elderly patients in whom more extensive procedures might be undesirable. Local excision of the tumour and the adjacent duodenal wall with reconstruction of the biliary and pancreatic ducts is suitable as a palliative procedure in patients unfit for more extensive surgery or when pancreaticoduodenectomy would not be curative. In the 5 cases reported in this series, all symptoms were relieved. Two patients are still alive and 3 have died 8, 9, and 12 months after operation respectively.

Since duodenal carcinoma spreads primarily by lymphatic extension, the ideal treatment is removal of the primary lesion and its lymphatic drainage pathways, as in pancreaticoduodenectomy. The operative morbidity of this procedure is 18·5 per cent and the 5-year survival is 40 per cent (Warren and others, 1962).

DISCUSSION

The 5 patients reported in this series were over the age of 50 years, and 4 had obstructive jaundice at the time of admission. There were no specific clinical features to indicate the nature of the pathology, and the diagnosis in each case was established at operation, although previous barium studies in 1 case suggested the diagnosis.

There were no specific biochemical changes in this series. Very high levels of alkaline phosphatase usually indicate hepatic metastases.

The importance of barium studies of the upper gastro-intestinal tract in patients with obstructive jaundice and occult blood in the stools cannot be overstressed. Tumours of the duodenum of more than 1 cm. are usually demonstrable. Hypotonic duodenography (Kreel and Mackintosh, 1968) is advisable when barium studies alone are unsatisfactory. Cholangiography is advisable in patients submitted to surgery for obstructive jaundice, and particularly when the diagnosis is in doubt. In this series the site of obstruction was demonstrated in each case. Percutaneous transhepatic cholangiography (George, Young, Walker, and Sherlock, 1965) is best performed in the immediate preoperative period and the subsequent surgical relief of the obstruction removes the danger of bile leakage from the puncture site.

Careful palpation of the second part of the duodenum should reveal intraluminal neoplasms, but it may be extremely difficult to locate small tumours and duodenotomy should be performed without hesitation when necessary.

The choice of treatment depends on the extent of the lesion and the general condition and age of the patient. Pancreaticoduodenectomy should be performed when feasible as this gives the best results. The operative morbidity is 18·5 per cent and the 5-year survival is 40 per cent (Warren and others, 1962). In the present series radical surgery was not possible in any case and local excision of the tumour and adjacent duodenal wall was performed. This procedure resulted in the relief of symptoms in each case but was not curative. Three patients survived for 8, 9, and 12 months, respectively, but then died with metastases. Two patients are still alive 16 and 18 months, respectively, after operation, but 1 of these had hepatic metastases at the time of operation.

Carcinoma of the duodenum should be considered in the differential diagnosis of all cases of obstructive jaundice. Careful radiological investigation is the most important diagnostic approach and radical surgery holds the best prognosis.

Acknowledgements.—I wish to thank Miss P. George, F.R.C.S., Consultant Surgeon, Royal Free Hospital, for permission to publish these cases and for assistance in preparation of the manuscript. I would also like to thank the Departments of Pathology and Photography, Royal Free Hospital, for the illustrations.

BILATERAL DOUBLE NIPPLES

BY TERENCE BRIGHTMORE
WESTMINSTER HOSPITAL, LONDON

SUMMARY

Two cases are reported of bilateral double nipples occurring within the areolae of the normal breasts. The association of congenital lesions of the nipple and certain diseases is discussed.

ALTHOUGH the incidence of supernumerary nipples is fairly common their occurrence within the areola of a normal breast is rare, and the presence of such bilateral double nipples is extremely rare (de Cholnoky, 1939). The following 2 cases exhibiting this condition are therefore of interest.

CASE REPORTS

Case 1.—A 37-year-old white female presented at the Breast Clinic of the Royal Marsden Hospital with a 6-month history of bilateral breast tenderness which was unassociated with menstruation. She was nulliparous from choice. There was no other personal or family history of relevance. The upper outer quadrant of her right breast was granular and slightly tender. Within the areola of each breast was a double nipple. On the right side the nipples were distinctly separate, but on the left the nipples were less well demarcated (*Fig.* 1). The patient had been unaware of this condition.

Case 2.—A 28-year-old white female was noted to have bilateral double nipples at a Westminster Hospital antenatal clinic (*Figs.* 2, 3). She had never been aware of this abnormality, although she had noticed a small mole beneath her left breast. As a child she had been told that she had a 'leaky heart valve' and at various times the presence of a cardiac murmur had been noted. There was no cardiac murmur present at any time during obstetrical surveillance or at a further examination 7 years later. Her husband possessed a supernumerary nipple below his left breast. There was no other personal or family history of relevance. No breast abnormalities were noted in her son who was delivered at full term. She did not breast feed him because she did not produce enough milk.

DISCUSSION

The nipple and epithelial lining of the ducts and alveoli of the human breasts are derived from the milk-lines, which are specialized areas of ectodermal thickening on the ventral surface of the embryo extending obliquely on each side from the axilla to the inguinal region. Normally, the milk-lines disappear during embryonal development, and the final disposition of one breast on each side of the median plane in the pectoral region is dependent on the persistence of ectodermal and mesodermal differentiation and growth in this area. In the region of the fourth intercostal space the future lactiferous tubules develop from an ectodermal ingrowth around which mesenchyme proliferates to form the supportive tissue of the breast. In the centre of this ingrowth a shallow pit is formed from which the nipple arises by a process of ectodermal differentiation. At term the foetus possesses fully developed ducts which open into the nipple.

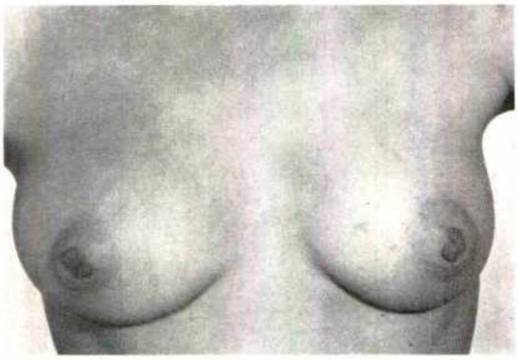

FIG. 1.—*Case* 1. The double nipples are best demarcated on the right side.

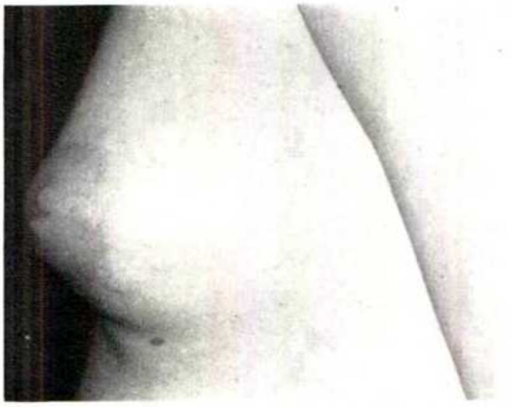

FIG. 3.—*Case* 2. Double nipples on the left side and a submammary mole.

Kajava (1915) classified supernumerary breast tissue into eight categories:—

1. Complete breast: mammary gland tissue, nipple, and areola.
2. Glandular tissue and nipple.
3. Glandular tissue and areola.
4. Glandular tissue only.
5. Nipple and areola with an area of fat replacing mammary glandular tissue—pseudomamma.
6. Nipple only—polythelia.
7. Areola only—polythelia areolaris.
8. Patch of hair only—polythelia pilosa.

The most common forms noted were polythelia and pseudomamma. Kajava (1915) restricted the term 'nipple' to the protuberance in the centre of the areola. Most authors writing on polythelia use the term 'nipple' in a non-restrictive sense as consisting of a papilla (or protuberance), aerola, follicles, and hair (Bruce, 1879). It is rare for supernumerary nipples to contain all of these structures.

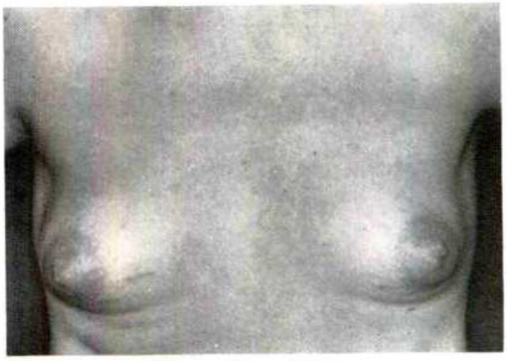

FIG. 2.—*Case* 2. The double nipples are best demarcated on the left side.

Guest (1923) found an incidence of accessory nipples of 0·4 per cent in 20,000 school-children, with a female to male ratio of 2 : 1. In adults the incidence has been recorded as 1 per cent (Hamblen, 1945) and 1–2 per cent (de Cholnoky, 1939), while Evans (1959) found that 5 per cent of healthy adults possessed supernumerary nipples. The laterality and sex incidence are approximately equal in adults, and the presence of more than one accessory nipple is uncommon. In a number of cases a hereditary predisposition has been noted, and Klinkerfuss (1924) recorded a family in which polythelia was present in four generations.

Supernumerary breast tissue may be found anywhere between the axilla and the groin along the site of the milk-line. Accessory nipples are usually found between the breast and the umbilicus and are most common immediately beneath the breast. They are infrequently observed below the umbilicus or above the normal breast. Intra-areolar polythelia is rare and probably originates in utero as a dichotomy of the developing nipple. The rarity of bilateral intra-areolar double nipples is confirmed by the presence of only one report in the literature. Butts (1954) reported a Bush negress of Suriname in her middle twenties with bilateral symmetrical intra-areolar double nipples who was suckling her second child. Each nipple functioned independently. Most authors regard supernumerary breast tissue occurring along the site of the milk-line as an atavistic phenomenon (Lichtenstern, 1878; Darwin, 1888). Brouha (1905) thought that the milk-line had no phylogenetic significance. Hughes (1950) regarded the atavistic explanation of polythelia occurring along the site of the milk-line as an exploitation of this line, and he believed that supernumerary nipples should be regarded merely as accidents of development.

Polythelia is rare in apes (Hartman, 1927), and Mathews and Baxter (1948) could find only 12 recorded cases.

Wakeley (1951) noted that it was curious that so little attention was paid to malformation and diseases of the nipple. A number of authors, however, have drawn attention to the association of congenital abnormalities of the nipples and neurosis, peptic ulceration, cardiovascular disease, migraine, and renal and gonadal hypoplasia.

Harper (1948, 1951) regarded supernumerary nipples as a skin vestige reflecting the early mammalian history of man. He also regarded vascular naevi as vestiges of the respiratory plexus of amphibians, and pigmented moles as primitive skin structures equivalent to the pigmented reptilian tactile organs such as are found in crocodile jaws. He concluded that these atavistic characteristics of skin are accompanied by an unstable central nervous system, as both skin and the central nervous system are derived from ectoderm. He recorded an increased incidence of neurosis in patients with polythelia, vascular naevi, and pigmented moles.

Zălaru (1965) observed an increased incidence of peptic ulceration in cases of polythelia.

Evans (1959) and Czernicka (1964) recorded an increased incidence of polythelia in patients suffering from cardiovascular disease. Evans (1959) noted polythelia only along the site of the milk-line, and in a series of 1059 healthy subjects the incidence was 5 per cent. He found that the incidence of polythelia was much higher in patients with systemic hypertension who had enlarged left ventricles (35 per cent), pulmonary hypertension with right ventricular hypertrophy (44 per cent), and cardiomyopathy (44 per cent).

Ask-Upmark (1954) suggested an association between inverted nipples and migraine, although he offered no explanation. Pronounced eyebrows (due to hypervascularity) and migraine were also linked, and he thought that the common factor in these cases was the behaviour of the arterial system and that this had a genetic basis.

Fleisher (1966) noted that nipples which were lateral to the midclavicular line ('wide-set') were associated with bilateral renal hypoplasia and gonadal dysplasia. If 'wide-set' nipples are present and there are no signs of gonadal dysplasia, then a high index of suspicion of bilateral renal hypoplasia is warranted.

Barnes (1962) thought that the amount of tethering of the nipple to the underlying tissues was more important than its size. The success of lactation often depends on the presence of firm prominent nipples, which are capable of erection, as depressed nipples predispose to cracking as a result of prolonged and ineffective efforts of the infant's gums to grip an insufficiently erectile structure (Saner, 1950).

Although Aird (1958) regarded supernumerary nipples as of no significance, the possibility of the coexistence of the above-mentioned diseases should be borne in mind when confronted with a patient who possesses a congenital abnormality of the nipple.

Acknowledgements.—I should like to thank Professor H. Ellis for his comments; Mr. W. P. Greening and Mr. R. de Vere for permission to report the cases who were under their care; the Departments of Medical Photography at the Royal Marsden and Westminster Hospitals for the illustrations; and Miss H. Rolls for secretarial assistance.

SOME CLINICAL ASPECTS OF IDIOPATHIC RETROPERITONEAL FIBROSIS

By M. J. MITCHINSON

DEPARTMENT OF PATHOLOGY, UNIVERSITY OF CAMBRIDGE

SUMMARY

A series of 40 patients with idiopathic retroperitoneal fibrosis is discussed with reference to some of the clinical observations. Among other conclusions it appears that corticosteroids should be used more in the treatment of this disease.

OBSTRUCTION of the ureters by retroperitoneal fibrosis of unknown cause has been described over three hundred times since Ormond drew attention to the condition in 1948. The ailment is now well known; authors of recent reviews include Comings, Skubi, Van Eyes, and Motulsky (1967), Webb and Dawson-Edwards (1967b), and Saxton, Kilpatrick, Kinder, Lessof, McHardy-Young, and Wardle (1969). The aetiology is obscure and has not yet been clarified by the undoubted association of some cases with methysergide administration (Graham, 1967). The author has therefore collected and studied clinical data, necropsy reports, pathological material, and sections from 40 patients suffering from fibrosis in the retroperitoneal tissues of the lower abdomen (Mitchinson, 1969). The only criterion for inclusion in this series was lack of obvious cause. The principal pathological findings and aetiology are discussed elsewhere (Mitchinson, 1970). The following observations are based on the clinical data in these 40 patients.

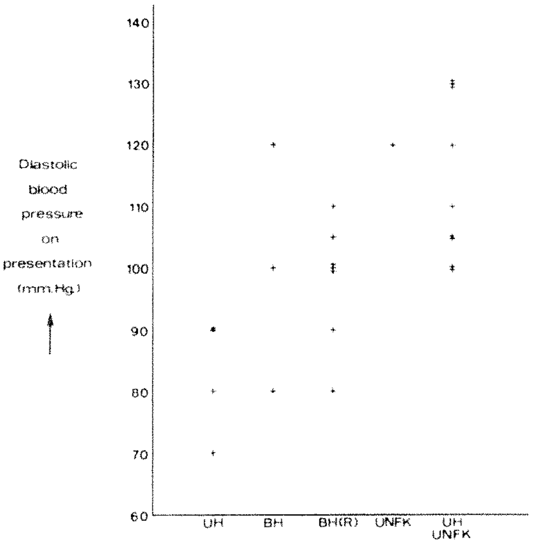

FIG. 1.—The relationship of the degree of renal damage (assessed by pyelography) to hypertension. UH, Unilateral hydronephrosis. BH, Bilateral hydronephrosis. (R), Retrograde pyelography only. UNFK, 'Non-functioning' kidney on intravenous pyelography.

CLINICAL PRESENTATION

Males outnumbered females by 3 to 1, and the usual time of onset of the disease was in middle age, as in previously published accounts (Packham and Yates-Bell, 1968).

Presenting symptoms were similar to those described by other authors and were mainly due to blockage of hollow organs by the progressive inflammation and fibrosis spreading in the retroperitoneal tissue of the lower abdomen. The presentation was due to ureteric blockage in all but 2 patients, who complained of claudication (due to narrowing of the aorta) and abdominal distension (due to narrowing of the colon) respectively. It is important to note that only 4 patients presented with oliguria; the majority had complaints such as loin pain (16 patients), often radiating to the groin (10), vague abdominal or low-back pain (19), vomiting (16), anorexia (7), and considerable weight-loss (11). Only 1 patient had polyuria and polydipsia, which is a recognized but rare complaint in this disease (Tulloch, 1960).

Physical signs were meagre. Eight patients were tender in the loin, and 4 in an iliac fossa. Five had oedema of the legs (due to venous blockage). The only frequent finding on examination was hypertension.

Hypertension.—Although the blood-pressure had not always been recorded at least 17 patients had diastolic measurements of 100 mm. Hg or more on presentation. *Fig.* 1 shows that the observations in this series supported the common assumption that hypertension in this disease is due to renal damage. Two patients who had had one kidney removed showed a gradual increase in blood-pressure during increasingly severe involvement of the remaining kidney. In 3 patients hypertension was relieved by surgical removal of a non-functioning kidney—an important measure which is not always taken.

A few patients presented with what may have been complications of their hypertension (epistaxis in 1, heart failure in 3, headaches in 5). None had evidence of hypertension preceding the disease.

There was no evidence in this series that narrowing of the renal arteries or aorta, or compression of the kidney by fibrosis, contributed to the hypertension.

Measurement of blood-pressure in the legs is not often performed. In future such measurements in suspected cases of retroperitoneal fibrosis might occasionally reveal a degree of aortic narrowing which would be helpful in diagnosis.

CLINICAL INVESTIGATION

Urinary infection was uncommon on presentation (2 males, 3 females), although 10 more patients developed this complication after instruments had been passed into the upper urinary tract, and 1 patient became infected after corticosteroid therapy. These findings conflict with the oft-repeated statement (e.g., Rust and Maas, 1967) that the disease frequently presents as urinary infection.

Pyelography in almost all cases showed the typical ureteric obstruction and medial deviation at the level of vertebra L.3 or L.4. The ureter above the obstruction was often kinked owing to increase in length as well as in diameter, as remarked upon by Hanley (1967).

In 1 patient lymphangiography was performed and was normal. Such exceptions limit the value of the investigation, which has been found useful by some (Bookstein, Schroeder, and Batsakis, 1966; Virtama and Helela, 1967).

The erythrocyte sedimentation rate (E.S.R.) was above 45 mm. in the first hour (Westergren) soon after presentation in all except 3 of the 31 cases tested; 8 had readings exceeding 100 mm. in the first hour. Serial measurements suggested that the raised E.S.R. was due to the activity of the inflammatory process in the retroperitoneum rather than to the degree of renal involvement. This investigation was extremely useful in assessing the progress of the disease, especially in response to treatment.

Plasma protein electrophoresis in 13 patients showed raised α_2-globulins in all cases and raised γ-globulins in 8.

^{131}Iodine hippuran renograms proved useful, especially in assessing changes following therapy (Jose, 1967).

Systemic Idiopathic Fibrosis.—It is now well known that the inflammation and fibrosis which characterize this disease occasionally spread forwards to involve the mesentery or upwards along the aortic axis. In addition, the mediastinum, thyroid, and perhaps the orbit and porta hepatis may be similarly affected. It is not yet clear whether any other disease is related.

In the present series of retroperitoneal fibrosis 4 patients also showed evidence of mediastinal fibrosis, and 1, possibly 2, of thyroid disease resembling Riedel's thyroiditis. Indeed, 1 patient presented initially with a superior vena cava syndrome, and another with a thyroid swelling (described by Turner-Warwick, Nabarro, and Doniach, 1966).

Such widespread involvement has led to suggestions that the disease is a 'connective-tissue disease', and the occasional observation of concomitant arthritis or arteritis has tended to support the idea. In the present series 2 (female) patients had arthritis of a rheumatoid type and 1 (male) had arteritis resembling polyarteritis nodosa. Several others had chronic inflammation of the larger elastic arteries, sometimes including the aorta or a coronary artery.

One patient, out of 10 tested, had 'L.E.' cells reported on one occasion. Other tests and necropsy in this case showed no evidence of lupus erythematosus. The latex slide test for the 'rheumatoid factor' was positive in 1 out of 9 patients tested; this patient's Rose-Waaler test was negative, as in 6 other patients, including 1 with arthritis. A search for thyroid auto-antibodies in 21 patients showed no significant difference from controls who were matched for age and sex.

In summary, the disease is certainly potentially widespread, and involvement of organs distant from the ureters must always be sought. Analogies with 'connective-tissue diseases' are tempting but not yet well supported.

DIFFERENTIAL DIAGNOSIS

When a typical pyelographic appearance, including medial deviation of the ureters, has been demonstrated, any other inflammatory disease is most unlikely, and only retroperitoneal malignant neoplasm remains to be excluded. Such mimicry can be produced by a wide variety of neoplasms, and the hazard is well known (Webb and Dawson-Edwards, 1967a); carcinoma of the prostate is probably the commonest. Unfortunately, the most exhaustive investigations, even including laparotomy and biopsy, have proved eventually to be imperfect in excluding neoplasm in some cases. Such considerations should not be allowed to delay the relief of ureteric blockage by one means or another.

TREATMENT

The conventional treatment of ureteric obstruction has been ureterolysis. The results of 38 well-documented ureterolyses in the series are shown in *Table I*, where 'success' is defined as a functioning kidney (assessed by pyelography) with no more than very slight hydronephrosis at least 6 months post-operatively. The good results are self-explanatory. It is possible that the only short-term failures in this series were when the kidney was already irreparably damaged.

Table I.—ASSESSMENT OF SHORT-TERM RESULTS OF URETEROLYSIS

PREOPERATIVE RADIOLOGICAL ASSESSMENT OF KIDNEY	SUCCESS	FAILURE	REASONS FOR FAILURE	
			No Return of Function	Severe Infection
Hydronephrosis on intravenous pyelogram	18	0	—	—
Hydronephrosis on retrograde pyelography	5	4	0	4
'Non-function' on intravenous pyelogram	3	8	7	1

However, this method of assessment does not show some of the disadvantages of surgical treatment which require attention:—

1. Seven out of 12 patients with unilateral ureteric obstruction developed contralateral ureteric involvement subsequently, usually after a few months but on one occasion 2 years later.
2. Four ureters were found to be obstructed again after successful ureterolysis, usually within 1 year but in 1 case 9 years later, by progression of the disease.
3. The above complications can usually be satisfactorily relieved by further surgery, but this multiplies the operative risk. This is admittedly small. Only 1 patient in this series died in the immediate post-operative period, of pneumonia.
4. When ureterolysis is unsuccessful in restoring function to a non-functioning kidney a second operation (nephrectomy) is required to relieve the hypertension.
5. Ureterolysis treats only one complication of the disease, which may continue to affect other organs

such as the aorta, coronary arteries, mediastinum, or thyroid.

Most observers would conclude that these disadvantages do not detract significantly from the surgical approach to treatment, but there is some evidence that oral corticosteroid therapy deserves wider trial. Corticosteroids are difficult to assess when surgical treatment coincides with their use, but at least 3 patients in this series showed evidence suggesting the rapid efficacy of medical treatment alone. Corticosteroids lack most of the above five disadvantages of surgical treatment but are not without their own disadvantages. When used alone they may also postpone the recognition of a neoplastic mimic of retroperitoneal fibrosis. A discussion of the 3 patients referred to and a suggested compromise between surgical and corticosteroid treatment have been presented elsewhere (Mitchinson, Withycombe, and Arden-Jones, 1971). More observations on the use of corticosteroids in practice are required before there is sufficient evidence on the relative merits of surgical and medical treatment.

In 7 patients, nephrostomy was performed, usually as an interim measure; urinary infection invariably followed and was associated with a poor prognosis. Retrograde pyelography was also occasionally apparently responsible for introducing infection, but less frequently and with less serious sequelae. If uraemia is severe, indwelling ureteric catheters are probably a better interim measure than nephrostomy, if the diagnosis has been made.

CONCLUSIONS

Some aspects of idiopathic retroperitoneal fibrosis merit more attention than they have received; for example, the complication of renal hypertension, the rarity of infection if instruments are not passed into the urinary tract, the widespread nature of the disease, the usefulness of the E.S.R. as a guide to management, and the possibility of the more frequent use of corticosteroids in treatment.

Acknowledgements.—Some of the cases in the series have been reported elsewhere (Jones and Alexander, 1966; Turner-Warwick and others, 1966; Jose, 1967). To these authors and to many other surgeons, physicians, and pathologists my thanks are due for their help and permission to study their patients. I am particularly grateful to Dr. Deborah Doniach who performed and assessed the thyroid auto-antibody tests and to Dr. R. C. B. Pugh for advice.

PLATELET ADHESIVENESS AND LIPOPROTEIN LIPASE ACTIVITY IN PATIENTS WITH BENIGN AND MALIGNANT DISEASE OF THE PROSTATE*

By J. M. HAM, M. JONES, AND D. KEMP

DEPARTMENT OF SURGERY, THE PRINCE HENRY HOSPITAL, SYDNEY

SUMMARY

Platelet adhesiveness and lipoprotein lipase (clearing factor lipase) activity have been measured in 22 patients with benign prostatic obstruction and in 20 patients with prostatic carcinoma.

The total platelet counts and the number of adherent platelets were significantly higher and the lipoprotein lipase responses to heparin were significantly lower in the patients with carcinoma.

These results are relevant to the use of oestrogens in the treatment of prostatic carcinoma since these drugs might accentuate the abnormalities found here.

IT has recently been shown that patients with prostatic carcinoma who are treated with oestrogens are more likely to develop thrombo-embolic complications than untreated controls (Veterans Administration Co-operative Urological Research Group, 1967). The reasons for this effect of oestrogens are uncertain. However, the problem may be similar to that found in women taking oral contraceptive agents containing both oestrogens and progestogens in whom significant factors may be alterations in platelet behaviour (Bolton, Hampton, and Mitchell, 1968) and in plasma lipid composition (Wynn, Doar, and Mills, 1966; Brody, Kerstell, Nilsson, and Svanborg, 1968). We have previously demonstrated a reduction in lipoprotein lipase activity in these women (Ham and Rose, 1969). We suggested that this reduction might be one significant factor in the alteration of plasma lipids, since the enzyme has an important role in the transport of lipid across the vascular endothelium.

---

* Based on a paper presented to the Surgical Research Society of Australasia in May, 1970.

In 1964 Slack, Seymour, McDonald, and Love demonstrated an inverse relationship between the lipoprotein lipase activity and the platelet adhesiveness in patients with ischaemic heart disease and in controls. Subsequently, it has been shown that after surgical operations platelet adhesiveness is increased (Ham and Slack, 1967) and lipoprotein lipase activity is reduced (Ham and Slack, 1969). A direct relationship between the enzyme activity and platelet adhesiveness has been postulated (Ham, 1969).

This evidence suggested that oestrogen therapy in patients with prostatic carcinoma might produce changes in platelet behaviour and in lipoprotein lipase activity. However, it was necessary to establish first whether these patients were abnormal before commencing oestrogen therapy, and this was the reason for the present study.

MATERIALS AND METHODS

The object of the investigation was to measure platelet adhesiveness and lipoprotein lipase activity in untreated patients with prostatic carcinoma and in a control group of patients with benign prostatic obstruction. There were 20 patients with carcinoma and 22 controls.

Table I.—AGES, BODY-WEIGHTS, AND BLOOD-UREA LEVELS OF THE PATIENTS (MEAN ± STANDARD ERROR)

	Benign Disease	*Malignant Disease*
Age (years)	68 ± 1·8	71 ± 1·8
Body-weight (kg.)	66 ± 2·7	69 ± 2·8
Blood-urea (mg. per 100 ml.)	38 ± 2·8	41 ± 2·5

All the patients admitted to the study were in-patients in a single urological unit. Their mean ages, body-weights, and blood-urea levels are shown in *Table I*. Seven controls and 8 patients with carcinoma were admitted with acute retention. The remaining patients had symptoms of chronic urinary obstruction, and 6 patients with carcinoma had bone pain as well. All patients had operations subsequent to taking blood samples (cystoscopy and biopsy, prostatectomy, or transurethral resection) and the clinical diagnosis was confirmed histologically. All patients with carcinoma had clinical and pathological evidence of invasive carcinoma, the extent of the disease (Bennett, Dowd, and Harrison, 1970) being Stage II in 7 patients, Stage III in 5 patients, and Stage IV in 8 patients.

Blood samples were taken at approximately 8.30 a.m. after a 10-hour fast, using the methods of collection and processing which have been described previously (Ham and Slack, 1967, 1969). The samples were collected immediately before and 10 minutes after an intravenous injection of 10 I.U. heparin per kg. body-weight. The same brand of heparin (Evans Medical Ltd., 1000 I.U. per ml.) was used throughout. The pre-heparin sample was used to measure the haematocrit, total platelet counts, platelet adhesiveness, pre-heparin enzyme activity, and plasma inhibition of lipoprotein lipase. The enzyme response to heparin was measured in the post-heparin sample.

The haematocrit was measured in duplicate using a microhaematocrit method. Platelet counts and platelet adhesiveness were measured using the Wright rotating bulb (Ham and Slack, 1967); the platelet adhesiveness was expressed as the percentage of adherent platelets. Enzyme activity and plasma inhibition were measured by the methods of Slack and others (1964) and Ham and Slack (1969) respectively.

The significance of the differences was tested by Student's t-test. When the results were not normally distributed, as in the case of the platelet counts, the test was performed after logarithmic transformation. Values for P of less than 0·05 were accepted as significant.

RESULTS

The results are shown in *Table II*. The mean haematocrit was significantly lower in the patients with carcinoma and the mean total platelet count and the number of adherent platelets were significantly higher than in the control group. There was no significant difference in the platelet adhesiveness measurements, in the pre-heparin enzyme activity, or in the plasma inhibition of lipoprotein lipase. However, the mean post-heparin lipoprotein lipase activity was significantly lower in the carcinoma patients.

Table II.—ANALYSIS OF RESULTS (MEAN ± STANDARD ERROR)

FACTOR	BENIGN DISEASE	MALIGNANT DISEASE	SIGNIFICANCE OF DIFFERENCE
Haematocrit (per cent)	45 ± 0·8	40 ± 1·3	$P < 0·01$
Total platelet count ($\times 10^3$ per c.mm.)	223 ± 20	294 ± 31	$P < 0·05$
Number of adherent platelets ($\times 10^3$ per c.mm.)	75 ± 9	105 ± 15	$P < 0·05$
Platelet adhesiveness (per cent)	34 ± 1·7	34 ± 2·2	N.S.
Pre-heparin enzyme activity (µEq. per ml. per min.)	0·020 ± 0·006	0·017 ± 0·006	N.S.
Post-heparin enzyme activity (µEq. per ml. per min.)	0·25 ± 0·02	0·19 ± 0·02	$P < 0·05$
Plasma inhibition (per cent)	−19 ± 3	−19 ± 5	N.S.

N.S. = Not significant.

DISCUSSION

The basic reason for this investigation was to determine whether untreated patients with prostatic carcinoma had abnormalities in platelet behaviour or in lipoprotein lipase activity. However, the design of the investigation also provided an opportunity for a comparison between patients with a benign disease and those with a malignant disease producing similar clinical features. There have, of course, been previous studies of coagulation factors in patients with malignant disease (Eastham, 1964; Miller, Sanchez-Avalos, Stefanski, and Zuckerman, 1967; Davis, Theologides, and Kennedy, 1969), and it has been shown that such patients may have an increase in the total platelet count and in the number of adherent platelets. In these earlier studies the controls were normal subjects and it is therefore difficult to determine whether the findings were related to a direct effect of the tumours or to secondary non-specific effects (e.g., weight-loss). In the present study the two groups of patients had similar clinical features and presumably the tumours were responsible for the differences found. It is, of course, uncertain whether the findings are specific to prostatic carcinoma or whether they apply to other forms of malignant disease.

This investigation has demonstrated a significant increase in the total platelet count in the patients with carcinoma, together with a similar increase in the number of adherent platelets. The platelet adhesiveness (percentage of adherent platelets) was similar in the two groups. It is important to note that the haematocrit was significantly reduced in those with carcinoma, and Hirsh, McBride, and Wright (1966) have shown that a decrease in the haematocrit is accompanied by a decrease in the platelet adhesiveness measurement. Thus, differences in platelet adhesiveness might have been shown if the measurements had been performed after correction for the differences in haematocrit.

The mean lipoprotein lipase response to heparin was significantly decreased in the patients with prostatic carcinoma. This reduction was not related to a difference in plasma enzyme activity before the heparin injection, nor was it due to increased plasma inhibition of lipoprotein lipase. Presumably, the tissue enzyme activity was reduced, and since triglyceride uptake in adipose tissue is directly proportional to its lipoprotein lipase content (Garfinkel, Baker, and Schotz, 1967) this reduction might contribute to an alteration in plasma lipid composition.

Finally, patients with prostatic carcinoma are frequently treated with oestrogens in large doses. In other studies (Wynn and others, 1966; Bolton and others, 1968; Brody and others, 1968; Ham and Rose, 1969) oestrogens have been shown to produce abnormalities in platelet behaviour, increases in plasma lipids, and a reduction in lipoprotein lipase activity. Thus, such therapy in patients with prostatic carcinoma might accentuate the abnormalities found here—abnormalities which may be important factors contributing to the increased risk of thrombo-embolism in these patients.

Acknowledgements.—Our thanks are due to Miss E. Gray, Dr. J. A. A. Saalfield, Dr. J. S. Taylor, and Dr. R. H. Farnsworth for their assistance. Riker Laboratories kindly supplied the Ediol used for the enzyme estimations.

This work was supported by a grant from the New South Wales State Cancer Council.

RETICULO-ENDOTHELIAL SYSTEM ACTIVITY DURING HOMOGRAFT REJECTION AND IMMUNOSUPPRESSION

BY R. W. BLAMEY,* JANE M. BAKER, AND D. L. CROSBY
SURGICAL UNIT AND TENOVUS INSTITUTE FOR CANCER RESEARCH, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF

SUMMARY

Reticulo-endothelial system activity was measured in the rat by the rate of colloid clearance. Activity was increased following homograft rejection, and in the presence of tumour-specific antigen. Increased activity was also found during immunosuppression with cyclophosphamide, and with methotrexate, despite marked lowering of the white blood-counts.

It is concluded that reticulo-endothelial system activity does not parallel the activity of the lymphoid system in transplantation immunity.

RETICULO-ENDOTHELIAL system activity may be measured by the rate of colloid clearance from the blood-stream (Biozzi, Benacerraf, and Halpern, 1953). Increased activity has been demonstrated in this way after injection with BCG vaccine (Old, Clarke, Benacerraf, and Goldsmith, 1960), and in response to the administration of sheep red blood-cells in sensitized animals (Gabrieli, 1955).

---

* Present address: Department of Surgery, St. Vincent's Hospital, University of Melbourne.

An increased rate of clearance has been found to accompany skin homograft rejection (Fisher and Fisher, 1964). A study was planned to investigate the relation of reticulo-endothelial activity to the degree of immunological activity in transplantation immunity.

MATERIALS AND METHODS

Wistar rats were used for the experiment; these were of a uniform strain, but were not inbred, and each weighed between 210 and 260 g. Each rat was paired with a control of equal weight.

Table I.—Carbon Clearances in Groups of Animals receiving Homografts and in Control Groups

Time after Operation (days)	Group*	No. of Animals	Carbon Clearance ($T_{\frac{1}{2}}$ in minutes)	Mean Difference (± S.E.)	Significance (P)
4	Operation Homograft	10 9	15·36 16·16	0·80 ± 2·35	> 0·4
7	Operation Homograft	10 10	9·39 9·60	0·21 ± 0·84	> 0·4
14	Operation Homograft	10 9	18·90 4·96	13·94 ± 1·57	< 0·0005
21	Operation Homograft	10 11	16·73 13·50	3·23 ± 1·77	< 0·05
21	Autograft Homograft	10 10	16·92 12·58	3·34 ± 1·23	< 0·01

* Control animals which simply had skin removed are listed as 'operation'.

The uptake of colloidal carbon was studied by the method of Biozzi and others (1953), by injecting 30 mg. of a carbon suspension per 100 g. body-weight into the femoral vein of the anaesthetized animal. Blood samples, 0·1 ml., were then taken under general anaesthesia at 1-minute intervals for 15 minutes from the retro-orbital plexus. The animal was then killed, the spleen was removed and weighed, and tissues were taken for histological examination. The carbon content of the blood samples was estimated in a Unicam SP500 spectrophotometer, at 675 mm. after haemolysis in 4 ml. 0·1 per cent sodium carbonate. Each sample was compared with the sample taken before the injection of carbon.

The colloidal carbon preparation is cleared from the blood-stream exponentially. Graphs of clearance were plotted, and the $T_{\frac{1}{2}}$ of the carbon in the blood-stream of each animal thus obtained (the clearance results are expressed as the time taken for half of the carbon to be cleared from the blood-stream, $T_{\frac{1}{2}}$). Clearance was constant in normal animals as long as the same preparation of colloidal carbon was used, but varied somewhat with different preparations. For this reason animals in an experimental group were tested with the same preparation of carbon as their controls.

Skin-grafts.—Full-thickness skin-grafting between female Wistar rats was carried out by removing a 1-cm.^{2} patch from the back of the donor and placing it in a similar site on the recipient. The panniculus carnosus was scraped off before applying the graft, which was secured with interrupted silk sutures and left without a dressing. If an animal removed the stitches down one side of the graft it was excluded. Grafts were observed daily, and rejection was judged to have occurred when the graft became hard and impliable. Control animals had a piece of skin, approximately 1 cm.^{2}, removed from the back, and the raw area was allowed to granulate. One control grouped was autografted.

Carbon clearances were determined 4, 7, 14, or 21 days after grafting, or after skin removal in the controls.

Immunosuppression.—The maximum doses of cyclophosphamide* and of methotrexate† which could be tolerated by male rats were determined. Groups of rats were then given intramuscular injections of these drugs, or of cortisone, according to the following schedules:—

Group 1. Cyclophosphamide, 5 mg. per 100 g. body-weight, on alternate days for 7 days.

Group 2. Cyclophosphamide, 5 mg. per 100 g. body-weight, on alternate days for 21 days.

Group 3. Cyclophosphamide, 5 mg. per 100 g. body-weight, on alternate days, followed by no treatment for 7 days.

Group 4. Methotrexate, 0·6 mg. per 100 g. body-weight, on alternate days for 7 days.

Group 5. Methotrexate, 0·4 mg. per 100 g. body-weight, on alternate days for 21 days.

Group 6. Methotrexate, 0·6 mg. per 100 g. body-weight, on alternate days for 7 days, followed by no treatment for 7 days.

Group 7. Cortisone acetate, 5 mg. per 100 g. body-weight, on alternate days for 7 days.

Group 8. Cortisone acetate, 5 mg. per 100 g. body-weight, on alternate days for 21 days.

At the end of the period of treatment, peripheral white blood-counts were made and carbon clearances determined in the animals. The control groups received no treatment.

Clearance after Homografting.—The mean rejection time of the skin homografts was 9 days. All the grafts were soft at 7 days and had become hard and black by 14 days.

The clearance of carbon was accelerated 14 days after homografting compared with animals that had simply had a piece of skin removed (*Table I*). This rate of clearance was maintained at 21 days, in comparison with an autografted group and a control group. There was, however, no difference in clearance between grafted and control animals at 4 and 7 days after grafting.

---

† American Cyanamid Co., New York, U.S.A.

Immunosuppression.—The clearance of carbon in animals on all the cyclophosphamide régimes (*Table II*) was increased despite a marked reduction in the white blood-counts. The animals did not lose weight. Spleen weights were increased in the groups of animals studied at 2 and 3 weeks after treatment had started. Spleens from all the animals on cyclophosphamide showed depletion of lymphoid elements.

Methotrexate treatment (*Table II*) gave similar results to cyclophosphamide with the exception that clearance was not increased after only 1 week's treatment. The effects on body-weight, spleen weight, and white blood-count were similar to those with cyclophosphamide.

Table II.—CARBON CLEARANCES IN GROUPS OF ANIMALS RECEIVING IMMUNOSUPPRESSIVE DRUGS AND IN CONTROL GROUPS

GROUP	NO. OF ANIMALS	MEAN WHITE BLOOD-COUNT	CARBON CLEARANCE ($T_{\frac{1}{2}}$ in minutes)	MEAN DIFFERENCE (±S.E.)	SIGNIFICANCE (P)
Cyclophosphamide					
1 Week	15	4600	12·39	6·02 ± 2·26	<0·05
Control	15	13,400	18·41		
1 Week with recovery	13	7000	10·65	5·51 ± 2·34	<0·02
Control	14	13,600	16·16		
3 Weeks	9	1800	6·87	9·09 ± 2·49	<0·002
Control	9	13,600	15·96		
Methotrexate					
1 Week	9	7200	16·97	0·52 ± 5·20	<0·5
Control	9	13,000	16·45		
1 Week with recovery	11	20,000	10·23	10·46 ± 2·68	<0·0005
Control	11	14,600	20·69		
3 Weeks	11	8000	11·91	6·62 ± 1·41	<0·005
Control	11	15,000	18·53		
Cortisone					
1 Week	15	13,200	21·79	8·18 ± 2·21	<0·002
Control	15	15,000	13·61		
3 Weeks	11	14,000	18·36	0·98 ± 2·56	<0·4
Control	11	14,000	19·34		

Animals treated with cortisone (*Table II*) showed a slowing in clearance after 1 week's treatment, but at 3 weeks the clearance was the same as in normal animals. Body-weight was constant and spleen weight did not alter; there was no fall in the white blood-count.

DISCUSSION

The hypothesis has been advanced by Marshall and Knight (1969) that reticulo-endothelial activity, as measured by particulate clearance from the blood-stream, bears a constant relationship to immunological response in transplantation immunity. This suggestion arose from the observation of an increased rate of carbon clearance in rats following application of a skin homograft (Fisher and Fisher, 1964). Clearance of ^{32}P-labelled *Salmonella typhimurium* was used by Marshall and Knight who showed a similar increase in activity in mice bearing large skin homografts; the magnitude of the response was related to the size of the graft employed. Increased reticulo-endothelial system activity in rats during the growth of methylcholanthrene-induced sarcomas has been reported by Blamey, Crosby, and Baker (1969). These tumours bear tumour-specific antigens. There was again a direct relationship between the size of the tumour and the observed increase in carbon clearance. It was suggested that the increased clearance might reflect a reaction to tumour-specific antigen.

If reticulo-endothelial system activity reflects accurately host–graft reaction, then immunosuppression should decrease reticulo-endothelial system activity.

The present studies confirm the finding of Fisher and Fisher (1964) that an increased carbon clearance follows homograft rejection. However, in the present experiments the increase was found at 14 and 21 days after grafting, and not at 7 days when immunological activity must be present. This conflicts with the report of both Fisher and Fisher (1964) and Marshall and Knight (1969), who detected a change in reticulo-endothelial system activity before rejection had taken place. The demonstration here of a clear increase in carbon clearance only after rejection had occurred casts doubt on the proposal that reticulo-endothelial system activity reflects immunological activity as regards transplant rejection, and suggests that it may reflect other factors, such as phagocytic activity at the graft site.

The demonstration of increased carbon clearance during immunosuppression clearly does not support the hypothesis of Marshall and Knight (1969). The increase was seen in animals on doses of drugs sufficient for considerable immunosuppression, as demonstrated by the associated leucopenia.

Chare and Boak (1969) have shown a similar increase in reticulo-endothelial system activity in mice treated with antilymphocytic serum. They also produced an increased rate of carbon clearance by the injection of dead cells. It may be that the production of dead cells for phagocytosis is a common factor in homograft rejection, tumour growth, immunosuppression, and the graft–host syndrome (Howard, 1964), which stimulated the reticulo-endothelial system. This accords with the observed response to cortisone, where the immunosuppressive effect of the drug is not accompanied by a cytotoxic effect.

Whatever the explanation of the effect of these agents on the reticulo-endothelial system it is clear that the action is very different to that on the lymphoid cells, which are suppressed. This raises the question of whether the lymphoid and the reticulo-endothelial systems ought to be considered as two separate entities rather than as a single functional unit. There have been recent reports of the appearance of reticulum-cell sarcomas in patients undergoing immunosuppression (Doak, Montgomerie, North, and Smith, 1968). The stimulatory effect of immunosuppressive drugs on the reticulo-endothelial system may be of relevance to this.

THE EFFECT OF ELECTRICAL STIMULATION OF THE LEGS ON POSTOPERATIVE THROMBOSIS

BY G. E. MOLONEY, M. TESSA MORRELL, AND R. H. FELL[*]

RADCLIFFE INFIRMARY, OXFORD

SUMMARY

Stimulation of the muscles of the lower limbs during surgery was evaluated as a means of preventing postoperative leg-vein thrombosis and pulmonary embolism. Of 285 patients submitted to a major operation, 113 were stimulated and 172 were not. The two groups were closely similar in age, operations, anaesthesia, diseases, and severity of disease, but there was a negligible difference in the rates of postoperative thrombosis.

A RATIONALE and method for prophylactic per-operative muscle stimulation were described by Doran and White (1967), but their method has the disadvantages of producing frequent, vigorous movements of the legs during surgery and of not exercising the thighs and buttocks. However, two independent within-patient trials of that method using ^{125}I fibrinogen to assess the venous thrombosis rate showed conflicting results (Browse and Negus, 1970; de Jode, Khurshid, and Walther, 1970). Moloney and Fell (1968) described a method of producing less frequent, undulating movements of the whole of both lower limbs during operation, and the result of a trial of that method is presented here.

The trial was not controlled in the sense that alternative matched patients were stimulated, for it s difficult in a series of patients, including many emergencies (40 per cent of admissions), coming to urgery to achieve continuity of comparison. During he period of the trial the choice of treatment was mostly random, with one surgeon tending to use stimulation and another not. The observer did not know the design of the trial and saw every patient admitted. In the event the two groups of patients were closely similar in respect of age, nature of diseases and operations, surgeons (G. E. M. and two senior registrars) and anaesthetists, and the post-operative management was the same for both groups. Operating time was similar for each surgeon.

MATERIALS AND METHODS

The patients were those admitted to one surgical firm between June, 1968, and July, 1969, undergoing a major operation. Patients with appendicitis were excluded because of considerable variation in the severity of the disease. Seven patients in whom the onset of venous thrombosis preceded operation were also excluded. Many other patients having intermediate and minor procedures were stimulated but were not included in the survey. Although over 300 patients were stimulated, none showed adverse reactions other than transient flushing of the skin at the site of the electrodes.

Each patient was seen daily from the time of admission until the time of discharge by one observer (M. T. M.), who recorded relevant facts and looked for signs and symptoms of leg-vein thrombosis and pulmonary embolism. Signs and symptoms noted were leg pain, particularly muscle pain on walking, swelling, tenderness, pitting oedema, tense swelling of the calf, dilatation of superficial veins, and alteration in skin temperature. Diseases other than thrombosis may cause such signs but nearly always bilaterally and symmetrically, e.g., tenderness in rheumatoid arthritis and in diabetes mellitus, oedema in heart failure and in hypoproteinaemia; an arterial leg lesion is easily distinguished. Because in the diagnosis of thrombosis particular significance was attached to signs and symptoms occurring in one leg only or asymmetrically in time in both legs, some cases of bilateral thrombosis may not have been diagnosed. Pulmonary embolism was diagnosed only when chest signs and symptoms were almost certainly related to that condition.

Table II.—INCIDENCE OF LEG-VEIN THROMBOSIS AND PULMONARY EMBOLISM RELATED TO AGE IN A PRE-SURVEY GROUP OF PATIENTS

AGE (years)	TOTAL NO. OF PATIENTS	LEG-VEIN THROMBOSIS	PULMONARY EMBOLISM
10–	1	—	—
20–	4	1	1
30–	4	—	—
40–	10	1	—
50–	8	1	—
60–	12	3	—
70–	7	3	—
80–	2	1	1
Total	48	10 (20·8 per cent)	2

Stimulation was carried out by a purpose-built machine (Rank Precision Industries Ltd.) which delivered a surged alternating current, lasting 3 seconds, every 7·5 seconds. The machine was connected to the appropriately covered stimulating electrodes, which had been placed in the positions described by Moloney and Fell (1968), as soon as the patient was anaesthetized. Stimulation was continued from that time until the operation ended. The peak output voltage (between 100 and 200 V.) was adjusted by the anaesthetist to give firm, easily palpable contractions of the calves, thighs, and buttocks, and visible movements of both feet throughout the operation. The operating-theatre personnel were isolated from the apparatus by a rubber macintosh covering the patient's legs. Patients were stimulated whenever possible, but as a result of two operations being carried out simultaneously, faults in the apparatus, holidays, etc., less than half of the patients were treated. Overhydration and low-molecular-weight dextrans were not employed.

Most patients were operated on in the supine position, with the legs elevated to 15° on Sorbo-rubber pads. Eight patients were operated on in the lithotomy position and 7 in the lateral renal position.

Limb blood-flow measurements were made, but the methods and results are outside the scope of this paper.

RESULTS

The number of patients stimulated was 113 and not stimulated 172. The incidence of leg-vein thrombosis was 22 (20 per cent) in the stimulated group and 43 (25 per cent) in the unstimulated group (*Table I*). The difference is not statistically significant: $\chi^2=0{\cdot}9$, $P>0{\cdot}05$. Another similar group of (unstimulated) patients was studied in the same way before the trial was begun and is available for comparison (*Table II*); 10 out of 48 (21 per cent) had venous thrombosis.

Table I.—INCIDENCE OF LEG-VEIN THROMBOSIS AND PULMONARY EMBOLISM

AGE (years)	UNSTIMULATED PATIENTS			STIMULATED PATIENTS		
	Total No.	Leg-vein Thrombosis	Pulmonary Embolism	Total No.	Leg-vein Thrombosis	Pulmonary Embolism
10–	5	—	—	—	—	—
20–	5	1	1	4	1	—
30–	17	2	—	9	—	—
40–	21	3	1	18	2	—
50–	23	8	—	18	4	—
60–	48	12	1	30	3	1
70–	34	9	—	28	10	—
80–	19	8	4	6	2	1
Total	172	43 (25·0 per cent)	7	113	22 (19·5 per cent)	2

The number of pulmonary emboli in each group is too small for conclusions to be drawn.

There were 13 deaths in the unstimulated group and 3 in the stimulated group. One death in the unstimulated group was caused by a pulmonary embolus in a patient who was expected to live. The other deaths resulted from progression of the illnesses causing admission, several patients being emergencies. For the purpose of the survey, thromboses and embolism diagnosed clinically were recorded, any found at autopsy being ignored. Subtraction of the number of deaths from the total in each group does not significantly alter the results.

The two groups have a comparable age distribution (*Table I*). Age and operation are the only two factors known definitely to affect the incidence of thrombosis and embolism.

Specific operations are done for specific diseases and the two cannot be dissociated in groups of patients such as those studied in the present survey. Further, most postoperative complications have an association with, and are really part of, the disease–operation complex, making separate assessment difficult and somewhat artificial. It must also be remembered that patients with the same disease tend to be of similar ages, thus making a clear distinction between age and disease impossible. When every patient has had a major operation it seems most logical to divide the patients according to disease but taking cognizance of the type of operation. This was done for each age-group (*Table III*). The numbers in each category are small but the pattern of distribution is similar for both the stimulated and unstimulated groups except in the category 'other diseases requiring laparotomy'. The proportion of patients in that category relative to the total number is twice as great in the unstimulated group (17 per cent) as in the stimulated group (7 per cent), but elimination of that category causes no significant change in the final result.

It is possible that acute illness may influence the tendency to venous thrombosis. *Table IV* shows the stimulated and unstimulated groups divided according to emergency or waiting-list admission. Emergency admission in this series is an indication of acute illness rather than the time of operation, most emergency patients being operated on after the day of admission. A greater proportion of waiting-list than of emergency patients were stimulated and the former have a slightly lower incidence of thrombosis. Statistical comparison of the corresponding groups, however, shows no significant difference: for emergencies $\chi^2 = 0{\cdot}36$, $P > 0{\cdot}05$; for waiting-list patients $\chi^2 = 2{\cdot}7$, $P > 0{\cdot}05$.

Although this was an uncontrolled survey the stimulated and unstimulated groups are comparable in important respects. Peroperative muscular stimulation does not appear to reduce the incidence of postoperative leg-vein thrombosis.

Stimulated	0	2	1	2	2	2	3	0	2	2	1	0	1	—	—	1	1	—	—	2	—	—	—	—	—
Total	0	4	6	5	4	9	8	4	6	3	2	2	2	—	—	1	1	—	—	3	1	1	1	1	1

The time of onset of clinically overt thrombosis is shown in *Table V*. Nearly all thromboses in both groups occurred within 9 days of operation. Thrombosis would be unlikely to occur, therefore, after a patient has been discharged from hospital.

DISCUSSION

In comparing statistically two groups of patients with regard to the effect of a form of treatment carried out in one of the groups, the important factor is that the groups should match in all other respects. Whether matching is done prospectively or retrospectively (or occurs fortuitously) matters less. Assessment of the two groups in the present series has shown them to be sufficiently alike for statistical comparison to be valid.

Investigation by phlebography and by ^{125}I-fibrinogen uptake has revealed that venous thrombosis is clinically overt in a third to a half of cases (Negus, Pinto, Le Quesne, Brown, and Chapman, 1968; Kakkar, 1969). However, these methods are time-consuming, expensive, especially if a large number of patients are involved, and occasionally dangerous. Clinical assessment reveals the incidence which would resemble that found should muscle stimulation become an established procedure. In practice the clinical determination of thrombosis will continue to be used (except in some specialized centres) until a practicable safe screening test is devised.

In the comparison of two similar groups of patients the partial incidence revealed by clinical diagnosis is satisfactory as long as the proportion of those with thrombosis diagnosed in each group is the same, and as long as the total number of patients in each group is large enough to obliterate any small differences. The clinical manifestations of thrombosis form a spectrum from non-existent to severe, and in large groups of patients the spectrum is likely to be fully covered and stable so that in each individual group the proportion of those with thrombosis which is clinically diagnosable will be similar. In the present study the range of the severity of symptoms and signs of thrombosis in each group were the same. If stimulation had reduced the incidence of venous thrombosis or only its average severity there would have been fewer cases diagnosed in the stimulated group because the spectrum of clinical manifestations would have shifted towards non-existence.

Doran, Drury, and Sivyer (1964) compared the legs of each patient, one leg only being stimulated, but although it is known that in conscious subjects voluntary exercise of one limb does not alter the blood-flow through the other three limbs (Lind, Taylor, Humphreys, Kennally, and Donald, 1964) it is not known whether the same applies to patients who are passively exercised and influenced by a combination of anaesthetic drugs. This difficulty in a within-patient trial is overcome by a between-patient trial, as carried out here.

Doran, White, and Drury (1970) found that leg raising to 15° appeared to have a similar effect to muscle stimulation in reducing the incidence of thrombosis, but in the present trial, however, the combination of stimulation and leg raising made no difference in the incidence of postoperative thrombosis.

No direct evidence has yet been produced (and would be difficult to obtain) that actual clots are formed during the time of operation, although changes leading to thrombosis are probably initiated.

We conclude that the exact cause and timing of deep-vein thrombosis are not known. If immobility during surgery was a major cause of postoperative thrombosis then our trial should have been successful. There must, therefore, be other more important aetiological factors, and we found no reason for persisting with the use of electrical stimulation of the muscles of the lower limbs during operation as a means of preventing postoperative leg-vein thrombosis and pulmonary embolism.

Acknowledgements.—We wish to thank Dr. B. O. Scott, of the Department of Physical Medicine, Radcliffe Infirmary, and Mr. R. L. Taylor, of Rank Precision Industries Ltd., Bessemer Road, Welwyn Garden City, for their help in designing and producing the special stimulator used in this trial.

SHORT NOTES OF RARE OR OBSCURE CASES

BILATERAL URETERIC OBSTRUCTION CAUSED BY BENIGN PELVIC LIPOMATOSIS

By P. L. GOLDING,* M. SINGH, and B. WORTHINGTON†

DEPARTMENTS OF MEDICINE, UROLOGY, AND RADIOLOGY, THE LONDON HOSPITAL

SUMMARY

A second case of bilateral ureteric obstruction owing to diffuse pelvic lipomatosis is reported. The clinical features and possible aetiological factors are discussed. The condition may be mistaken for a pelvic neoplasm due to high fixation of the bladder and colon, but it is felt that the diagnosis can be made on the basis of characteristic radiological findings. Surgical intervention is unsuccessful in replacing the bladder and colon to their normal positions but may be necessary for relief of obstruction.

ENGELS (1959) first described a very unusual condition in which the bladder and sigmoid colon are surrounded, elevated, and compressed by seemingly normal but grossly excessive amounts of fat. Since then 6 other cases have been added by Leuzinger, Bahr, Miller, and Shipman (1961) and Fogg and Smyth (1968), and a case with some similar pathological features but without visceral displacement was reported by Bender and Kass (1970). The condition is rare and has hitherto been regarded as entirely innocuous. We report here a case with severe bilateral ureteric obstruction, the second example in the literature where the ureters have been affected (Bender and Kass, 1970).

The condition is quite different from pericystitis or retroperitoneal fibrosis and probably constitutes a separate disease entity related perhaps to other visceral lipodystrophies. It presents a number of difficulties in diagnosis and management which raise problems of unusual practical and theoretical interest.

CASE REPORT

D. B., a merchant seaman, aged 39 years, first began at the age of 26 (1956) to have attacks of vague central abdominal pain which became gradually worse. By 1960 he was getting recurrent attacks of low-grade fever, nausea, vomiting, headaches, frequency of micturition, and dysuria. He was constipated, producing ribbon-like stools surrounded by large amounts of mucus but no blood. In February, 1964, now aged 34, he complained of suprapubic tenderness and was found to have a large irregular tender mass arising from the pelvis. He was admitted to St. Peter's Hospital under Mr. D. M. Wallace. An I.V.P. at that time showed a high bladder, left hydronephrosis, and a normal right ureter. At cystoscopy, which was difficult because of the position of the bladder, there appeared to be a papilliferous change at the bladder neck, but biopsy of this showed only polypoidal cystitis and epithelial hyperplasia. At laparotomy on 21 Feb., 1964, the bladder and sigmoid colon were found to be displaced upwards by a large amount of fat filling the pelvis. Although the left ureter was distended, no definite obstruction could be found. On opening it, bougies were easily passed through the ureteric orifice into the bladder.

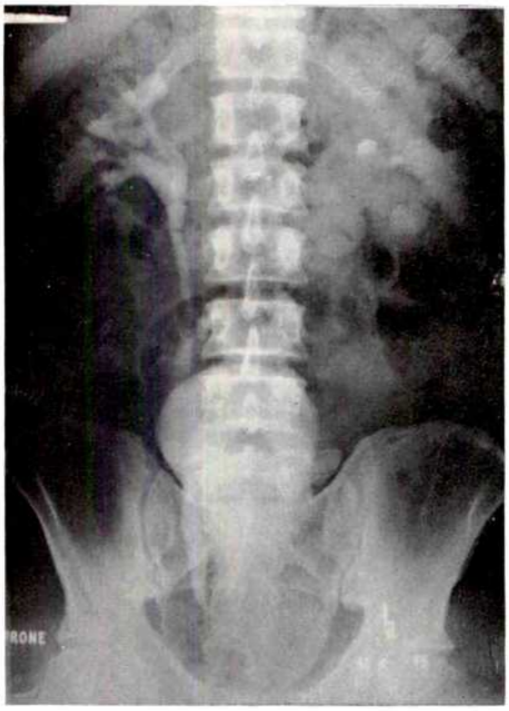

FIG. 1.—I.V.P. in June, 1964. The bladder is seen to be pear-shaped with its fundus projecting out of the pelvis. The collecting tract on the left side is grossly dilated and there is commencing dilatation on the right.

Following operation his former symptoms remained and, in addition, he began to suffer perineal ache and soreness. Four months after operation an I.V.P. showed some dilatation of the other (right) ureter and an increasing hydronephrosis of the left (*Fig.* 1). Cystoscopy in July, 1964, and September, 1965, demonstrated the left half of the bladder to be oedematous and swollen. He defaulted thereafter from St. Peter's.

---

* Requests for reprints to Dr. P. L. Golding, Department of Medicine, The London Hospital, Whitechapel, London, E.1.

† Present address: Nottingham Group Hospitals.

He came to the London Hospital in 1969 now complaining of flushing of the face, dysuria, perineal soreness, and nausea which were becoming unbearable. On examination he had marked clubbing of fingers and toes and a large tender suprapubic mass. Rectal examination was remarkable, the pelvis seeming surprisingly empty and the prostate impalpable. Investigations were as follows: haemoglobin, 14·5 G.; white-blood count, 4300; E.S.R., 22 mm. per hour; urea, 39 mg. per 100 ml.; creatinine clearance, 63 ml. per minute. Chest radiographs, lung function, and 5-hydroxyindolacetic acid (5-HIAA) excretion were normal. Specific complement-fixation tests for lymphogranuloma venereum were negative. The urine was sterile and contained neither cells nor casts.

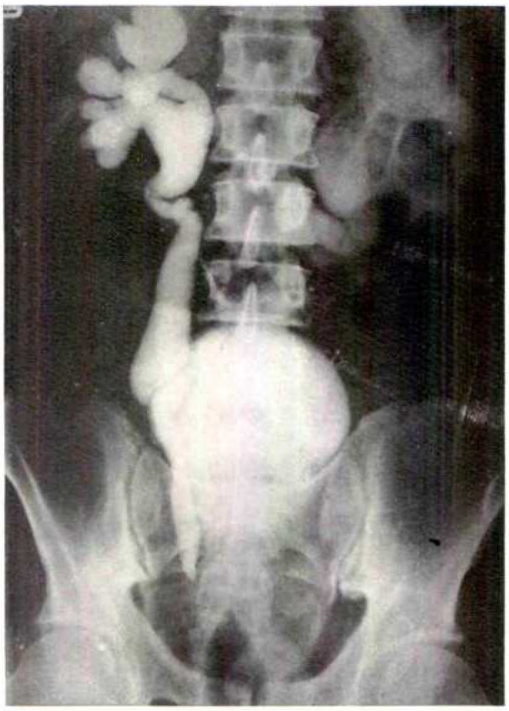

FIG. 2.—I.V.P. in April, 1969. There is gross dilatation of the collecting tract on both sides; the appearance of the bladder is unchanged.

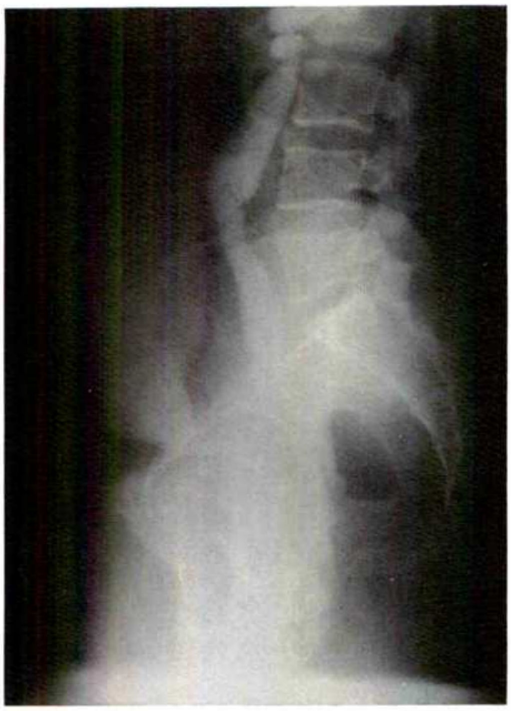

FIG. 3.—I.V.P. in April, 1969. Lateral view showing elevation of the base of the bladder with a uniform circumferential compression of its lower part. The ureter shown is seen to be dilated down to its point of entry into the bladder.

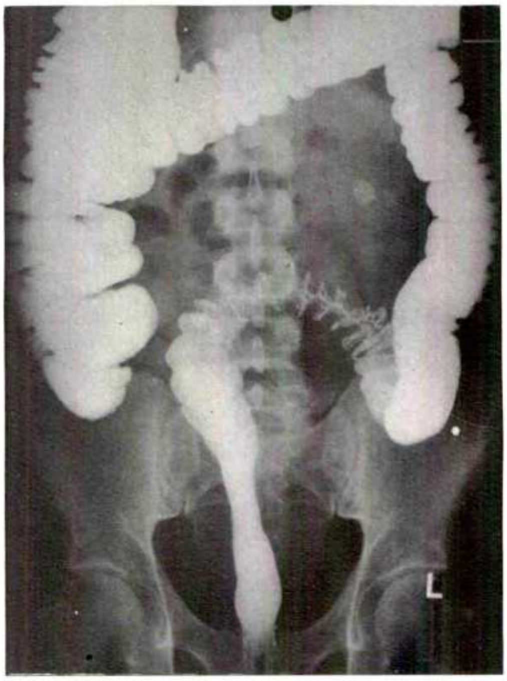

FIG. 4.—Barium enema showing a narrowing of the rectum and distal sigmoid colon which rises vertically from the pelvis.

Sigmoidoscopy revealed normal mucosa but an excess of mucus; the rectum appeared as if straightened out and showed none of the usual deviations or 'valves' of Houston. A rectal biopsy was normal. On cystoscopy the bladder wall was oedematous and the left wall of the bladder outlet was occupied by tissue not unlike the lateral lobe of the prostate. An I.V.P. (*Figs.* 2, 3) showed the bladder to resemble an inverted pear with its fundus high in the abdomen. The pelvi-caliceal systems and ureters were dilated down to the entry into the bladder. The appearances indicated a uniform extrinsic compression of the bladder, elevating its floor and narrowing its coronal and sagittal diameters. A barium enema (*Fig.* 4) showed that the rectum and sigmoid colon rose vertically from the pelvis, consistent with uniform extrinsic compression. A lymphangiogram showed normal pelvic and abdominal nodes with no evidence of lymphatic obstruction.

At operation the bladder was found to occupy the position of a 20-week-pregnant uterus. Both ureters were grossly distended, and distally they were encased in a mass of fibrofatty tissue which appeared to be obstructing them. The whole bladder was encased in a hood of fat which infiltrated the muscle-fibres of its posterior wall. The sigmoid colon was also surrounded by this tissue and was adherent to the fundus of the bladder. The fat was tough, dense, and firm and made it impossible to dissect the ureters free distal to the superior vesical vessels. They were, therefore, divided and reimplanted into the bladder using a tunnel-and-cuff technique. The large hood of fat around the bladder was removed with some difficulty, as was a large mass of fat lying between the left external iliac artery, ureter, and bladder. A thorough search of the abdominal contents and mesentery failed to show any other deposits of fatty tissue.

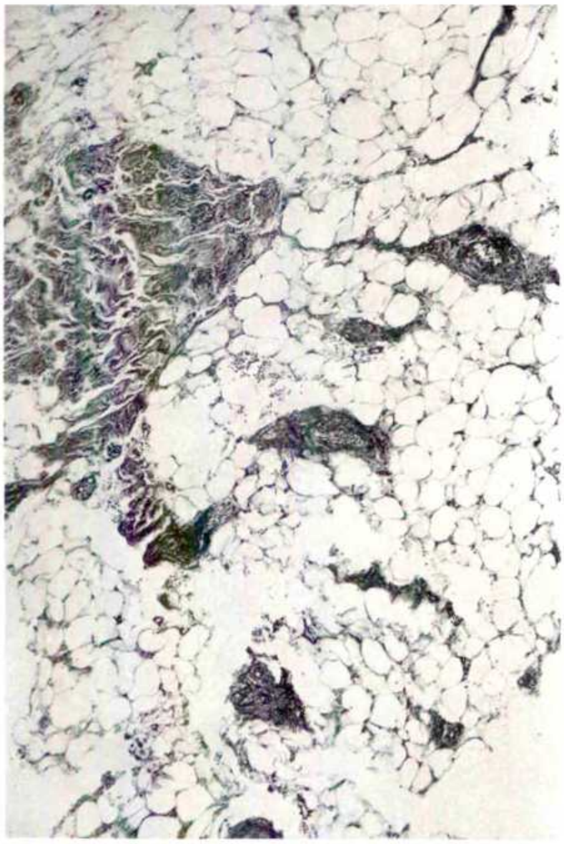

FIG. 5.—Normal fat and fibrous tissue which was removed from the fundus of the bladder and which was infiltrating the wall. Van Gieson. (× 16.)

Histologically the tissue was composed of normal-looking fat cells, with no evidence of inflammation or granulomata and only a few scattered areas of fibrosis. The fat was infiltrating the muscle-fibres of the bladder wall (*Fig.* 5).

Since discharge his symptoms have remained, but there has been no further deterioration in renal function as assessed by creatinine clearance and blood-urea. The bladder remains fixed in the same position and the sigmoidoscopic appearances are unchanged. A postoperative I.V.P. 1 month after operation showed that both ureters were less dilated (*Fig.* 6).

DISCUSSION

Twelve other cases of diffuse pelvic lipomatosis have appeared in the literature (Engels, 1959; Leuzinger and others, 1961; Fogg and Smyth, 1968; Bender and Kass, 1970). Some presented with symptoms of recurrent urinary-tract infection, low-grade fever, and suprapubic tenderness, whilst others had minimal complaints and were only found on routine investigation of unrelated conditions. Most cases complained of mild constipation, but mucus-covered stools have only been reported in the present case and in 1 of Engels's patients. A suprapubic mass resembling a pelvic neoplasm was found in 8 cases, and in some of these the prostate was not felt on rectal examination.

The radiographic appearances were similar in all cases except that of Bender and Kass (1970), but only 1 other case had hydronephrosis at presentation. The radiological features of the condition were (1) undue radiolucency of the soft tissues of the pelvis (Fogg and Smyth, 1968); (2) a high, pear-shaped bladder with circumferential compression of its base; (3) the rectosigmoid rising vertically from the pelvis, and (4) no evidence of loss of distensibility, contractility, emptying, or altered mucosal pattern in either the bladder or the rectum. Three cases had histological changes of chronic cystitis, but in all cases the rectal mucosa was normal.

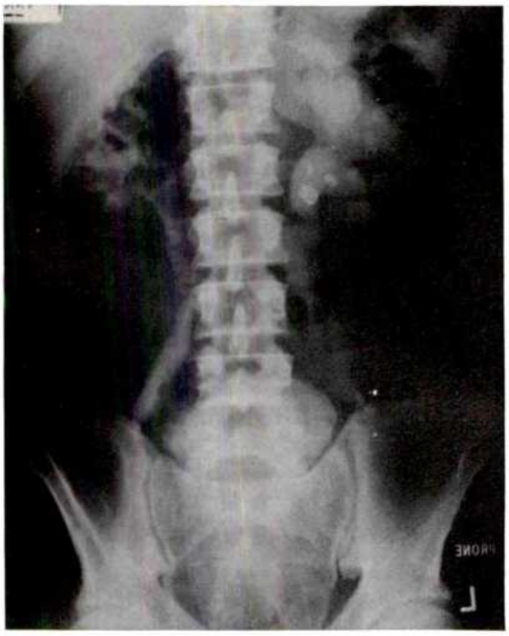

FIG. 6.—I.V.P. in June, 1969, showing the ureters to be less dilated but the appearance of the bladder remains unchanged.

All the patients who were explored were found to have excess fat distributed diffusely throughout the pelvis with the exception of the case of Bender and Kass (1970), where firm, non-tender masses were fixed to the lateral walls of the pelvis. In 4 out of 5 cases with fibrosis and adhesions, areas of chronic inflammation were seen in the adipose tissue. In all cases the fat cells have been histologically normal, although it is admittedly difficult to distinguish hyperplastic from benign fatty tissue and it is of interest that in our case the fat was found to be infiltrating the bladder wall despite its benign histological appearance.

The natural history of the condition is unknown as no long-term follow-up has been reported. However, in 3 cases there was evidence of progressive hydronephrosis. The aetiology is unknown. Engels (1959) suggested that the findings in most of his cases could be explained by the late and exaggerated results of chronic lower urinary-tract infection, accompanied by non-specific inflammation of the perivesical tissues. But many cases had neither adhesions nor urinary-tract infection, and such an excessive deposit of fat is not described as a consequence of infection elsewhere in the body. An isolated lipodystrophy was described by Crane, Aguilar, and Grimes (1955) and Rogers, Demetrakopoulos, and Hyams (1961) in patients whose mesentery was involved by tumour masses composed of nodules of structurally altered fat cells which were smaller than normal and were supported by a delicate reticular framework. The cells were abnormal, some were multinucleate and in others the nucleus was central, small, round, and hyperchromatic. None of these features was present in this case.

The recurrent relapsing inflammatory symptoms and tenderness recall the systemic variant of Weber-Christian disease (Steinberg, 1953; Ogden, Bradburn, and Rives, 1965). However, in these cases the visceral fat was confined to the mesentery, there was subcutaneous involvement, and characteristic lipid-laden macrophages were present in mesenteric fat.

Lipomas possess a definite capsule and those described in the pelvis are usually presacral, where they displace the colon anteriorly but cannot produce the characteristic bladder deformity seen in these cases.

Neither malignant nor granulomatous reactions were present excluding liposarcoma, traumatic fat necrosis, sclerosing lipogranuloma, and xanthogranuloma.

This condition seems to be a diffuse benign proliferation of normal fat cells in the pelvis from no known cause. It produces symptoms and signs because of pressure perhaps added to by fibrosis following the introduction of infection. Surgery may be needed in order to relieve obstruction or to establish a diagnosis. In none of the reported cases has it been feasible to remove enough of the fat to allow the displaced bladder and rectum to return to their normal position.

Acknowledgements.—We would like to thank Dr. J. Ellis, Mr. D. M. Wallace, and Professor J. Blandy for permission to publish this case, and Dr. J. Landells for reviewing the histology. We would also like to thank Mr. Ruddock, London Hospital Photographic Department, for the photographs.

HYDROPNEUMOTHORAX COMPLICATING PERFORATED PEPTIC ULCER

BY J. W. P. BRADLEY AND L. P. FIELDING*

HAREFIELD HOSPITAL, MIDDLESEX

SUMMARY

A case of duodenal ulcer perforation complicated by hydropneumothorax, probably due to a congenital diaphragmatic defect, is described. No such case has previously been reported.

CASE REPORT

Mrs. B. D., aged 49, was admitted as an emergency with a diagnosis of pyloric stenosis. The patient had complained of epigastric pain for 1 week, had vomited, and had passed a melaena stool during the 24 hours prior to admission.

Peptic ulcer symptoms had been present for 12 years with exacerbations two or three times a year. Her twin sister also had peptic ulcer symptoms.

On examination the patient was pale and had a dry furred tongue. The pulse-rate was 90 per minute, regular, and of good volume; blood-pressure was 120/80. The abdomen was soft and without guarding and was neither distended nor rigid. There was no intra-abdominal mass but epigastric discomfort was present. On the day of admission a barium meal was carried out which confirmed the clinical diagnosis of pyloric stenosis (*Fig.* 1).

Thirty hours after admission the patient complained of sudden severe abdominal pain and right chest pain radiating to the right shoulder tip. Subsequently there was an episode of retching and she vomited a little barium.

The patient now showed the signs of generalized peritonism and an erect abdominal radiograph demonstrated free gas under the diaphragm. Furthermore, a chest radiograph taken at the same time showed a right-sided hydropneumothorax (*Fig.* 2).

Oesophagoscopy was performed under a general anaesthetic but an oesophageal lesion was not seen. A right chest tube was inserted and connected to an underwater seal. It immediately drained 500 ml. of dark brown fluid. A laparotomy was then carried out. Gas and free fluid were present in the peritoneal cavity. The lower oesophagus was normal. The stomach was very large. There was severe pyloric deformity and a 1·5-cm. perforation in the anterior wall of the duodenum. There was a small hole in the dome of the right hemidiaphragm to the right of the central tendon, about 2 mm. in diameter, through which the point of a haemostat could be passed into the pleural cavity. There was generalized inflammation of the peritoneum but this was not locally greater around the hole in the diaphragm.

---

* Present address: Surgical Registrar, St. Helier Group, Surrey.

The diaphragmatic defect was closed, the duodenal perforation was oversewn, and a total vagotomy and gastro-enterostomy was carried out. After peritoneal toilet the abdomen was closed.

The patient made an uneventful recovery. She was given a course of ampicillin and neither chest nor abdominal sepsis was a problem. A right basal effusion resolved slowly and the patient was discharged from hospital on the twenty-first postoperative day.

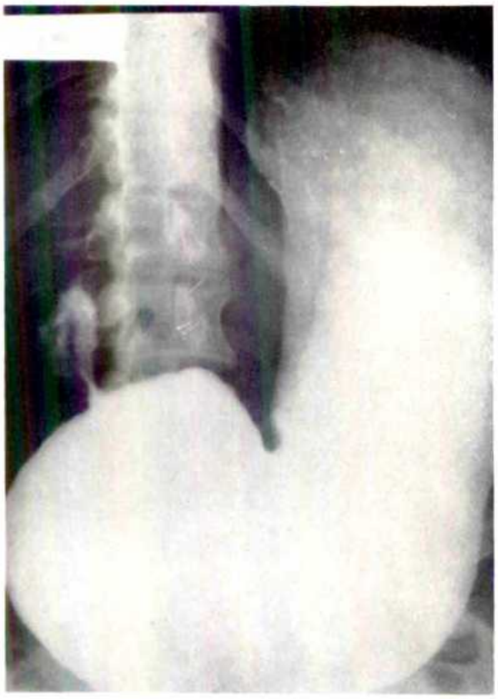

FIG. 1.—Barium meal showing pyloric stenosis.

DISCUSSION

A search of the *Index Medicus*, both manually and by Computer Medlar methods, and a review of the chest section of *Excerpta Medica* failed to find a reference to a similar case. Killen and Gobbel (1968), in their monograph, discuss spontaneous rupture of the oesophagus, in which spontaneous pneumothorax is a frequent finding. Perforated duodenal ulcer, however, is not listed as a cause, but only as part of the differential diagnosis of spontaneous pneumothorax. These authors also state that only 0·2 per cent of spontaneous pneumothoraces are due to subphrenic abscess. It is of note that inflammatory changes were not present around the diaphragmatic defect in our case.

Shapiro (1955) discussed the aetiology of spontaneous pneumothorax associated with pneumoperitoneum used in the treatment of pulmonary tuberculosis. Spontaneous pneumothorax is a rare complication of this technique and 36 cases were documented in his review. Only 5 of these patients developed spontaneous pneumothorax immediately after induction of the pneumoperitoneum. Shapiro postulated that a congenital hole in the diaphragm explained the aetiology in this small group. The larger group developed spontaneous pneumothorax at varying time intervals (i.e., a few days to months) after induction of pneumoperitoneum. In these cases Shapiro suggested that a muscular defect is present in the diaphragm bringing the pleura and the peritoneum into contact. The pressure gradient across the diaphragm causes herniation and bleb formation at this point; these blebs can be seen on radiographs and at thoracoscopy. A sudden rise of intra-abdominal pressure may cause bleb rupture and allow air to pass from the abdomen to the chest.

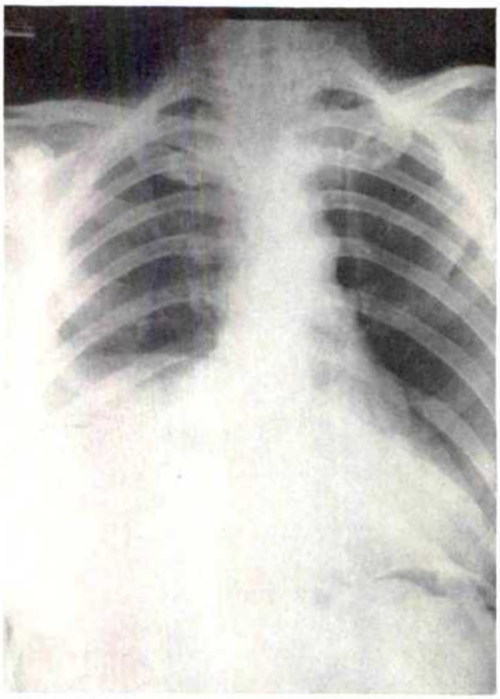

FIG. 2.—Chest radiograph showing air under the left hemi-diaphragm and right-sided hydropneumothorax.

Finn and Jowett (1970) reported 2 cases of hydrothorax developing acutely after the institution of peritoneal dialysis. These authors also said that chronic right-sided pleural effusions are not uncommon after repeated peritoneal dialysis. These two groups appear to parallel those described by Shapiro (1955). Finn and Jowett (1970) also state that pleural effusion, particularly right-sided, can complicate ascites and that post-mortem examinations have demonstrated small defects in the diaphragm in some cases.

These parallel clinical situations lead us to conclude that small defects in the diaphragm occur especially on the right side. Gas or liquid may traverse such a defect to occupy the pleural cavity.

Acknowledgements.—We would like to thank Miss M. P. Shepherd, F.R.C.S., and Dr. D. R. McPherson, F.F.R.

A CASE OF RETROPERITONEAL HAEMANGIOMA

BY S. J. A. POWIS AND D. I. RUSHTON
THE QUEEN ELIZABETH HOSPITAL, EDGBASTON, BIRMINGHAM

SUMMARY

A case is reported of a retroperitoneal haemangioma occurring in a 26-year-old multiparous patient. The literature is reviewed and the pathology considered.

RETROPERITONEAL tumours are rare, only 0·2 per cent being so situated in a series of 60,000 tumours seen at the Memorial Hospital, New York, between 1926 and 1951 (Pack and Tabah, 1954a). The incidence of benign retroperitoneal tumours varies from 13 per cent (Braasch and Alberto, 1967) to 34 per cent (Pack and Tabah, 1954b). Of these very few are haemangiomas, fewer than 30 cases having been reported to date.

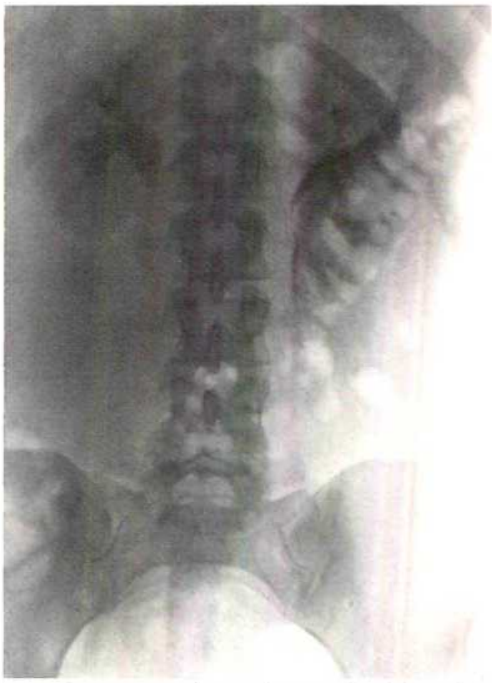

FIG. 1.—Intravenous pyelogram demonstrating hydronephrosis and displacement of the right kidney.

CASE REPORT

A 26-year-old woman, mother of 4 children, aged 7, 6, 2 years, and 10 months, when first seen gave a history of a painless abdominal swelling of 6 weeks' duration. She had not suffered any alteration of appetite or bowel habit, her weight remained unchanged, and, apart from the presence of a mass, she had no symptoms.

Physical examination showed the presence of a visible mass on the right side of her abdomen extending from the costal margin to the iliac fossa. The mass, which was firm and lobulated, was dull to percussion but not attached to the anterior abdominal wall. No other clinical abnormality was detected.

Laboratory investigations showed haemoglobin to be 86 per cent (12·6 g. per cent), white blood-count, 6000 per c. mm. with a normal differential count, and E.S.R., 28 mm. per hour. Urea, electrolytes, and liver-function tests were all within normal limits.

Intravenous pyelography (*Fig.* 1) showed a right hydronephrosis in a kidney which was displaced upwards. A soft-tissue mass was seen compressing and displacing the ureter medially, producing obstruction at the level of the 3rd lumbar vertebra.

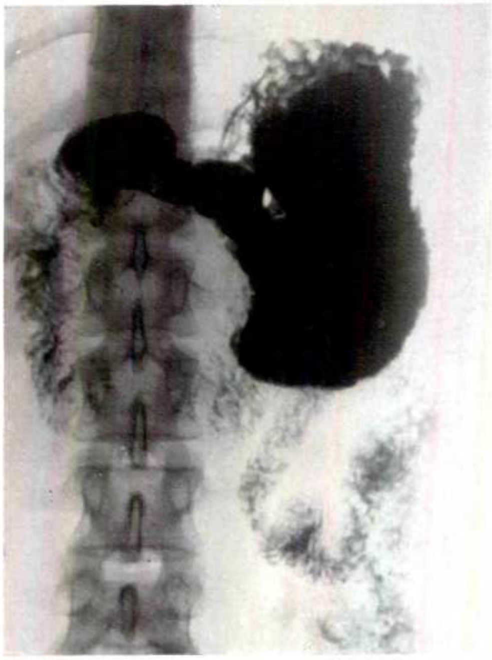

FIG. 2.—Barium meal showing upward displacement of the greater curvature of the stomach.

Barium meal and follow-through showed that the greater curvature of the stomach was displaced upwards (*Fig.* 2) and the hepatic flexure of the colon was displaced downwards (*Fig.* 3). There was no intrinsic lesion in the gastro-intestinal tract.

The diagnosis of a retroperitoneal tumour was made and a laparotomy performed. At operation a retroperitoneal tumour, 16–23 cm. in diameter, was found which was mobilized without undue difficulty, after reflecting the ascending colon medially and the duodenum upwards and freeing the mass where it was firmly attached to the head of the pancreas. The only remaining point of attachment was by a vessel, 0·75 cm. in diameter, running to the infrarenal inferior vena cava. After division of this vessel the mass was removed.

Postoperatively there were no complications and the patient was discharged on the fourteenth postoperative day.

Naked-eye examination of the specimen showed it to be a bosselated, smooth, cystic tumour, measuring

23 × 16 × 10 cm. (*Fig.* 4). The cysts varied in diameter, the maximum being 8 cm., and were filled with blood and thrombus of recent and older origin. The cut surface had a honeycomb appearance (*Fig.* 5), the lining of the cysts being smooth with focal areas of nodularity and the space between them consisting of fibro-fatty tissue. The venous connexions were demonstrated, but no major arteries were seen.

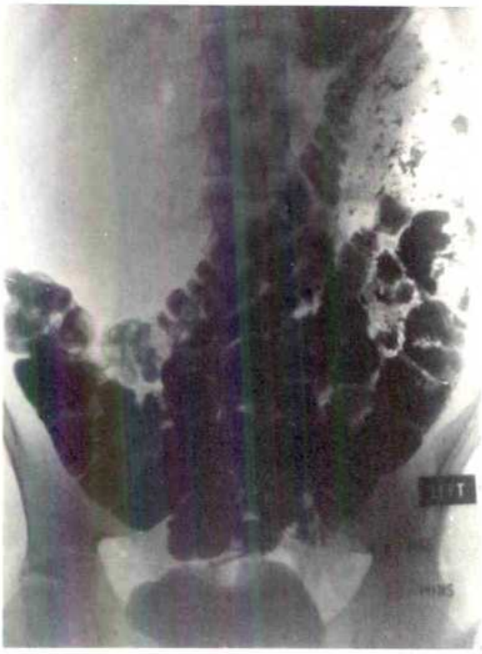

FIG. 3.—Barium follow-through showing displacement of the hepatic flexure.

Microscopically the tumour consisted of large vascular spaces lined by endothelium, beneath which were collections of smooth-muscle fibres, fragmented elastic tissue, and fibrous stroma. The smooth muscle frequently demonstrated discrete pads which projected into the lumen and some of these were covered by plaques of fibrous tissue. Haemosiderin-laden macrophages were seen in some of these fibromuscular pads, indicating an origin from organized thrombus. The intercystic stroma consisted of fibrous and adipose tissue together with smooth muscle and scanty lymphoid follicles.

DISCUSSION

The morphology and origin of the tumour confirm the clinical impression that the lesion was a venous haemangioma. The origin from below the right renal vein in the segment of the inferior vena cava derived from the postrenal segment of the right supracardinal vein (McClure and Butler, 1925) suggests the possibility that the tumour was derived from the remnants of the anastomosis between the supra- and post-cardinal veins, possibly in relation to anastomoses developing in the mesonephros.

The increase in size of the lesion is unlikely to be the result of active growth, even though pregnancy is known to be associated with the appearance or progression of angiomas. Haemangiomas are hamartomatous tumours (Willis, 1962) and, as such, rapid growth is unusual and may be an indication of malignancy, of which there is no evidence in this case. Indeed, it is possible that this tumour represents a variety of cirsoid aneurysm which, as Willis (1962) indicates, cannot be entirely separated from angiomata on morphological grounds. The probability is that the increase in size results from thrombosis and obstruction to the outflow of blood, with or without

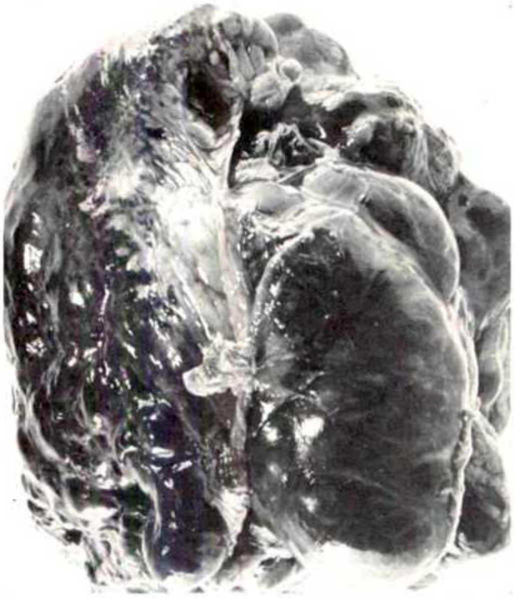

FIG. 4.—Smooth surface of the multicystic retroperitoneal tumour.

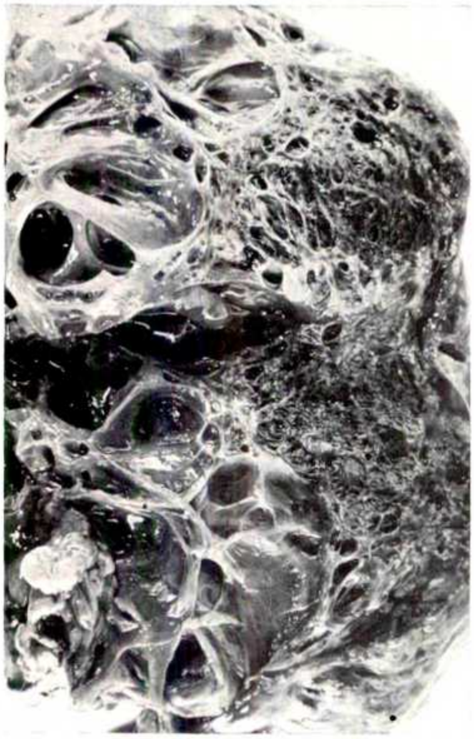

FIG. 5.—Cut surface of the tumour demonstrating multiple smooth-lined cysts.

the opening up of previously collapsed vascular channels.

That the tumour should present clinically soon after pregnancy yet be absent at delivery is significant, since in the puerperium there is an increased tendency to develop thrombotic episodes particularly in the venous system (Bonnar, Prentice, McNicol, and Douglas, 1970).

Acknowledgement.—We are grateful to Mr. V. S. Brookes, under whose care this patient was admitted, for allowing us to report this case.

A SINGLE CONGENITAL ARTERIOVENOUS FISTULA OF THE HAND

BY R. M. GREENHALGH, D. S. ROSENGARTEN, AND J. S. CALNAN

DEPARTMENT OF SURGERY, ROYAL POSTGRADUATE MEDICAL SCHOOL AND HAMMERSMITH HOSPITAL, LONDON

THE following case of an arteriovenous fistula of the hand had several unusual features; in particular, there was pain in the shoulder and axilla and the axillary artery was dilated.

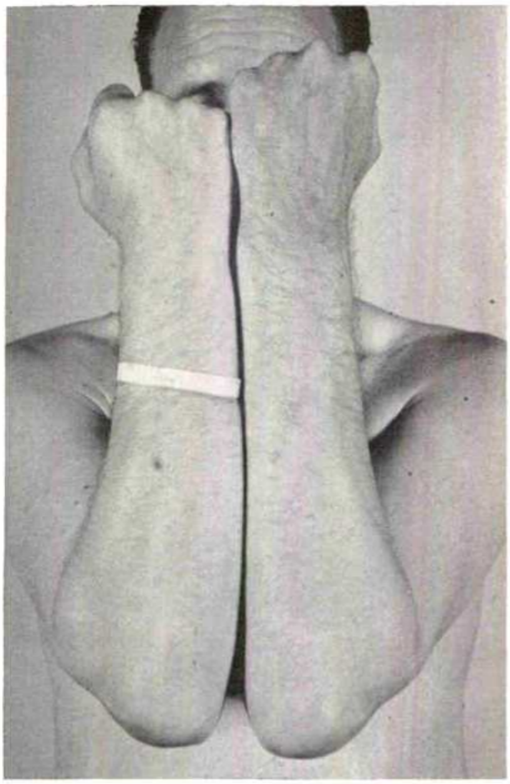

FIG. 1.—Photograph showing the increased length of the left forearm.

CASE REPORT

Mr. A. H., a laboratory technician aged 39, presented with pain in the left shoulder and a feeling of fullness in the left axilla, heaviness in the arm, and a throbbing pain in the hand whenever he exercised it. These symptoms had been getting steadily worse for 18 months. The shoulder pain radiated up the neck, across the chest, and down the arm. Although he was right-handed he had become incapacitated.

In 1946, when he was 16, a cricket ball struck the ulnar border of his left hand whilst he was batting: the hand became very painful, swollen, and discoloured. The symptoms subsided, but he was never quite free from trouble and, by 1950, the little finger became gangrenous and required amputation. In 1954 the ring finger became painful, swollen, and discoloured and an arteriogram showed an arteriovenous fistula. The left hand was explored and the ring finger was amputated. In 1960 the middle finger had developed a flexion deformity and was straightened by an operation on the skin.

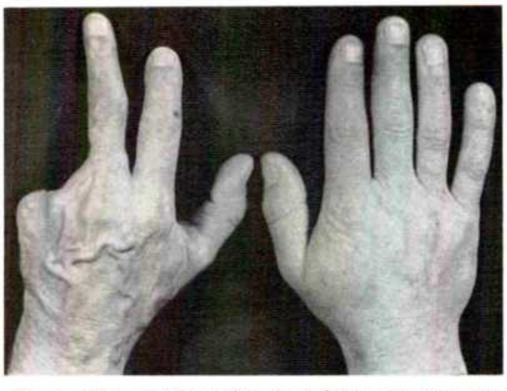

FIG. 2.—The condition before the definitive operation. Note the dilated veins on the dorsum of the hand. Compare with the normal right hand.

When first seen, general examination showed a fit man, the pulse-rate was 84 beats per minute and regular, and there was no cardiac enlargement or cardiac failure. The blood-pressure was 130/70 mm. Hg in all limbs. There were no abnormal neurological signs. Chest radiographs and electrocardiograms were normal.

Examination of the arms showed that the left forearm was 5 cm. longer than the right (*Fig.* 1) and that there were large dilated pulsatile veins on the dorsum of the left hand (*Fig.* 2). The ulnar border of the hand proximal to the site of the amputated fingers was purplish in colour. The

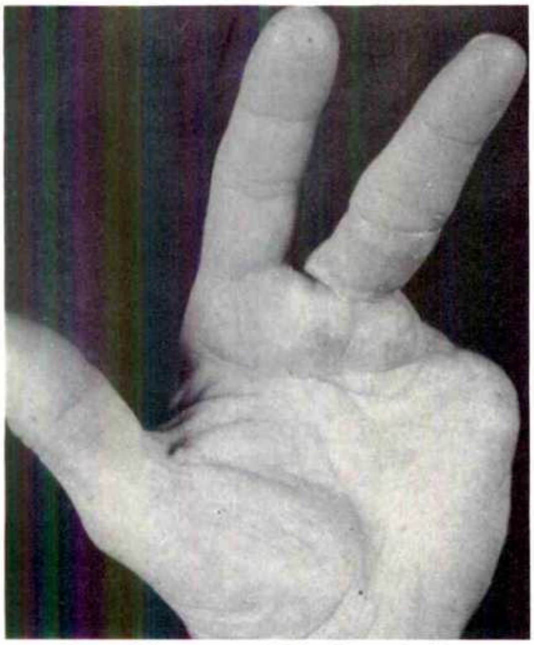

FIG. 3.—Palmar aspect of left hand shown in *Fig.* 2.

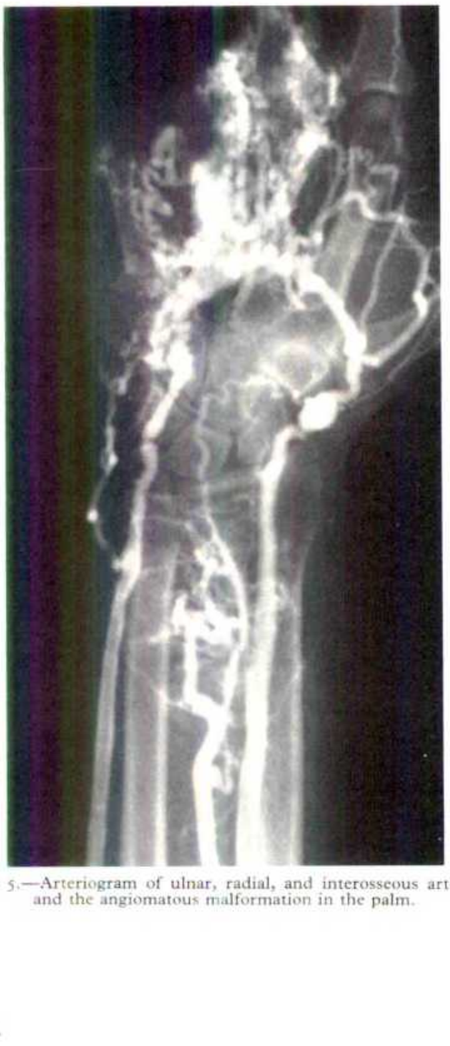

FIG. 5.—Arteriogram of ulnar, radial, and interosseous arteries and the angiomatous malformation in the palm.

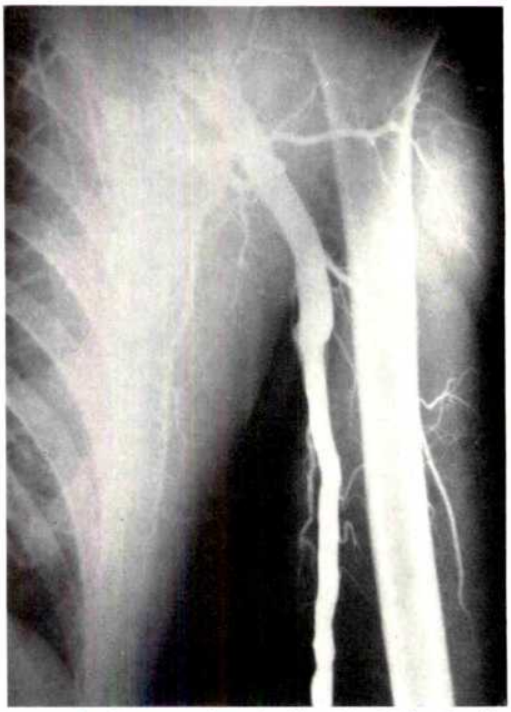

FIG. 4.—Arteriogram to show the dilated brachial and axillary arteries.

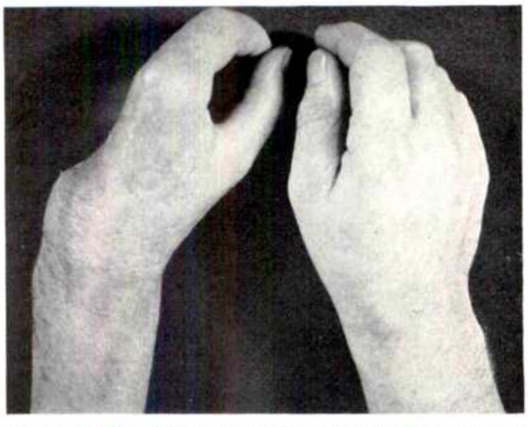

FIG. 6.—Results of ablative operation. Note the absence of veins on the dorsum of the left hand and the finger-to-thumb grip.

middle finger had a flexion deformity (*Fig.* 3) and was almost useless. The skin below the elbow was warmer on the left than on the right. There was a thrill from the hand to the axilla which corresponded to a buzzing machinery bruit, loudest over the third, fourth, and fifth metacarpals. Occlusion of either the radial artery or the ulnar artery reduced the intensity of the bruit in the hand, while occlusion of both of these vessels or of the brachial artery stopped the bruit and the pulsation of the veins on the dorsum of the hand. Occlusion of the brachial artery had no effect upon the heart-rate or the pulse pressure (negative Branham's sign).

Routine blood tests were normal. Analysis of blood from the right femoral artery, a vein on the right arm, and a dilated vein on the dorsum of the left hand showed partial arterialization of that from the dilated veins (*Table I*).

Radiographs of the thoracic inlet, left shoulder, and cervical spine were normal. The arch aortogram showed that the left subclavian and axillary arteries were dilated (*Fig.* 4) and that the radial and ulnar arteries flowed into an arteriovenous malformation in the hand (*Fig.* 5). There were no signs of arteriovenous fistulae elsewhere.

OPERATION.—A combined operation was performed by a vascular and a plastic surgeon. A longitudinal incision was made from the flexor aspect of the wrist into the palm and then continued proximally up the forearm. The ulnar and interosseous arteries were tied in the forearm and the radial artery was left intact. The useless middle finger and the third, fourth, and fifth metacarpals were excised together with the arteriovenous fistula which was closely related to these bones (*Fig.* 5). Thus the transverse head of adductor pollicis, the hypothenar muscles, and some interossei were necessarily divided. The median and ulnar nerves were identified and spared. The dorsal flap of skin was mobilized and the wound closed (*Fig.* 6). After the operation the throbbing pain in the hand and the symptoms in the shoulder and axilla disappeared. Despite vigorous physiotherapy the index finger lost 30° of extension after 5 weeks. At this stage a second operation was done to free fibrous bands in the palm, and an abdominal wall pedicle flap was attached to provide extra skin in the palm. The inset was completed 4 weeks later. Healing was excellent and the patient was able to extend the index finger fully and to grip between the index finger and the thumb.

Table I.—ANALYSIS OF BLOOD

BLOOD	*p*H	P_{O_2} (mm. Hg)	P_{CO_2} (mm. Hg)	STANDARD BICARBONATE (m*N*)	BASE EXCESS (mEq.)
Normal values					
Arterial	7·33–7·45	80–100	36–44	23–28	—
Venous	7·27–7·43	20	46	24–29	—
Present case					
Right femoral artery	7·40	70	42	26	−1
Right-arm vein	7·37	35	45	25	−0
Left-hand dorsum vein	7·42	58	39	25	+1

DISCUSSION

Despite the history of trauma at the age of 16 years there are three reasons for considering that the fistula was congenital (Holman, 1937; Flanc, 1968).

First, the left forearm was 5 cm. longer than the right. Secondly, the arteriogram (*Fig.* 5) showed a bizarre vascular pattern suggestive of a congenital malformation. Thirdly, histological examination showed fibro-elastic intimal thickening with fragmentation of the internal elastic laminae of the feeding arteries, and so was reminiscent of the 'arteriovenous angioma' described by Malan and Puglionisi (1965). This type of congenital arteriovenous fistula has also been variously called 'red angioma' by Broca (1869), 'arterial cavernous angioma' by Virchow (1876), and 'arterial racemose angioma' by Aschoff (1914). Malan and Puglionisi (1965) reported 16 cases of arteriovenous angioma of which 4 had an extensive arteriovenous shunt and 12 were hypoactive. Only 1 of the 4 active arteriovenous angiomas was in the hand.

In the present case the shoulder pain and axillary 'fullness' were attributed to the dilated main arterial trunk (*Fig.* 4). It was envisaged that this was perhaps nipped between the scalene muscles and the first rib. If the shoulder pain had not subsided after resection of the fistula, scalenotomy would have been considered but fortunately was not necessary.

Acknowledgements.—We wish to thank Professor R. B. Welbourn for help in preparation of this paper and Mr. Peter Martin for allowing us to record his patient.

SPONTANEOUS RUPTURE OF THE STOMACH IN AN ADULT

BY CHRISTOPHER D. JEFFERISS*

WEST DORSET GROUP HOSPITALS

SUMMARY

A case of spontaneous rupture of the stomach in an adult is described following retching with pyloric stenosis. A table of the more recent of the 47 cases described in the world literature is given with references to all the reported cases.

SPONTANEOUS rupture of the stomach in an adult is a rare occurrence and the case to be reported is only the forty-seventh in the world literature. This case is also of interest in that the rupture happened shortly after admission to hospital so that the nature of the emergency was rapidly recognized and treated.

A brief review of the literature will be given covering the cases which have been reported since Albo, de Lorimier, and Silen reviewed all the cases that they found up to 1963, although of their 44 cases, 5 should be considered traumatic.

CASE REPORT

E. G. V., a housewife aged 58 years, was admitted to Dorset County Hospital on 19 Oct., 1968, with a 6-day history of epigastric pain, vomiting, and diarrhoea. For 4 months she had subsisted on a diet of semolina, Complan, and Benger's food for relief of classic peptic ulcer symptoms which had been diagnosed as 'hiatus hernia' and which had gradually progressed to copious foul-smelling vomits and eructations. Fourteen years previously she had had similar symptoms diagnosed as 'colitis', for which no treatment had been given after a negative contrast enema.

On admission she was dehydrated with a distended tympanitic abdomen (increase girth, 16 cm.) but had no pain. There was no succussion splash and no visible peristalsis. The rectum was empty. A tentative diagnosis of small-bowel obstruction was made but plain radiographs showed a grossly distended stomach containing air and fluid, indicating a marked and long-standing pyloric stenosis (*Fig.* 1). There was no pneumoperitoneum.

Shortly after the radiographs were taken the patient started to retch, suddenly developing severe abdominal pain and rigidity. She was hypotensive, slightly cyanosed, and markedly dyspnoeic. A diagnosis of perforation of the stomach was made and after 3 litres of saline had been infused intravenously laparotomy was performed.

The peritoneum was opened with a rush of air and foul free fluid revealing a collapsed but enormous stomach. There was a tear 18 cm. long on the lesser curve, of which 7 cm. was through all layers and the rest only through the serosal layer. The tear was sutured in one layer with difficulty owing to the friable nature of the gastric wall, and

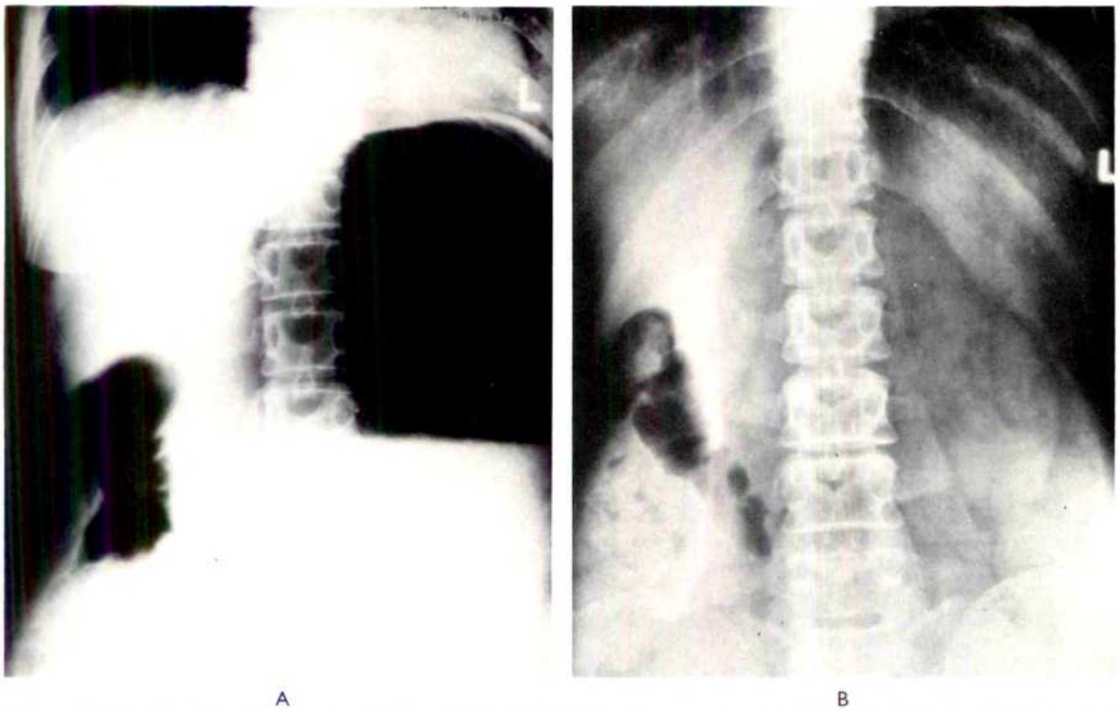

FIG. 1.—Radiographs taken on admission showing a grossly distended stomach containing air and fluid. A, Erect view. B, Supine view.

---

* Present address: Princess Elizabeth Orthopaedic Hospital, Wonford Road, Exeter EX2 4UE.

then vagotomy with anterior gastrojejunostomy was performed. The peritoneal cavity was cleaned and noxythiolin, 2·5 g. in solution, instilled with drains left to the pelvis and the site of the rupture.

The patient was ambulant and commenced a normal diet on the third postoperative day, being discharged home on the fourteenth postoperative day. At 1 month she was very well and only complained of occasional looseness of stools to direct questioning. She remained well until readmission to hospital with a short history of intestinal obstruction 6 months later, when she was found at laparotomy to have a carcinoma of the caecum from which she later died, peritoneal deposits being present at this time.

DISCUSSION AND REVIEW

The diagnostic criteria for rupture of the stomach according to Millar, Bruce, and Paterson (1957) are severe abdominal pain, tympanitic distension with rigidity, subcutaneous emphysema, and 'shock'. Many of the cases described lack subcutaneous emphysema, especially when diagnosis and laparotomy have been early. In the present case the suddenness of the onset of 'shock' was dramatic and was probably related to both the gross contamination of the peritoneum and to tension pneumoperitoneum, which might have been rapidly relieved by a needle, as reported by Olsen and Foley (1961) in the treatment of a similar condition occurring in children after tonsillectomy.

Table I.—SUMMARY OF 8 CASES REVIEWED IN THE LITERATURE SINCE 1963

AUTHOR AND YEAR	AGE AND SEX	COMMENTS	TIME BEFORE OPERATION	OPERATION	RESULT	SITE OF TEAR
Cronin, 1959	61 M.	Large meal, gastritis	Over 5 hours	Suture of tear	Died	Lesser curve
Shaldon, 1961	49 F.	10 years' peptic ulcer	Not stated	Suture of tear	Lived	Lesser curve
Mirsky and Garlock, 1965	40 F.	Vomiting	11 days	Suture of tear	Lived	Anterior wall
Fleming, Horton, and Wagget, 1966	45 F.	Pyloric stenosis	2 hours	Vagotomy and gastrojejunostomy	Lived	Anterior wall
Zakrys, Pawlowski, and Rajtar, 1966	64 M.	Pyloric stenosis, barium meal	Not stated	Total gastrectomy	Lived	Near lesser curve
Schwartz, 1966	65 F.	Effervescent alkalis	5 hours	Suture and gastrostomy	Died	Lesser curve
Gue, 1970	64 M.	In inguinal hernia	Not stated	Suture of tear	Died	Lesser curve
Jefferiss, 1971	58 F.	Pyloric stenosis	2 hours	Vagotomy and gastrojejunostomy	Lived	Lesser curve

The mechanism of rupture has been discussed by many authors including Cronin (1959) in his review of alimentary tract ruptures. It seems to be due to a closed-loop type of obstruction in the stomach associated with a sudden rise in intraluminal pressure caused by either attempts at vomiting or ingestion of bicarbonate for relief of ulcer symptoms. The usual cause of distal obstruction in the stomach is pyloric stenosis due to peptic ulceration, but Gue (1970) describes a case where the distal obstruction seemed to be caused by the stomach being contained within an inguinal hernia. Some of the cases previously recorded as spontaneous rupture of the stomach have resulted from the administration of oxygen by the nasal route to patients with normal stomachs, or have followed endotracheal [*sic*] intubation. These cases, 3 by Walstad and Conklin (1961), 2 by Baglio and Fattal (1962), and 1 described by Foex (1962), should be considered as traumatic as would a compressed-air injury of the rectum.

The site of rupture is commonly along the lesser curve or on the anterior wall. A mucosal tear is followed by dissection in the deeper layers of the stomach and a longer tear in the serosa. It seems that the site is determined to some extent by the relative fixity and poor distensibility of the gastro-oesophageal junction. The tears are usually described as being difficult to suture, and in the cases where organic outflow obstruction was present from peptic ulceration, vagotomy and gastrojejunostomy seem to have been successful when used. Certainly any surgical procedure should be done early, possibly preceded by paracentesis abdominis to relieve tension.

The condition was first described by Boerhaave in 1724 but was only separated later by Cruvelhier (cited by Glassman, 1929) from the common perforation of a peptic ulcer. In the further 8 cases which I have traced (*Table I*) since Albo and others (1963) reviewed the literature, the preponderance of females continues and there is an increasing number of survivors as early operative measures are undertaken. In the case described by Mirsky and Garlock (1965) there was a delay of 11 days before surgery but the patient had an anterior perforation which had sealed itself off, which would seem an unlikely event with an extensive lesser-curve rupture.

Acknowledgement.—My thanks are due to Mr. W. A. L. Tucker, O.B.E., F.R.C.S., for allowing me to publish this case.

REVIEWS AND NOTICES OF BOOKS

Frozen Section in Surgical Diagnosis. By ANDREW A. SHIVAS, T.D., M.D., F.R.C.S.E., D.P.H., F.R.C. Path., and SUZANNE G. FRASER, A.I.M.L.T., University of Edinburgh. 8½ × 5½ in. Pp. 261 + ix. Illustrated. 1971. Edinburgh: E. & S. Livingstone. £6.

THIS is a book which surgeons the world over have been looking for. It will fill a very definite gap in the literature of pathology and surgery. The beautiful 204 colour illustrations prepared by that expert, the late T. C. Dodds, will be an ever-ready reference file for surgeons, pathologists, and students.

The modern surgeon, especially one who deals with neoplasia, will welcome this book; it will be his constant reference volume.

After a chapter on technical notes, the authors, who have devoted many years of their lives in perfecting their own techniques, deal with the common conditions in the breast, thyroid, and lymph-nodes, and finally consider other sites in the body where frozen sections often give a definite diagnosis of the condition. Sir John Bruce, who writes a foreword to this important monograph, says: 'This short, beautifully illustrated, and instructive book leaves clinicians with little excuse for unseemly approaches in the future and provides a basis on which the pathologist and his surgical confreres can meet on common ground.' We thoroughly endorse these candid remarks.

An excellent production.

Hepatic Encephalopathy. By FREDERICK STEIGMANN, M.D., and BERNARD F. CLOWDUS, II, M.D., Cook County Graduate School of Medicine, Illinois. 8¾ × 6 in. Pp. 201 + xii. 1971. Springfield, Ill.: Charles C. Thomas. $13.50.

THE authors of this monograph make use of the term 'hepatic encephalopathy' instead of the usual one of 'hepatic coma' because they consider that many patients with hepatic insufficiency demonstrate only an altered state of consciousness, intellect, and personality.

The authors have a matured clinical background which spans a period of over 35 years, and their clinical acumen is to be seen in this book.

This volume contains a wealth of material and provides a concise review of the established fundamental physiological, pathological, and biochemical factors involved in the production of hepatic encephalopathy. The various clinical manifestations of this condition are well described, including the neurological and psychiatric findings.

The diagnosis and prognosis are discussed in some detail.

The treatment, including prophylactic, general care, and specific treatment, is considered at length.

A bibliography at the end of the book contains 699 references.

As a reference volume this book could not be bettered.

Orthopädische Therapie. By G. CHAPCHAL, Nijmegen, and D. WAIGAND, Biberach. 10 × 7 in. Pp. 533 + xvi, with 299 illustrations. 1971. Stuttgart: Georg Thieme Verlag. DM.98.

THIS is a new book on orthopaedic treatment. The volume attempts to cover the whole field of orthopaedics and includes extensive chapters on physiotherapy and hydrotherapy. Most orthopaedic conditions are covered in this book, but an outstanding omission is the entire and now-important problem of the orthopaedic aspects of spina bifida. On the other hand, the management of varicose veins is described in considerable detail. Fractures and joint injuries are dealt with very briefly, but the various operative procedures are given in great detail.

The book contains a fair number of oversimplified line drawings, virtually no X-rays, and no clinical or operative photographs. The diagrams have been so simplified that they cannot really be followed unless the text is very carefully studied. The lack of fuller illustrations will undoubtedly limit the use of this volume which otherwise is beautifully printed and produced.

Principles of Medical Statistics. Ninth edition. By SIR AUSTIN BRADFORD HILL, C.B.E., D.Sc., Ph.D., Hon.D.Sc., M.D., F.R.C.P., F.R.S., Professor Emeritus of Medical Statistics in the University of London. 8¼ × 5¼ in. Pp. 390 + ix. Illustrated. 1971. London: The Lancet Limited. £1·25.

THIS is a book which should be in every medical library, for it is invaluable to every clinician and medical research worker who wishes to make a statistical review of cases.

The first edition appeared in 1937 and many of the subsequent editions have been reprinted, some more than once. These facts speak for themselves and reveal the importance and popularity of the book.

The author covers the difficult problems of medical statistics in a very comprehensive way. The collection and sampling of statistics and the presentation of statistics are all explained in a lucid manner. Clinical trials and clinical research are discussed at some length.

This book should be read by all medical students, for it will give them a sound idea how medical statistics are formulated.

The price of the book is most moderate.

Les Analgésiques et la Douleur. By G. VOURC'H, J. DE CASTRO, P. GAUTHIER-LAFAYE, J. F. GIUDICELLI, and P. VIARS. 9⅖ × 7 in. Pp. 583 + xx, with 96 illustrations. 1971. Paris: Masson et Cie. 150F.

A COMPREHENSIVE survey is given of the well-known and the recently developed analgesic drugs. The drugs are evaluated by the classic pharmacological methods. Though one chapter is dedicated to the antipyretic analgesics, salicylates, para-aminophenol derivatives (phenacetin), pyrozole and quinoline derivatives, the central analgesics, i.e., morphine and morphinomimetic substances, including the antimorphiates, cover the main part of the book.

One is amazed by the number of substances that are more powerful than morphine, but toxic side-effects like respiratory depression, circulatory collapse, muscle hypertonia, vomiting, and addiction are evident in nearly all of them. Demerol (pethidine, dolantine), though weaker, shows all the side-effects of morphine; its popularity does not seem justified. The authors are fairly satisfied with the antimorphiate pentazocine, where addiction should be slight; here one hesitates to agree. The extremely powerful analgesics like dextromoramide, fentanyl, and phenoperidine are very toxic as well, respiratory depression being a striking effect, but they are revolutionary ingredients in anaesthesia where controlled respiration offers no problem. In neuroleptanalgesia (1962) only moderate quantities of fentanyl are used; in analgesic anaesthesia and sequential analgesic anaesthesia (1969) larger doses of fentanyl or dextromoramide replace barbiturates and inhalation anaesthesia.

The antimorphiates like nalorphine show analgesic effects but cause uncomfortable psychic sensations, even hallucinations; their application is restricted to antidotal action in cases of respiratory depression.

The book is to be recommended.

Anaesthetics, Resuscitation and Intensive Care. Third edition. By WALTER NORRISS, M.D., F.F.A.R.C.S., and DONALD CAMPBELL, M.B., Ch.B., F.F.A.R.C.S., D.A., Consultant Anaesthetists, Glasgow Royal Infirmary. 8⅓ × 5⅓ in. Pp. 282 + xi. Illustrated. 1971. Edinburgh: E. & S. Livingstone. £1·50.

THE third edition of this small paperback will be as popular with students and resident medical officers as the former ones, for it gives them the information they require regarding anaesthetics, resuscitation, and intensive care.

This book is clear and concise and it is well illustrated with lucid drawings, diagrams, and photographs.

Recent Advances in Haematology. Edited by A. GOLDBERG, M.D., D.Sc., F.R.C.P., Regius Professor of Materia Medica, University of Glasgow, and M. C. BRAIN, D.M., F.R.C.P., Professor of Medicine, McMaster University, Ontario. 9 × 6 in. Pp. 387 + vi, with 43 illustrations. 1971. London: J. & A. Churchill. £4.

HAEMATOLOGY today is a large and separate branch of pathology and as the years go by it increases in importance. Haematology concerns many branches of medicine and surgery and for this reason this book will interest a wide variety of medical men.

Each of the ten chapters in the book covers in a very comprehensive way some subject which has practical importance to the clinician. To mention only a few: megaloblastic anaemias, disorders of iron metabolism, abnormal haemoglobins, treatment of malignant blood diseases, and leucocyte groups in man and their relation to transplantation antigens.

At the end of each chapter there is a very complete list of references from the world literature on that particular subject.

The 43 illustrations are excellent and enhance the value of the text.

This is an excellent book of reference on haematology.

Pathologie du Pied. Fourth edition. By JEAN LELIÈVRE, Paris. 9⅖ × 6⅕ in. Pp. 868 + xi, with 673 illustrations. 1971. Paris: Masson et Cie. 140F.

CONSIDERABLE time elapsed before surgery of the foot began to arouse the same interest as was accorded to surgery of the hand. In recent times several good books have appeared which deal with this particular branch. One of these is Jean Lelièvre's near classic, the fourth edition of which is now before us. Comparison with previous editions shows that numerous passages have undergone considerable alteration. Noteworthy among these is the section on orthopaedic shoes and their manufacture, still to most physicians a practically uncharted territory. A conspicuous feature is the frequent use of diagrammatic drawings, inspired as the author acknowledges in his preface by the artist Lesbouvit. Besides the common disorders one finds descriptions of practically all affections that may occur in the foot, resulting in an excellent book of reference. Surprisingly enough the book remains eminently readable, thanks to the easy and logical arrangement of the subject-matter. The disorders are described in the orthodox textbook way, but the actual surgical technique is treated in a special chapter at the end of the book; many procedures appear to be original. Unfortunately, some of these descriptions are too short for the uninitiated; the extensive accounts of the pathology and diagnosis, however, more than compensate for this.

One brief criticism: it seems fair that those specializing in foot surgery should also deal with foot fractures, but few will agree with the author that his territory ought to include the fractures of the ankle, however eloquently he pleads his case.

Technique des Plâtres et Corsets de Scolioses. By MARC OLLIER, Lyon. 9½ × 6¼ in. Pp. 130, with 132 illustrations. 1971. Paris: Masson et Cie. 48F.

THIS handy book is a technical manual for making casts and braces in the treatment of scoliosis, as practised in Stagnara's well-known centre in Lyon.

Marc Ollier, the chief physiotherapist, and obviously a master of his craft, has given a most detailed account of how to construct the various types of plaster casts. But he has not confined himself to the mere technical aspects—for each type of cast the indications and complications are clearly discussed. Very interesting is the comparison between the 'Lyon brace', with its more solid support of the trunk and freedom of the head and neck, and the dynamic corrective, but perhaps more cumbersome, Milwaukee brace. The author has tried to establish the indications for each. This well-produced book with its many photographs and line drawings is certainly 'a must' for those who treat their patients along the lines of Stagnara. In addition, anyone making plaster casts for scoliosis can find many tips not specific for the system described but of more general application.

The Continuing Education of the Surgeon. Edited by HAROLD G. BARKER, M.D., New York. 9 × 6 in Pp. 121 + x. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $11.75.

THIS book contains the transactions of the Twelfth Annual Meeting of the Allen O. Whipple Surgical Society.

The various papers stress the value of continual education of practitioners, and advise the more constant use of postgraduate lectures and demonstrations in hospitals.

The use of a tumour registry is supported by most surgeons.

The nine contributors to this volume stress the value of organized co-operation and not healthy competition. It is the discussions at the end of each paper that make this book of real interest.

Surgical Anatomy. Vols. 1 and 2. Fifth edition. By B. J. ANSON, M.A., Ph.D.(Med. Sc.), Chicago, and C. B. MCVAY, Ph.D., M.D., F.A.C.S., South Dakota. 10⅕ × 7⅕ in. Pp. 1282 + xl. Illustrated. 1971. London W. B. Saunders Company Ltd. £19·15.

THERE is a tendency today to cut short courses in anatomy and to lessen the hours spent in the complete dissection of the human body. This being so, it is essential that the medical student should have a very comprehensive course on surgical anatomy in his final-year studies.

This large two-volume work has become a world classic; since the first edition was published in 1933 it has gone from strength to strength and the new fifth edition, dedicated to that master surgeon Loyal Davis, will enjoy an international reputation.

One of the features of this work is the originality and clearness of the illustrations, over 3000 in number. With the ever-widening sphere of modern surgery, so the importance of surgical anatomy becomes more evident.

Surgeons the world over will wish to have these two important volumes in their personal library for ready reference.

Cardiovascular Surgery, 1969. Edited by EARLE B. MAHONEY, M.D., New York. 10 × 7⅝ in. Pp. 178. Illustrated. 1970. New York: The American Heart Association, Inc. $5.

THIS is the American Heart Association's Monograph Number 30, and it contains the papers which were presented at the Scientific Sessions held at Dallas, Texas, in November, 1970.

There is much to interest the cardiac surgeon as well as cardiologists. As one would expect, there are many papers on valve replacements. The internal mammary artery implantation seems to have come into its own and long-term 'follow-up' results are now published.

An interesting paper on congestive heart failure in infancy treated by early repair of ventricular septal defect is of real practical value.

It is interesting to note that the enthusiasm for cardiac transplantation of the past few years appears to be in abeyance.

There are papers on peripheral arterial and venous problems, and the coverage of cardiac surgery is excellent.

Urology and Renal Medicine. By J. E. NEWSAM, M.B., Ch.B., F.R.C.S., Consultant Urological Surgeon, Western General Hospital, Edinburgh, and J. J. B. PETRIE, B.Sc., M.B., Ch.B., M.R.C.P., Senior Medical Registrar, Renal Unit, Royal Infirmary, Edinburgh. 7⅝ × 4⅞ in. Pp. 259 + v, with 72 illustrations. 1971. Edinburgh: E. & S. Livingstone. £1·25.

THERE is much to be said for a joint authorship by a surgeon and a physician in a book on urology, because the coverage should thereby be more complete.

This paperback, intended primarily for undergraduates, is written in a clear concise manner and is illustrated with some excellent line drawings, halftones, and telling diagrams.

The chapters on disorders of the Renal Parenchyma, Renal Failure, and Dialysis and Transplantation are very good indeed.

This book will be of real value to students and those postgraduates who are preparing for higher medical and surgical diplomas.

Handbuch der Experimentelle Pharmakologie. Anticoagulantien. Edited by F. MARKWARDT. 9¾ × 6¼ in. Pp. 598 + xiv. Illustrated. 1971. Berlin: Springer-Verlag. DM.198.

THIS is the twenty-seventh volume of a Handbook of Experimental Pharmacology. This volume deals with anticoagulant therapy and includes the works of six authors from four different countries. The entire problem of the physiology and biochemistry of blood coagulation is discussed. The various drugs available for influencing and indeed diminishing blood coagulation are reported in the various chapters in great detail and the action of individual drugs on individual parts of the coagulation system are discussed. Each chapter has a very extensive list of references, and there are also extensive indexes to authors and subject-matter. There is no doubt whatever that this volume will become a standard work on anticoagulant therapy, but its price will limit the distribution to medical libraries rather than to individuals. It is hoped that the volume will appear in the English language as it really is a most comprehensive account of anticoagulant therapy, its indications, and its problems.

Venous Thrombosis and Pulmonary Embolism. By MICHAEL HUME, M.D., Boston, SIMON SEVITT, M.D., M.Sc., F.R.C. Path., F.R.C.P.I., Birmingham, and DUNCAN P. THOMAS, M.D., B.Sc., D.Phil., Boston. 9¼ × 6 in. Pp. 456 + xiii. Illustrated. 1970. London: Oxford University Press. £7·50.

THIS is an excellent monograph on a most important subject; it is the combined effort of a physician, a surgeon, and a pathologist. All three have had much to do with the problem of pulmonary embolism as a complication of venous thrombosis and therefore write from clinical experience.

The whole subject of venous thrombosis and pulmonary embolism is considered in a comprehensive manner. The pathological findings and experimental observations, together with circumstances associated with the disease, are critically examined.

The clinical features of pulmonary embolism are surveyed in a very practical way, while the use of radiology and lung scanning in the diagnosis of pulmonary embolism is stressed.

The problem of prevention of venous thrombosis and pulmonary embolism is discussed in some detail.

Medical and surgical treatments are surveyed.

An excellent bibliography is given at the end of each chapter.

As a reference book on this important problem this volume could not be bettered.

Shaw's Textbook of Gynaecology. Ninth edition. By JOHN HOWKINS, M.D., M.S., F.R.C.S., F.R.C.O.G., and GORDON BOURNE, F.R.C.S., F.R.C.O.G., St. Bartholomew's Hospital, London. 9 × 6 in. Pp. 823 + viii. Illustrated. 1971. Edinburgh: E. & S. Livingstone. £4·50.

THE ninth edition of this well-known textbook of gynaecology will in our opinion prove as popular as the long list of former editions. Nine editions, many of them reprinted, in 33 years proves the value and popularity of the work.

The name of Gordon Bourne appears for the first time and it would please Wilfred Shaw to know that one of his pupils was helping in the new edition of his book.

This book is printed in an attractive style and is well illustrated with good and telling illustrations, and, what is more, it is easy to read.

It should prove of real value to students and practitioners alike, and its price is moderate.

Simultaneous Prostatectomy and Inguinal Herniorrhaphy. By SIDNEY R. WEINBERG, M.D., F.A.C.S., New York, ALBERT KOVETIZ, M.D., U.S. Air Force, and STEPHEN M. LAZARUS, M.D., Brooklyn. 9 × 6 in. Pp. 51 + ix. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $6.75.

IN this small monograph the authors advocate a combined operation in which a retropubic prostatectomy is performed through a curved suprapubic incision. This incision is continued in a curved direction so as to afford access to the inguinal canal, and a radical cure of the inguinal hernia is carried out.

The authors maintain that the operation of simultaneous prostatectomy and inguinal herniorrhaphy does not represent any innovation in the physiological principles of surgery or surgical techniques. The bladder is drained by means of a Foley catheter and the retropubic space is also drained.

The clinical result and 'follow-up' seem to be very satisfactory.

This combined operation, while saving the patient an additional surgical procedure, does not materially increase the mortality and morbidity of simple abdominal prostatectomy.

Orthopédie Traumatologie. By SOCIÉTÉ FRANÇAISE DE CHIRURGIE ORTHOPÉDIQUE ET TRAUMATOLOGIE. 8¾×7 in. Pp. 233. Illustrated. 1969. Paris: Expansion Scientifique Française. 68F.

IN this volume twelve topics of interest are presented in the form of seminars. Each one is of value to the trainee orthopaedic surgeon as well as to the established practising clinician. The reviewer is struck by the meticulous thoroughness of the presentations.

Two subjects are outstanding in this collection of papers: club-foot and leg-lengthening. There is an excellent and practical description of the soft-tissue release operation for club-foot, with important technical details seldom found in standard writings.

A similar exhaustive and immensely practical description of the leg-lengthening procedure will be of great value to the surgeon who intends to do the operation and who has no previous experience of the technique or who is not satisfied with the results he has so far obtained.

The Scientific Basis of Medicine. Annual Reviews, 1971. Edited by IAN GILLILAND, M.D., F.R.C.P., and JILL FRANCIS, University of London. 8⅝×5⅝ in. Pp. 397+ix. Illustrated. 1971. London: The Athlone Press. £3·50.

THIS book has much for the specialist and general practitioner, for it gives the most recent advances on a wide range of medical and surgical topics.

Such topics as immunity to malignant disease in man, understanding of the muscle spindle, experimental cholelithiasis, the ageing eye, and new concepts of the function of the lymphatic system in the swollen leg are but a few of the excellent articles in this book.

It is a great advantage to all medical men to have an up-to-date book, each year, which gives them the results of scientific advance in the field of medicine.

Human Organ Support and Replacement. Edited by JAMES D. HARDY, M.D., F.A.C.S., Mississippi. 9¾×6¾ in. Pp. 453+xiii. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $30.50.

THIS large volume with its twenty-five contributors, mostly from America and Canada, covers a very important subject in a very comprehensive way. It is surely time that the world recognized that artificial devices and transplants have reached a level in which great progress has been made over the past decade. Following the success of renal transplantation it must be obvious that other organs will eventually be transplanted with equal success.

This book covers the whole subject of organ transplantation in a very practical way. It covers such diverse topics as histocompatibility typing, immunological modalities used in clinical allografting, organ storage, transplantation of the kidney, liver, stomach, small intestine, thyroid, parathyroid, adrenals, ovary, pancreas, spleen, lung, and heart. It also considers blood-vessel replacement and limb replacement.

A very complete list of important references is given at the end of each chapter. The illustrations throughout the book are clear and well chosen.

This book will be the reference volume on this important subject for many years to come.

Myoplastic Amputation, Immediate Prosthesis and Early Amputation. By MARIAN WEISS, M.D., Wierzejewskiego, Poland. 9×5⅘ in. Pp. 245+xii. Illustrated. 1971. Bethesda, Maryland: National Library of Medicine. $2.50.

THE operation of an amputation of the lower limb goes far back into history, but the experience of the two World Wars and the increase in accidents on the roads have advanced our knowledge of the best methods of amputation.

However, the immediate fitting of a prosthesis and early ambulation are new methods of treatment.

In this book the types of amputation of the lower limbs, the immediate fitting of a prosthesis and early walking by the patient, and postoperative care are discussed in detail. Some patients are encouraged to walk the same day as the operation. These new methods are said to eliminate neuroses and other psychopathological conditions.

This new method certainly warrants a trial in this country.

International Encyclopedia of Pharmacology and Therapeutics. Section 8: Local Anaesthetics. Edited by P. LECHAT, Paris. 9×6 in. Pp. 377+ix. Illustrated. 1971. Oxford: Pergamon Press Ltd. £6.

THIS volume covers the field of local anaesthesia in a very complete and comprehensive way. The various contributors to the ten chapters come from different clinics and institutes in Sweden, Switzerland, United States, West Germany, and France.

The blocking effects of some local anaesthetics commonly used in clinical practice are considered in detail. The absorption, distribution, metabolism, and excretion of local anaesthetics are discussed.

The toxicity and irritancy of local anaesthetics are described in a lucid manner.

Every facet of the subject of local anaesthetics has been covered in this book, and this being so it makes the book a useful reference volume on this subject.

Surgical Treatment of Coronary Arteriosclerosis. By RENE G. FAVALORO, M.D., Ohio. 10×6¾ in. Pp. 132+xvi. Illustrated. 1971. Edinburgh: E. & S. Livingstone. £6·75.

THIS is a useful monograph on the surgical treatment of coronary arteriosclerosis, an all-too-common condition in these modern times.

The author gives a very practical and interesting account of the preoperative evaluation and distribution of the severity of the coronary obstruction.

Preoperative preparation, anaesthesia, and postoperative care are stressed.

The author is at his best in describing the direct myocardial revascularization operations, such as pericardial patch-graft reconstruction and saphenous vein-graft reconstruction. The value of indirect myocardial revascularization by internal mammary artery implant procedures is examined.

The book is well illustrated and some of the selective coronary cine-angiograms are excellent.

This is a book which all cardiac surgeons will wish to possess, and postgraduate students who are studying for higher degrees or diplomas will find it most useful.

Why go on using substitutes

when you can have the real thing?

Why use second best when you can use DEXON - the only material specifically *designed to be a suture*

DEXON is the most documented suture in the history of surgery. It is far stronger than gut, handles like silk, absorbs uniformly and predictably yet retains its strength throughout the critical healing period. Above all, DEXON is inert therefore tissue reaction is minimal.

So why not change to DEXON

the Ideal Suture

- you owe it to your patients and to yourself -

DEXON*

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·10	£2·80	£3·20	£3·80	£4·30	£4·80	£5·90	£6·90
4	2·70	3·90	4·60	5·40	6·16	6·90	8·40	9·90
6/8	4·50	5·80	7·10	8·30	9·60	10·80	13·40	15·90
10/12	7·20	9·80	11·70	13·70	15·70	17·70	21·80	25·40
14/16	8·70	11·10	13·50	15·90	18·30	20·70	25·50	30·30
18/20	11·40	15·10	18·20	21·30	24·50	27·70	33·90	39·00
COVERS	1·50	2·10	2·70	3·30	3·90	4·50	5·70	6·90

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 58. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St. Martin's House,* 159 *Clapham High Street, London, S.W.*4.

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

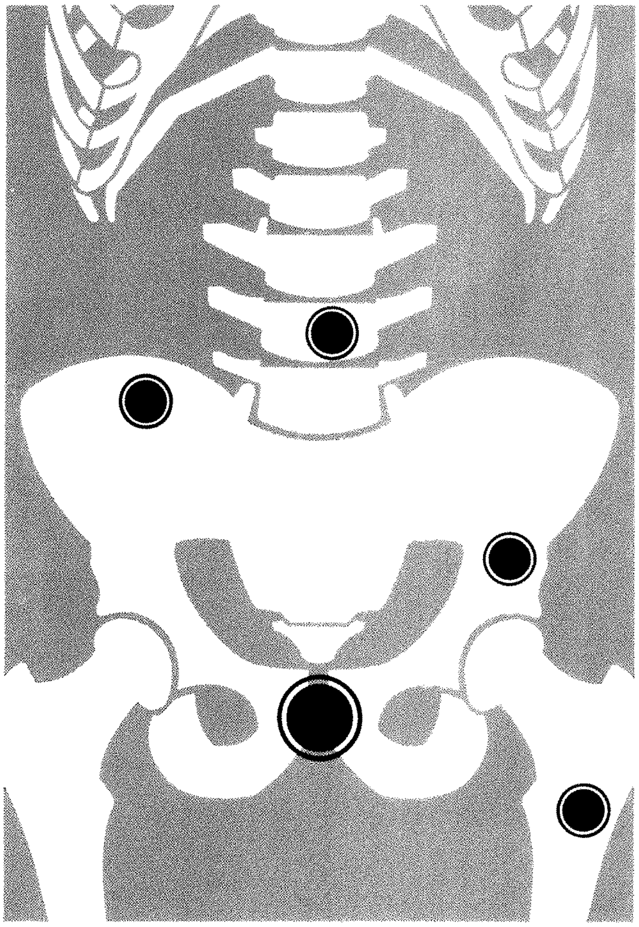
In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



Response is rapid. **Honvan** is a practical alternative to surgery in acute urinary retention caused by prostatic carcinoma.

Gastric tolerance of **Honvan** is good and side effects comparatively rare.

Honvan is available for both intravenous and oral administration.

a selective cytotoxic action
– in prostatic carcinoma

The most important pipe cleaner in the world...

Eschmann Embolectomy Catheter

- ✳ Pure latex balloon—soft when inflated to conform to arterial irregularities
- ✳ X-ray opaque — so you can see what it's doing
- ✳ Graduated along the shaft — so you can see where it is
- ✳ Colour coded — to help find the right size quickly
- ✳ Sterile—in rigid protective pack
- ✳ Made with care and tested with concern

It all adds up to the most important pipe cleaner in the world.

Manufactured by

ESCHMANN

Shoreham-by-Sea, Sussex

Available from established surgical dealers.

Matburn M

The supreme four section operation table. . .*

This is the supreme four-section operation table: grouped head-end control, the fullest range of positions and a series of over fifty accessories give the M the flexibility to meet the demands of any branch of surgery, and any procedure from routine examination under anaesthesia to advanced neurosurgical operations.

Built to the highest standards of engineering skill and precision, Matburn M combines absolute rigidity with easy mobility when required.

*More Matburn M Operation Tables are sold in this country every year than any other table.

ORIGINAL PAPERS

THE RESPONSE TO THERAPY OF SKELETAL METASTASES FROM MAMMARY CANCER

ASSESSMENT BY SCINTIGRAPHY*

BY C. S. B. GALASKO† AND F. H. DOYLE

BREAST CLINIC, DEPARTMENT OF SURGERY AND DIAGNOSTIC RADIOLOGY, ROYAL POSTGRADUATE MEDICAL SCHOOL, LONDON

SUMMARY

Clinical, radiological, and scintigraphic methods were used to assess the response of 30 patients undergoing treatment for advanced mammary cancer. Scintigraphy provided more information than radiology in 13 patients. In 2 patients scintigraphy indicated that sclerotic metastases which had not altered radiologically following treatment were probably 'healing'. In another 4 patients who developed apparently 'new' sclerotic metastases on serial radiographs the scintigrams indicated that these lesions probably represented 'healing' of lesions which had been too small for identification on the original radiographs.

A VARIETY of treatments for advanced mammary carcinoma, ranging from simple hormonal therapy to major ablative endocrine surgery such as pituitary ablation, hypophysectomy, and adrenalectomy, is available. The treatment is usually staged, progressing from simple hormonal therapy to major surgery. Response to a particular form of treatment should be assessed quickly and objectively so that if the patient has failed to respond, therapy can be altered. Obviously if a remission has been induced then the treatment should be continued.

The commonest site for distant metastases from mammary cancer is the skeleton (Willis, 1948; Ackerman and del Regato, 1954; Haagensen, 1956). In patients with untreated metastatic involvement of bone the lesions are commonly lytic and rarely sclerotic. A mixture of lysis and sclerosis is sometimes seen. The response of skeletal metastases to treatment is often difficult to assess. With remission of disease, bones with lytic metastases may radiologically return to normal or the lytic areas may become sclerotic (Graham, 1965). The development of new lytic lesions or the enlargement of existing ones indicates progression of the disease. From radiographs it is impossible to differentiate sclerotic lesions due to progression of disease from those due to 'healing' (Joplin, 1965). The clinical assessment of response is also unreliable as many metastases are asymptomatic (Galasko, 1969a.) The pain of skeletal metastases may be relieved by endocrine treatment even though the lesions continued to enlarge on serial radiographs.

In 1961 Gynning, Langeland, Lindberg, and Waldeskog reported on 3 patients whose advanced mammary cancer had responded to hormonal treatment. Their skeletal metastases, which had been present on their initial radiographs and which had concentrated strontium-85, lost their avidity for the isotope after treatment. The scintigraphic examination of these patients was limited to a specific area of the skeleton. The use of scintigraphy of the axial skeleton in the assessment of response to treatment has not previously been reported. We have compared serial scintigrams, radiographs, and clinical findings in the assessment of the response to treatment of patients with advanced mammary cancer.

MATERIALS AND METHODS

Skeletal scintigrams were obtained in 30 patients before treatment for their advanced mammary cancer was started and again after an interval of 3–4 months. The method of scintigraphy has previously been described (Galasko, Westerman, Li, Sellwood, and Burn, 1968; Galasko, 1969b). One and a quarter hours after the intravenous administration of 1·5 m.c. of fluorine-18 each patient was examined with a gamma-camera (Pho-Gamma Mark II, Nuclear Chicago). The fluorine-18 was obtained from the Medical Research Council Cyclotron Unit, Hammersmith Hospital. In all cases the camera was used with a 11·4-cm. collimator, which was obtained by bolting 7·6-cm. and 3·8-cm. multichannel collimators together.

---

* Based on a paper presented to the Surgical Research Society in July, 1970. Some of the material was presented by C. S. B. G. to the University of the Witwatersrand for the degree of Master of Surgery.

† Present address: Nuffield Orthopaedic Centre, Oxford.

With the patient seated, pictures were taken of the left, right, and posterior aspects of the skull, the cervical, dorsal, and lumbar spines, the left and right

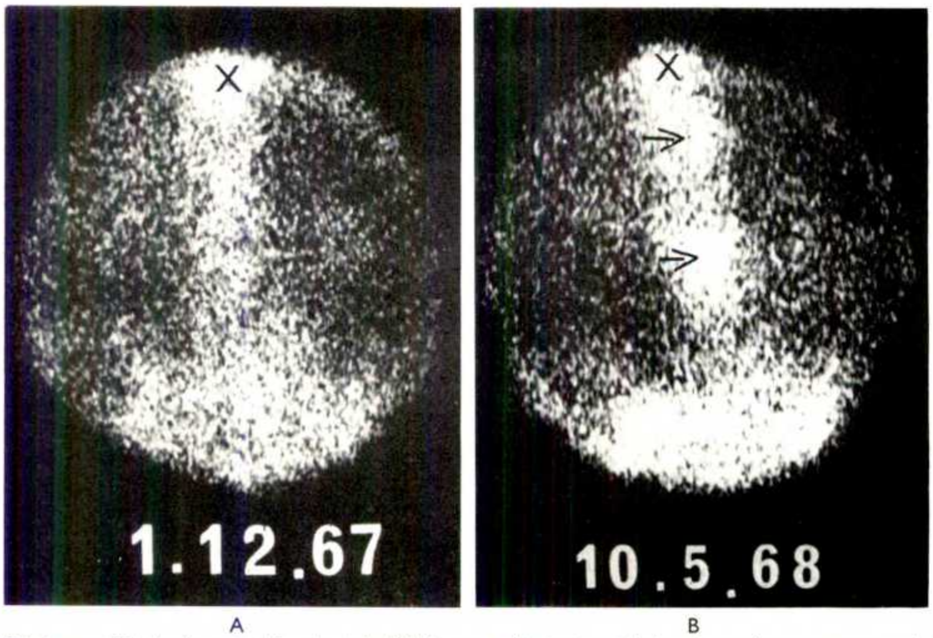

FIG. 1.—Scintigrams of the lumbar spine of a patient who failed to respond to treatment for her advanced mammary cancer. A, Scintigram before treatment for advanced mammary cancer was begun. No definite lesion can be seen. B, Scintigram obtained 5 months later. Lesions can be seen in two lumbar vertebrae (arrowed). The area of apparently increased uptake (X) is due to an 'edge effect' of the crystal.

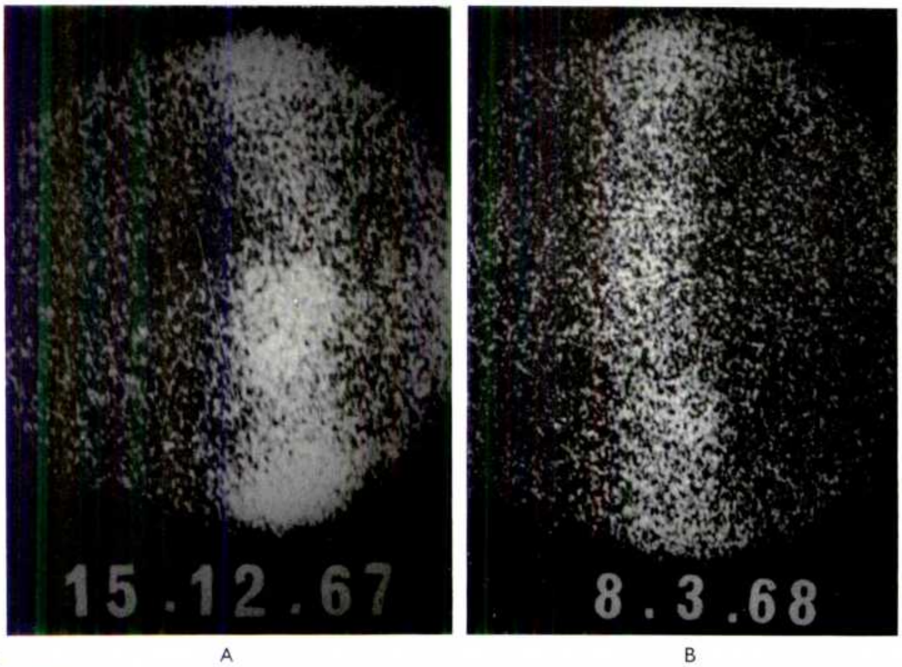

FIG. 2.—Scintigram of the dorsal spine in a patient whose mammary cancer responded to therapy. A, Multiple lesions can be seen in the scintigram which was obtained before therapy was commenced. B, Three months later the scintigraphic appearance of the dorsal spine had virtually returned to normal.

shoulder regions (including the proximal humeri), the left and right rib cages, and the posterior aspect of the pelvis. The patient then emptied her bladder (fluorine-18 being excreted in the urine) and a series of supine pictures were taken. These included the central, right, and left anterior aspects of the pelvis, the left and right proximal femora, and the sternum. These seventeen pictures constituted the axial skeletal scintigram.

Within a few days of the scintigram being taken each patient had a radiographic skeletal survey. This consisted of a lateral radiograph of the skull, antero-posterior and lateral views of the cervical, dorsal, and lumbar spine, and postero-anterior and antero-posterior radiographs of the chest and pelvis respectively.

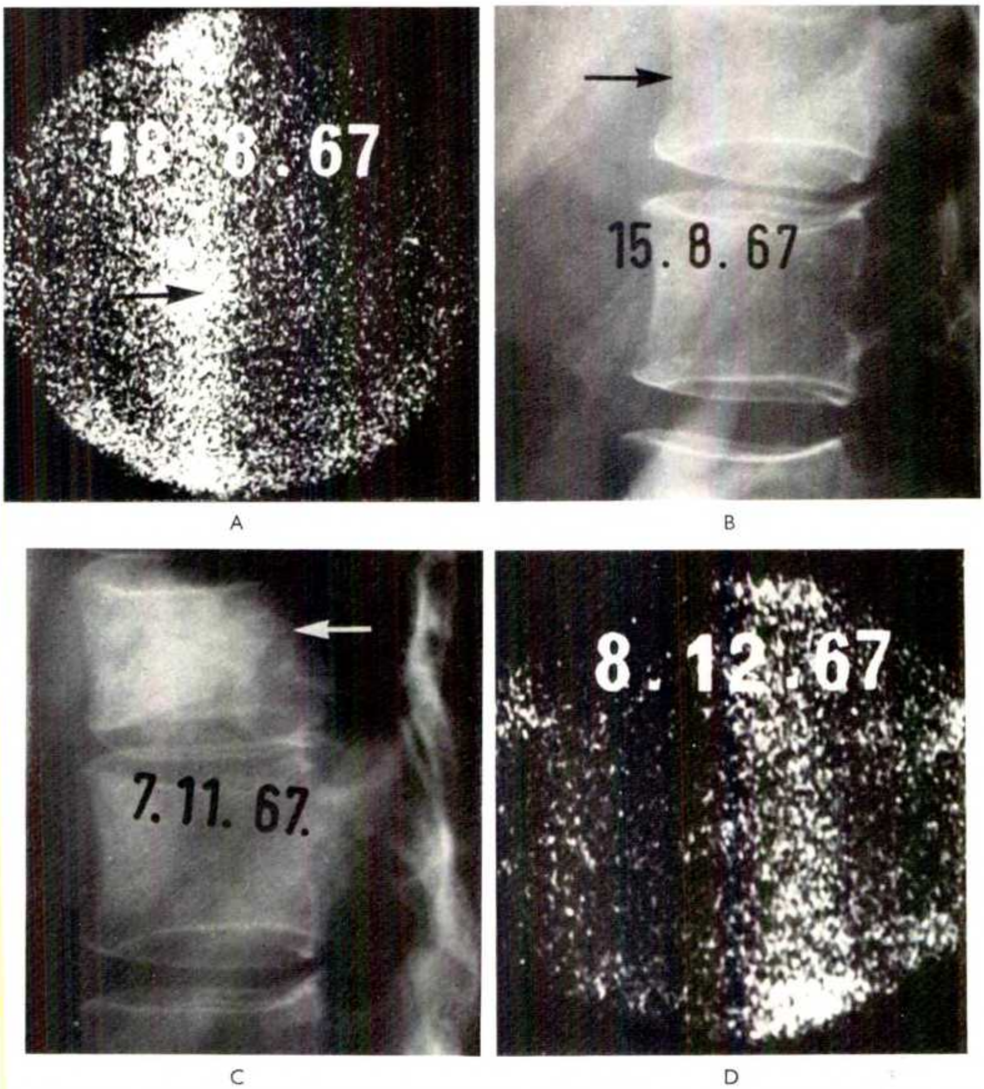

FIG. 3.—A patient who developed 'new' sclerotic metastases which were visible on the radiographs. Scintigrams and radiographs of the 11th and 12th dorsal vertebrae taken before treatment for advanced mammary cancer was started and repeated 3 months later. A, On the initial scintigram a lesion can be seen (arrowed). B, The initial radiograph was normal. C, Three months later diffuse sclerosis of the 11th dorsal vertebra was apparent (arrowed). D, The lesion was no longer apparent on the scintigram.

RESULTS

A summary of the results is given in *Table I*. Two patients with inoperable local tumours had no skeletal metastases. The primary tumours disappeared with treatment and their radiographs and scintigrams remained normal. In 10 patients the scintigraphic, radiological, and clinical findings were in agreement. Nine patients had deteriorated (*Fig*. 1) and 1 had gone into remission (*Fig*. 2). In 5 patients the scintigraphic and radiological findings indicated progression of the disease, even though all 5 had experienced some relief of pain. In 9 patients the scintigrams provided more information than the serial radiographs. Six patients had deteriorated and 3 had gone into remission. The details of these patients are shown in *Table II*. The only 2 patients whose lesions were initially sclerotic are included in this group. Both went into remission. Although the radiographic appearance of the lesions did not alter they diminished in number and size on the scintigram.

In 4 patients the findings were particularly interesting. In all 4 the primary breast tumour disappeared with treatment. Three of the patients had had lytic lesions on their initial radiographs and these had sclerosed with treatment. Following treatment each patient had developed apparently 'new' sclerotic lesions. In all 4 patients the apparently 'new' sclerotic lesions had been identified on the initial scintigram and had disappeared with treatment. On the initial scintigram, lesions which had not been radiologically present had been demonstrated in each patient (*Fig.* 3). With treatment these lesions had disappeared.

Table I.—SUMMARY OF RESULTS

No. of Patients	*Comparison of Scintigraphic, Radiological, and Clinical Findings*
2	Did not have skeletal metastases but local mammary tumour regressed on treatment
10	Scintigraphy, radiology, and clinical impression in agreement
5	Scintigraphy and radiology in agreement; clinical impression fallacious
9	Scintigraphy proved more informative than radiology
4	Apparently 'new' sclerotic metastases on radiographs; 'healing' on scintigram

Table II.—DETAILS OF 9 PATIENTS IN WHOM SCINTIGRAPHY PROVIDED MORE INFORMATION THAN RADIOGRAPHY

NO. OF PATIENTS	CLINICAL IMPRESSION	RADIOLOGICAL FINDINGS	SCINTIGRAPHIC FINDINGS
3	Deterioration	No lesions	Further lesions
2	No change	No lesions	Further lesions
1	Improvement (temporary)	No lesions	Further lesions
1	Remission	No lesions	Fewer lesions
2	Remission	No change of sclerotic lesions	Fewer lesions

The scintigram gave additional information, not otherwise available, in 13 (43 per cent) of the 30 patients (*Table I*).

DISCUSSION

We interpret our findings as follows. The majority of skeletal metastases evoke an osteoid reaction in the invaded bone (Milch and Changus, 1956; Galasko, 1971a). This osteoid has a high avidity for 'bone-seeking' isotopes (Charkes and Sklaroff, 1965; Galasko, 1971b). Charkes and Sklaroff (1965) suggested that when metastatic lesions remitted the osteoid calcified, matured, and lost its increased avidity for isotopes. In our view the loss of avidity for fluorine-18 by skeletal metastases, lytic or sclerotic, indicates healing. This confirms the observations of Gynning and others (1961). The apparently 'new' sclerotic lesions which were shown radiologically by patients on treatment represent healing of the lesions which, although detected scintigraphically, were too small to be recognized radiologically. Skeletal metastases have been recognized scintigraphically many months before their radiological detection (Corey, 1962; Charkes, Sklaroff, and Young, 1966; Spencer, Herbert, Rish, and Little, 1967; Galasko, 1969b). Our findings are in agreement with the observations of Joplin (1965), who stated that it was impossible on radiological grounds to differentiate sclerotic metastases due to progression of the disease from sclerotic lesions which occurred as a result of 'healing'. With scintigraphy we now may be able to differentiate these two different types of sclerotic lesions.

We believe that skeletal scintigraphy is not only an important diagnostic tool in the investigation of patients with mammary cancer but is also of considerable value in the assessment of response to treatment. Radiographic skeletal surveys, on their own, may be misleading in that undeclared lesions may sclerose on treatment.

Acknowledgements.—The authors wish to thank Professor J. F. Fowler for providing facilities in the Department of Medical Physics at the Royal Postgraduate Medical School, London, Mr. D. D. Vonberg and his staff of the Medical Research Council Cyclotron Unit, London, who supplied the isotope, and Professor R. B. Welbourn and Mr. J. I. Burn under whose care these patients were admitted.

CARCINOMA OF ABERRANT BREAST TISSUE

A REPORT OF 3 CASES

By G. M. R. SMITH and W. P. GREENING
THE BREAST UNIT, ROYAL MARSDEN HOSPITAL, LONDON

Summary

Three cases of carcinoma of aberrant breast tissue are described and the literature is briefly reviewed. It is suggested that subcutaneous nodules of uncertain origin around the periphery of the breast should be viewed with suspicion and treated by early excision.

The incidence of accessory breast tissue is probably about 1–2 per cent (Speert, 1942; Cogswell and Czerny, 1961), and it is approximately twice as common in females as in males (Geschickter, 1945).

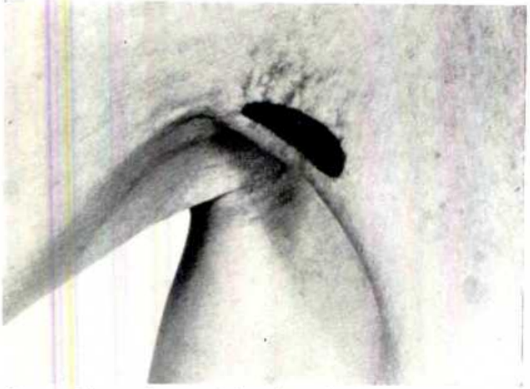

Fig. 1.—*Case* 1. Scar marked to show the site of excision of the tumour.

Copeland and Geschickter (1950) have suggested that a useful distinction may be drawn between supernumerary breasts, which usually have a nipple or areola in association with persistent or atrophic glandular tissue, and aberrant breast tissue, which is without a nipple or areola. Supernumerary breasts are most commonly present along the site of the embryological milk-line, running from axilla to groin, but may also occur in other situations, including the cheek, neck, shoulder, midline of chest or abdomen, flank, hip, thigh, and buttock (Cutler, 1961). Aberrant breast tissue, in contrast, is found in proximity to the normal breast, and consists of accessory fragments of breast tissue beyond the periphery of the gland. It may occur in the axillary, sternal, infraclavicular, or epigastric regions. The axillary site is the most common.

Tumours of aberrant breast tissue are rare. Carcinoma occurs more frequently than benign tumours (Geschickter, 1945). Copeland and Geschickter (1950) described 9 cases. Seven of these occurred in the axilla and 2 in the sternal region. Chiari (1958) collected 57 cases of carcinoma of aberrant breast tissue from the literature and added 3 of his own. Forty-three of these occurred in the axilla, 6 in the infraclavicular region, 6 in the sternal area, and 5 in the epigastrium, close to the xiphisternum.

CASE REPORTS

Case 1.—A woman, aged 43 years, was seen in 1957 with a small, painless nodule of recent origin in the right axilla. On examination a soft, subcutaneous swelling, measuring 1 cm. in diameter, was present on the anterior axillary fold. Axillary lymph-nodes were not enlarged, and no masses were palpable in the breasts. The swelling was thought to be a lipoma or sweat-gland tumour and was excised (*Fig.* 1). Histological examination showed that it was an anaplastic carcinoma of the breast.

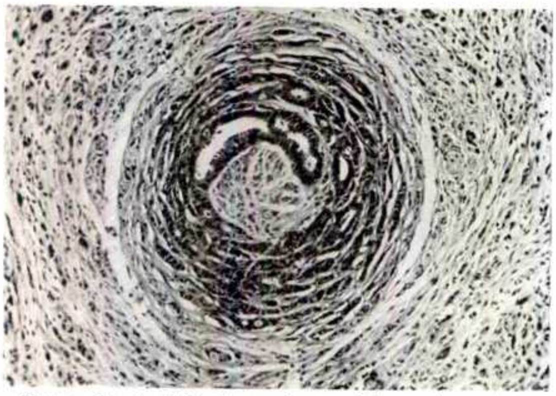

Fig. 2.—*Case* 2. Infiltrating carcinoma of aberrant breast tissue. H. and E. (× 80.)

Postoperatively, she received a course of radiotherapy to the axilla and supraclavicular region (5050 rad). She remains recurrence-free 13 years later.

Case 2.—A Turkish woman, aged 54 years, first noticed a nodule in the right axilla in 1958. Excision-biopsy was advised but she refused this. By 1966 the swelling had grown larger and was fixed to overlying skin. It was excised in Turkey. Histological examination revealed a carcinoma of indeterminate origin. Re-excisions for local recurrence were done in 1968 and in May, 1969. Histological examination now showed the features of carcinoma of the breast.

In July, 1969, she was seen in England. A firm nodule, measuring about 1 cm. in diameter, was present in the right axilla, adjacent to the previous scar. At least two enlarged lymph-nodes were palpable deep to the nodule. No masses were present in the breasts. The nodule was widely excised with the surrounding fat and lymph-nodes. Histological examination showed an infiltrating carcinoma of the breast (*Fig.* 2) with secondary deposits in three lymph-nodes.

Postoperatively, she received a course of radiotherapy to the right axilla and supraclavicular region (4500 rad).

When last seen, in September, 1970, she was recurrence-free.

Case 3.—A woman, aged 49 years, was seen in July, 1970, with a painless swelling in the right axilla. This had been present for about 6 weeks. On examination a subcutaneous nodule, measuring 1·5 cm. in diameter, was present in the upper lateral part of the right axilla. Axillary lymph-nodes were not enlarged, and no masses were palpable in the breasts. The swelling was thought to be an epidermoid cyst or sweat-gland tumour. Excision-biopsy was done. Histological examination showed an infiltrating, intraduct and intralobular carcinoma of mammary origin. A few duct and lobular structures of breast type were also present.

Three days later the wound was widely excised with the axillary fat and lymph-nodes. Histological examination showed a small amount of residual carcinoma together with aberrant mammary tissue. No secondary carcinoma was seen in 18 lymph-nodes.

Postoperatively she received a course of radiotherapy to the axilla and supraclavicular region. When last seen, in November, 1970, she was recurrence-free.

DISCUSSION

Carcinoma of aberrant breast tissue is a rare condition. Chiari (1958) found only 3 cases in a series of 918 patients who were operated on for carcinoma of the breast over a 10-year period, and several equally large series have included no cases. The condition is, therefore, likely to be misdiagnosed unless it is borne in mind whenever an unusual swelling is seen in the area around the breast. The cases described here demonstrate this, for in each instance the correct diagnosis was not made until the tumour had been excised and examined histologically. This serves to emphasize that any subcutaneous nodule in the area around the periphery of the breast, and especially in the axilla, should always be viewed with suspicion and treated by early excision.

The presence of aberrant breast tissue is often noticed only when breast engorgement takes place during pregnancy and lactation, or when tumour formation occurs within it (Razemon and Bizard, 1929). There is no convincing evidence that this tissue is more prone to malignant change than normal breast parenchyma, and excision of aberrant breast tissue which is not causing symptoms and contains no tumour is, therefore, not normally indicated (de Cholnoky, 1951).

Carcinoma of aberrant breast tissue may be treated by wide local excision (Cogswell and Czerny, 1961) or by radical mastectomy (Copeland and Geschickter, 1950; Chiari, 1958). De Cholnoky (1951) advocates wide local excision with the removal of adjacent lymph-nodes as the treatment of choice and suggests that the breast should only be removed if any suspicious nodules are palpable within it. If mastectomy is not done, particularly careful follow-up is, of course, necessary to exclude any later manifestation of an occult primary neoplasm in the breast.

It has been suggested that the prognosis of carcinoma of aberrant breast tissue may be worse than that of carcinoma of the normal breast, because these tumours metastasize early to lymph-nodes (Cogswell and Czerny, 1961). Copeland and Geschickter (1950) noted that only 1 of their 9 cases survived for more than 5 years, and several other reported cases have shown a rapid progression to death. However, Chiari (1958), in a review of 60 cases, came to the conclusion that the clinical characteristics of carcinoma of aberrant breast tissue were the same as those of carcinoma of the breast, and he was unable to confirm that the prognosis of the two conditions differs significantly.

The present 3 cases were treated by local excision of the tumour, with the additional removal of the axillary lymph-nodes in 2 cases. The breast was not removed. Postoperatively each patient received a course of radiotherapy to the axilla and supraclavicular region. Follow-up to date has revealed no tumour recurrence, in 1 case 13 years after treatment.

Acknowledgements.—We wish to thank Dr. N. F. C. Gowing, Consultant Pathologist, Royal Marsden Hospital, and Dr. P. M. Peters, Royal Northern Hospital, for the histological reports. Thanks are also due to the Department of Photography, Royal Marsden Hospital, for the illustrations.

GLOMUS TUMOUR

A REVIEW OF 15 CLINICAL CASES

By J. STRAHAN* and H. W. C. BAILIE
COLERAINE HOSPITAL, NORTHERN IRELAND

SUMMARY

Fifteen cases of glomus tumour are recorded. Twelve patients presented with a solitary limb lesion. One patient had a glomus arising in a pilonidal sinus. Two members of one family had multiple lesions.

Complete surgical removal is curative, and malignancy is not a hazard. It is important to make a preoperative diagnosis, so that at operation a capsule can be looked for carefully. If no capsule is found an *en bloc* excision is imperative.

It is suggested that pain may sometimes be initiated by trauma, by thrombosis, or by the vascular congestion associated with menstruation and pregnancy.

GLOMUS tumours have been described in almost every part of the body. The typical clinical picture of the painful, bluish, circumscribed, skin nodule is now familiar to most clinicians. This condition was known as early as the eighteenth century, but the first clear clinical description was probably given by William Wood of Edinburgh (1812), who employed the term 'painful subcutaneous tubercle'. In 1924 Paul Masson published a description of the histological features which remains valid today.

Table I.—SUMMARY OF 15 CASES OF GLOMUS TUMOUR

CASE	SEX	AGE OF ONSET	SITE OF TUMOUR
1 (E. McG.)	F.	9	Left pretibial region
2 (A. M.)	F.	50	Calf of left leg
3 (E. S.)	F.	66	Subungual right middle finger
4 (M. H.)	F.	19	Subungual right thumb
5 (G. McF.)	F.	57	Plantar surface of right foot
6 (M. K.)	F.	33	Plantar surface of left foot
7 (S. E. M.)	F.	54	Pulp of right index finger
8 (M. O'H.)	F.	25	Plantar surface of right foot
9 (M. M.)	F.	64	Base of right thumb
10 (J. C.)	M.	77	Tip of left index finger
11 (P. M.)	F.	22	Pilonidal sinus
12 (J. M.)	M.	31	Left elbow
13 (J. McW.)	M.	29	Subungual left big toe
14 (H. A)	F.	26	Multiple (56)
15 (D. A.)	F.	28	Multiple (5)

The tumour is usually solitary, and typically it is found in the limb extremities where there is normally a concentration of glomus tissue, but no part of the body surface is exempt. Skeletal and visceral examples are rare. A wide spectrum of both histological and clinical features is now recognized in glomus tumours. The vascular glomus, resembling an angioma, differs greatly from the cellular tumour, but in all cases the hall-mark of histological diagnosis is the recognition of the characteristic 'glomus' cell in the vessel walls. The tumour usually has a well-defined capsule.

CLINICAL STUDY

Fifteen patients were seen at Coleraine Hospital in Northern Ireland over a period of 16 years (*Table I*). A histological confirmation of glomus tumour was obtained in 14 cases, there being no indication for surgical interference in the other. Thirteen patients were reviewed during 1969. Of the other 2 patients, 1 had died and the other had emigrated.

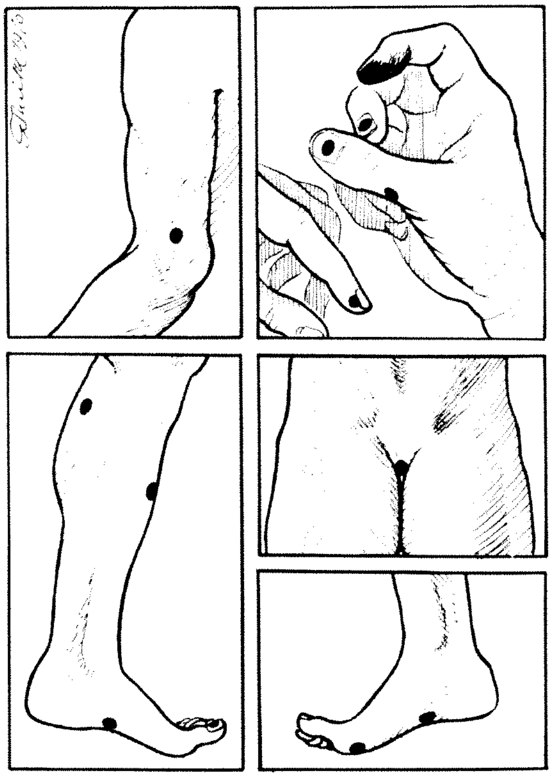

FIG. 1.— The site of the tumour in 13 patients with solitary glomus tumour.

There were 3 males and 12 females, with ages on presentation ranging from 19 to 77 years. Thirteen of the patients had a single lesion but multiple tumours occurred in 2 members of one family. The site of the tumour in the 13 patients with a single lesion is shown in *Fig.* 1.

Pain was the presenting symptom in 14 of the 15 patients. One female patient with a painless tumour of her thumb (*Case* 9) attended because she was worried about malignancy. Where pain originated in the digit it often radiated as far up as the trunk during severe paroxysms. The duration of the pain in this series varied from 4 to 20 years.

Seven of the cases meriting separate description are detailed below.

CASE REPORTS

Case 7.—A 55-year-old female patient first attended a surgical clinic in August, 1963. She was then known to have myxoedema and was on maintenance thyroid therapy. She had moderately severe angina with pain radiating to both arms which was helped by glyceryl trinitrite. Disk degeneration of the lower cervical spine had also previously been diagnosed. Her complaints were of paroxysms of severe pain in the tip of her right index finger, accompanied by a less severe 'soreness' radiating to her right ear. The patient appeared distressed and said that she was 'distracted', 'muddled', and 'could not concentrate'. There was a localized point of extreme tenderness in the index finger-tip, and although there was no sign of a tumour the tender area was explored. At operation no recognizable tumour was found, but a small biopsy was taken and histology showed definite overdevelopment of glomoid structures under a thickened epidermis. The pattern was diffuse without any evidence of encapsulation. Her symptoms persisted after this exploration, and a wider excision was carried out 1 month later. This again was not curative, and 10 months later the finger-tip was amputated through the distal interphalangeal joint. Histology again showed a widespread increase in glomoid structures.

The patient was not seen again until this present review. She was still having paroxysms of pain in the amputation stump of her right index finger, radiating proximally and precipitated by light touch, cold, and dependency of the hand. The pain was eased by elevation or heat. On close examination of the part there was one pinhead-sized nodule with slight adjacent bluish discoloration which was very sensitive to light touch. Both the patient and her daughter (who is a nursing sister) insisted that during these paroxysms of pain there was an obvious red blush of the finger-tip.

Case 8.—During her third pregnancy a 27-year-old housewife found a painful nodule in the sole of the right foot. The pain disappeared after her confinement but recurred with the next pregnancy 18 months later. The nodule also increased in size and she was referred to the surgical clinic in the 26th week of pregnancy. There was a tender bluish swelling, 2 × 2 cm., on the sole of the right foot. Surgical exploration was deferred until 5 weeks after delivery, when a pale-pink, lobulated, fatty tumour, superficial to the plantar fascia, was dissected out. There was no evidence of a capsule. Histology showed fibrofatty tissue in which there was a prominence of vascular spaces with glomus cells. Following this operation she was symptom-free for 2 years, but pain returned with her fifth pregnancy. The pain was aggravated by weight-bearing and she noticed a bluish discoloration in the operation site. After delivery, symptoms again improved.

When seen at review a pinhead-sized nodule with a bluish flare around it was noted in the scar line. She said that her pain, though not now severe, was always worse during the week before menstruation.

Case 10.—A 77-year-old-man with one arm went to his doctor with a painful index finger, saying that he had run a nailbrush bristle under the nail. He was referred to hospital, and on examination the finger-tip was red and extremely tender to light touch. Under anaesthesia the nail was trimmed and a small incision was made in the pulp when a bead of pus was obtained. Four weeks later, in spite of antibiotic therapy, the finger was still painful and the patient was very short in temper. A small pout of granulations had grown at the site of the incision. Radiographs of the finger showed no bony abnormality. At a further exploration a narrow tract led to a small encapsulated glomus tumour of the pulp on the tip of the bony phalanx. Removal of the tumour produced complete relief of symptoms and a restoration of confidence.

Case 11.—After 3 years of recurrent inflammation and discharge from a pilonidal sinus, a 25-year-old clerk was referred to the surgical clinic. Pain was mentioned in her history, but this was considered to be due to attacks of inflammation. At operation an *en bloc* dissection of the sinus was performed with primary closure. Histology revealed a large glomus in the wall of a chronically inflamed sinus.

When seen at review she was very pleased with the results of the operation and was completely free from pain. Only then did she reveal that before the operation, pain was such that she often had to sit with a book under one buttock to relieve it, and sometimes it had been so intense that she could not sit at all.

Case 13.—A 27-year-old bus driver purchased a new pair of shoes for his wedding day. He wore them on that day and then put them aside as he thought that they were too loose. Eighteen months later he tried them on again but found that the 'left shoe hurt his big toe'. Within the next few months he obtained five different pairs of shoes but each hurt the left big toe. The pain in the toe became more severe and often occurred at night. A light touch was sufficient to cause a paroxysm of severe pain spreading up to the instep. When examined closely, a minute area of discoloration was seen under the nail which was very sensitive to touch. It was explored on two occasions through a window, but only in the second biopsy specimen were glomus elements detected. There was no sign of encapsulation.

At review 6 months later he still had pain.

Case 14.—A 26-year-old girl was referred to a consultant dermatologist following an eruption of purpuric-like spots on the limbs and trunk. She had no symptoms apart from menorrhagia with no obvious cause. A diagnosis of multiple haemangiomata was suggested and was supported by biopsy of a nodule from the left thigh. No treatment was undertaken.

Some months later she was referred for a surgical opinion with a painful nodule in the back of the neck near the hairline. The nodule measured 1·5 cm. in diameter and was bluish to red in colour. Multiple similar lesions (56 were counted) were widely scattered over the face, trunk, and limbs. These varied in size from tiny impalpable and completely collapsible lesions of less than 1 mm. to raised palpable nodules which were only partly compressible. The painful nodule was excised. It was encapsulated and pink in colour. Histologically, it resembled a cavernous haemangioma, but in many areas glomus cells were arranged in the walls of dilated vascular spaces. There was one area of thrombosis proceeding to organization. On review of the earlier biopsy it was possible to recognize glomus cells but no thrombosis in the vascular spaces. Apart from menorrhagia the patient was symptom-free.

Case 15.—The 31-year-old elder sister of *Case* 14 had five widely distributed skin nodules which had first been noticed at the age of 28. At review two of the nodules were slightly painful on deep pressure. No surgical treatment was offered.

DISCUSSION

Fourteen patients have had surgical excision of their tumours, but there was no indication for surgical interference in *Case* 15. All those patients in whom an encapsulated tumour could be shelled out at operation have had a very satisfactory result. Patients with unencapsulated tumours have had further trouble. The results of treatment are shown in *Table II*.

The glomus tumour is regarded not as a neoplasm but as a hamartoma because of its organoid structure. Malignancy is not a hazard and so-called 'recurrences' are almost certainly always incomplete removals of unencapsulated tumours. As the review of the cases described here has made clear, incomplete removal is all too frequent. Once it is recognized that the tumour does not possess an obvious capsule the surgeon should be prepared to change his approach and to carry out *en bloc* excision rather than to persist in any attempt to dissect out the tumour. As it is impossible to be certain before operation that the tumour has a capsule, care should be taken not to have the excision treated as a minor procedure. Linked to this is the obvious importance of an accurate preoperative clinical diagnosis. Many mistakes were made and delays in cure occasioned by misleading histories, as in *Case* 10, or by complete failure to recognize the condition and the possibility of surgical treatment, as in *Case* 4, who suffered severe pain for 5 years before she was referred for a surgical opinion. At this point we would emphasize the importance of warning the pathologist of the possibility of a glomus tumour.

Table II.—RESULTS OF TREATMENT RELATED TO PATHOLOGY

PATHOLOGY	NO. OF PATIENTS	RESULTS OF TREATMENT
Encapsulated	9	All cured by simple enucleation of the tumour
Uncapsulated	5	2 operations—cured 3 operations—cured 3 operations—residual symptoms 1 operation—residual symptoms 2 operations—residual symptoms
Total	14	

Case 11 appears to be the first recorded instance of a glomus tumour in a pilonidal sinus. It also seems to be a happy if unplanned example of the proper treatment of a glomus tumour.

Glomus tumours can be present for a long time without pain. Why they become painful is not at all certain, and attempts to correlate the histological picture with the presence or absence of pain have failed to show any constant characteristic. For example, the relationship between pregnancy, menstruation, and pain in *Case* 8 was striking. Also, in a further patient (*Case* 14) a painful lesion showed an organizing thrombus where a painless lesion showed no such pathology. Pathologists often describe sclerosis in these tumours which could well represent organized thrombus. Trauma may be the initiating factor in the onset of pain (Lendrum and Mackey, 1939). This occurred in only 1 patient in this series (*Case* 10). The presence of severe pain with a very localized and sensitive trigger-point should lead to the suspicion of a glomus tumour, even when there is no apparent swelling or discoloration. We suggest that there should be less reluctance in exploring such trigger-points.

When multiple lesions occur there is often a family history (Gorlin, Fusaro, and Benton, 1960; Hueston, 1961). These multiple tumours are often of the painless variety, although pain can erupt in a previously asymptomatic nodule.

Acknowledgements.—We would like to thank Mr. I. H. Greer who contributed 2 cases to this series, and also Dr. J. E. Morison for his most helpful advice and criticism.

THE EFFECT OF ENVIRONMENTAL TEMPERATURE AND NUTRITIONAL INTAKE ON THE METABOLIC RESPONSE TO ABDOMINAL SURGERY*

BY JOHN SPIVEY† AND IVAN D. A. JOHNSTON
DEPARTMENT OF SURGERY, UNIVERSITY OF NEWCASTLE UPON TYNE

SUMMARY

Ambient temperatures of 29° C. had no effect on the nitrogen balance after elective abdominal surgery in 15 well-nourished men compared with 29 similar patients nursed at 24° C. The catabolic response as measured by nitrogen balance is small following operation of moderate severity and can be abolished by an increased intake of nitrogen and calories.

SURGICAL operations of moderate severity are followed by an increased excretion of nitrogen in the urine and a negative nitrogen balance which lasts for 4 or 5 days. The losses of nitrogen are due in part to a reduction in the intake of food over the period of injury (Cuthbertson, 1936). Patients who are well nourished prior to operation lose more nitrogen than nutritionally depleted subjects. The nitrogen

[†] Present address: Robert Jones and Agnes Hunt Orthopaedic Hospital, Oswestry.

balance may be improved after injury by giving adequate sources of energy and nitrogen, but an obligatory catabolic response appears to persist in spite of apparently adequate intakes (Johnston, Marino, and Stevens, 1966).

Environmental factors have also been shown to diminish the metabolic response to injury. Caldwell (1962) showed that rats on a moderately restricted dietary intake excreted less urinary nitrogen when they were maintained at a temperature of 30° C. Barr, Burke, Liljedahl, and Plantin (1968) reported that, following severe burns, patients who were nursed at 32° C. in dry air had a reduced consumption of oxygen and maintained their nutritional state fairly easily.

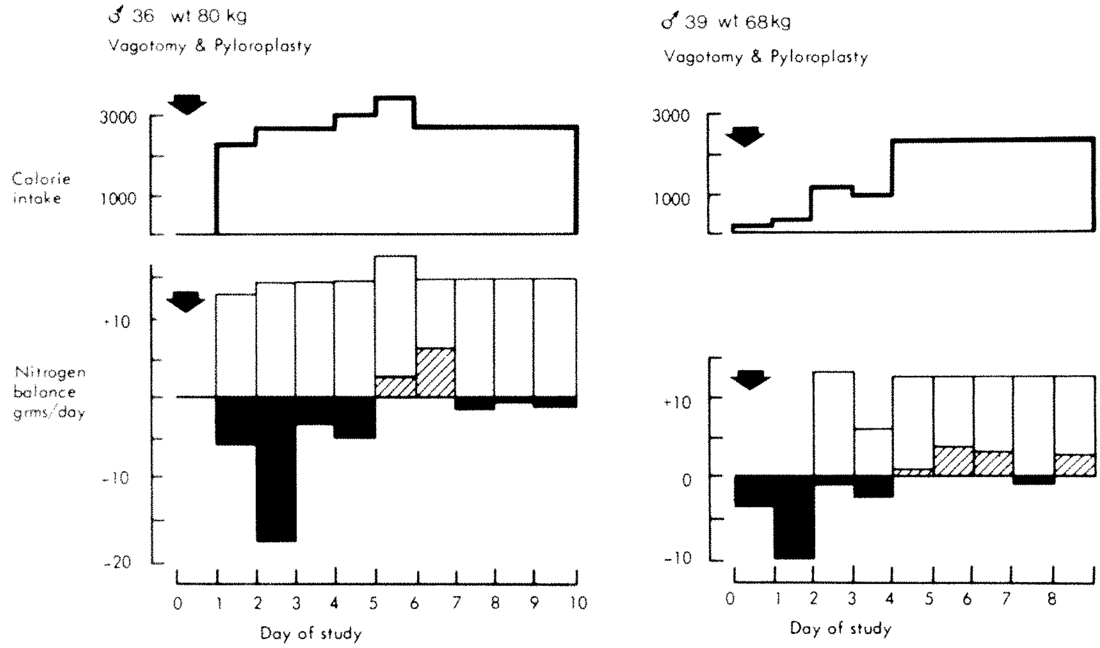

FIG. 1.—The calorie intake and nitrogen balance after vagotomy and pyloroplasty in 2 men of different weights receiving different intakes of food.

Davies and Liljedahl (1970) have subsequently shown that nitrogen losses in the urine of burned patients are reduced at high ambient temperatures of about 30° C. Cuthbertson, Smith, and Tilstone (1968) reported a similar reduction in urinary nitrogen in patients with closed limb fractures who were nursed at 30° C., and they suggested that high temperature reduces heat loss by the body, inhibits heat production, and thus reduces the breakdown of body protein to provide energy substrates.

Calorie intake and energy production are also closely related, and because of this an investigation was planned to study the effect of a high ambient temperature of about 30° C. on the metabolic response to surgical procedures of moderate severity in well-nourished men who were given varying calorie intakes in the postoperative period.

MATERIALS AND METHODS

Forty-four male patients aged between 21 and 67 years who were within 10 per cent of their standard weight, calculated in relation to sex, height, and age (Kemsley, 1952), were selected for study and were divided into two groups. The first group (29 patients) was nursed throughout at an ambient temperature of 24 ± 1·5° C., with a relative humidity of between 40 and 50 per cent. The second group (15 patients) was nursed at a temperature of 29 ± 1° C., with a relative humidity of 35 per cent for the first 3 days after operation. These patients were then transferred to the normal ward environment.

Table I.—DETAILS OF THE STUDY

FEATURE	GROUP 1	GROUP 2
Temperature of the environment (° C.)	24	29
Relative humidity (per cent)	40–50	35
No. of patients studied	29	15
Age range (years)	22–67	21–62
Mean age (years)	46·4	44·1
Weight range (kg.)	49–100	55–92
Mean weight (kg.)	70·3	69·9

Thirty-seven patients had vagotomy and pyloroplasty or gastro-enterostomy, 5 had partial gastrectomy, 1 had vagotomy alone, and 1 had a hiatal hernia repair. The age and weight of the patients and other details of the study are shown in *Table I.* Nitrogen balance studies were commenced on the day of operation and were continued for 8 days. The intake of nitrogen ranged from 0 to 272 mg. per kg. body-weight per day, and was maintained at a constant level in each patient. High intakes of nitrogen and calories in the postoperative period were achieved by using casein hydrolysate solution (aminosol, 10 per cent), soya bean oil emulsion (intralipid, 20 per cent), and sorbitol, 30 per cent. A potassium supplement of 80 mEq. per day was added to the parenteral intake. Parenteral feeding was replaced with nutritious fluids by mouth on the fourth postoperative day, and all the patients were given solid food on the fifth day. A constant intake was then maintained for the remainder of the study. The ratio of calories to nitrogen was maintained at about 200 calories to 1 g. of nitrogen at all times. The calorie and nitrogen intake during oral feeding was calculated from the tables of McCance and Widdowson (1964).

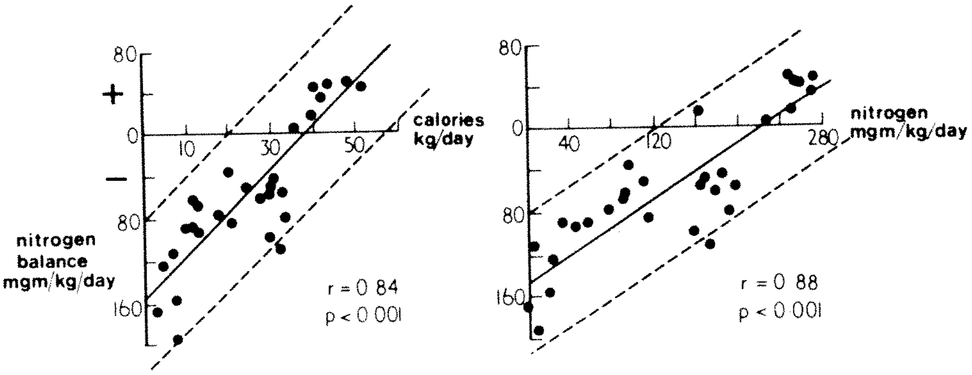

Fig. 2.—Regression analysis of the mean daily intakes of calories and nitrogen and the nitrogen balance in patients who were nursed at 24° C. (normal ward temperature) for the first 3 days after operation.

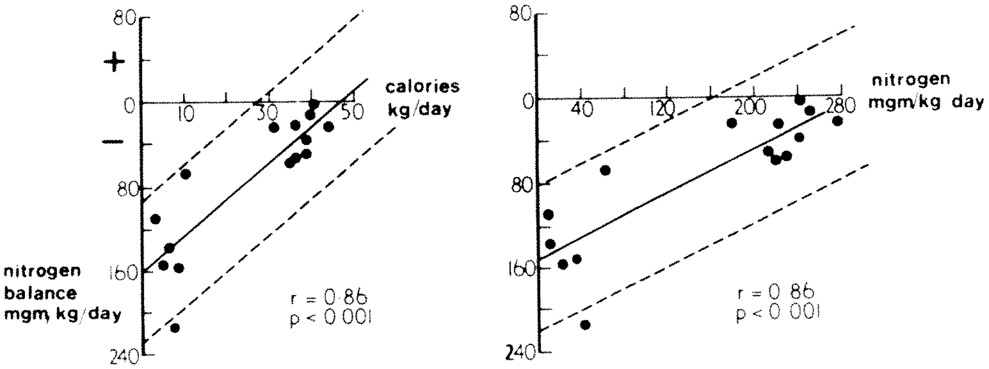

Fig. 3.—Regression analysis of the mean daily intake of calories and nitrogen and the nitrogen balance in patients who were nursed at 29° C. (high ambient temperature) for the first 3 days after operation.

Urinary nitrogen was measured in each 24-hour collection by the micro-Kjeldahl technique. The daily urinary creatinine output was estimated, and if the cumulative creatinine excretion after 3 days varied by more than 10 per cent from the excretion in the subsequent 3 days a collection error was assumed and the balance was discarded.

RESULTS

The postoperative balance studies from 2 patients of different weights are shown in *Fig.* 1. One patient had a low postoperative intake of calories and nitrogen while the other had a high intake. The balances of nitrogen are negative in both patients, and the nitrogen losses are greater in the heavier patient on a high intake. The obvious difficulty of comparing daily balance data from patients of different body-weight receiving different intakes of food was overcome by expressing all intakes and balances in terms of kg. body-weight.

The results are expressed as mean daily intakes and balances for each patient for the periods 1–3 and 5–7 days after operation.

The mean intake of calories and nitrogen was plotted against nitrogen balance, which was also expressed in terms of body-weight. The values for the 29 patients who were maintained at $24 \pm 1\cdot5^\circ$ C. are shown in *Fig.* 2. The balance of nitrogen remains negative when the intake is low and changes to positive as the intake rises. A regression analysis indicates that zero balance is achieved at a mean intake of 38 cal. per kg. per day and 223 mg. nitrogen per kg. per day ($P < 0\cdot001$). The 95 per cent confidence limits for the regression have been plotted.

The results for the 15 patients who were nursed at the higher temperature ($29 \pm 1^\circ$ C.) are shown in a similar fashion in *Fig.* 3. The relationship between intakes of calories and nitrogen and nitrogen balance is again significant ($P < 0\cdot001$). A regression analysis indicates that balance is achieved at an intake of 47 cal. per kg. per day and 296 mg. nitrogen per kg. per day. The observations for these patients, with the exception of 1 patient on a low intake, all fall within the 95 per cent confidence limits of the previous group. There is thus no evidence that after elective abdominal surgery of moderate severity, exposure to a temperature of 29° C. modifies the postoperative nitrogen loss during the first 3 days. A number of the patients who were nursed at high temperatures found the conditions uncomfortable.

The results for the period 5–7 days after operation have been analysed in the same way (*Fig.* 4). The patients were eating normally and most had a positive nitrogen balance at this time. A mean intake of 30 cal. per kg. per day and 152 mg. nitrogen per kg. per day was now sufficient to maintain nitrogen balance. The correlation between intake and balance remains significant ($P < 0.001$).

A comparison of the regression lines for the immediate and late postoperative periods shows a shift to the left in the period 5–7 days after operation (*Fig.* 5). This difference may represent the extent of

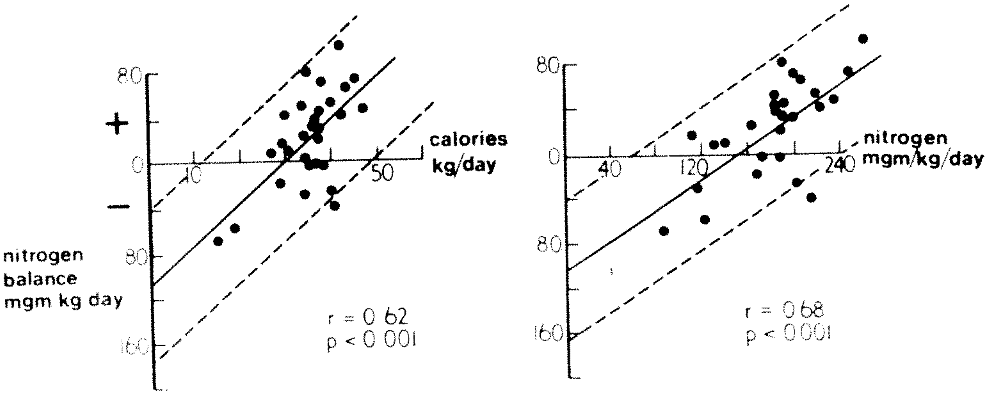

FIG. 4.—Regression analysis of the mean daily nitrogen and calorie intake and the nitrogen balance in patients 5–7 days after operation.

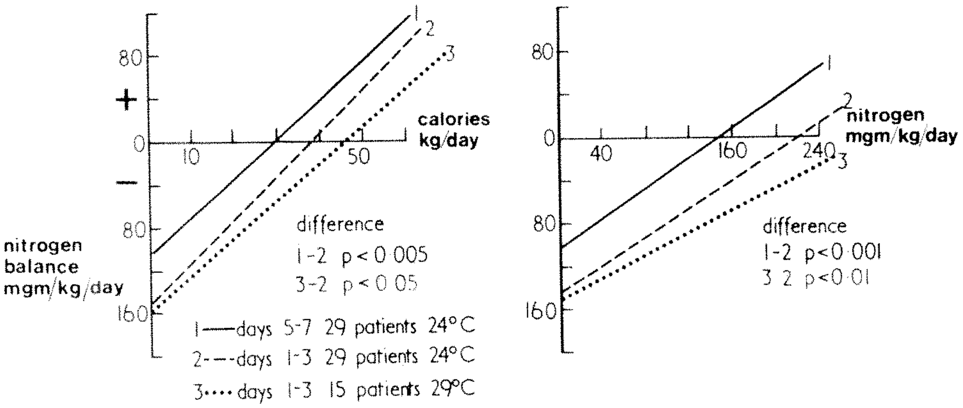

FIG. 5.—A comparison of the regression analyses of the intake/balance relationships in the early and late postoperative periods.

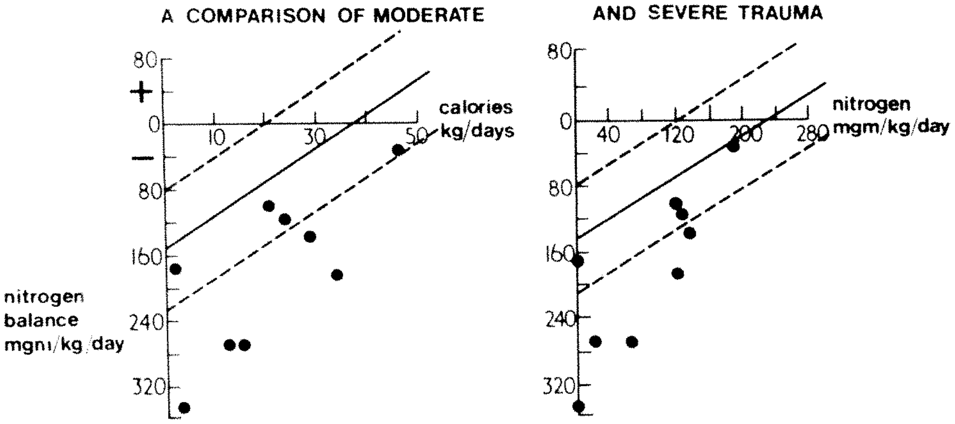

FIG. 6.—The relationship between calorie and nitrogen intakes and nitrogen balance after major trauma (each dot represents 1 patient) plotted against the regression analysis of data from patients after elective surgery of moderate severity.

the catabolic response in the postoperative period. The differences between the regressions was analysed using the formula:—

$$\frac{\text{Distance between slopes}}{\text{Standard error of distance}},$$

with n_1-2 and n_2-2 degrees of freedom. The difference was found to be significant (*Fig.* 5).

It was considered that if changes in body catabolism can be detected by this method of regression analysis then data from patients after major trauma should show a more marked shift to the right.

The mean daily intake, output, and balance data from 9 patients following multiple fractures, chest injury, and major neck and abdominal surgery for malignant disease were calculated from the second to the fourth day after injury or operation, and these results are shown alongside the regression analysis of the data obtained 1–3 days after elective surgery of moderate severity (*Fig.* 6). All the results fell below the regression line for the moderate injury group, and 5 results fell outside the 95 per cent confidence limits. These results indicate that very high intakes would be required to achieve a positive balance in such patients.

DISCUSSION

The results of this investigation have failed to show any reduction of postoperative nitrogen loss in the first 3 days after operations of moderate severity when the ambient temperature was raised to 29° C. Cuthbertson and others (1968) studied patients with closed fracture which is recognized as producing a more profound catabolic response than the operation in this study.

The present investigations show that the catabolic response following elective, uncomplicated abdominal operation is very small in terms of total nitrogen turnover, when allowances are made for diminished intake immediately after surgery. It may be that only the response to more major injury is affected by high ambient temperatures.

The results indicate that the negative nitrogen balance following moderate surgical trauma can be overcome by an increase in the calorie and nitrogen intake in the postoperative period. The required increase over resting requirements is modest and amounts to not more than 8 cal. per kg. per day and 70 mg. nitrogen per kg. per day in well-nourished men.

The nitrogen losses after major injury are much greater, so that the intakes necessary to achieve balance cannot be reached easily. These results suggest that the calorie and nitrogen requirements for balance after major injury are related mainly to the severity of the trauma.

It may be that in patients after major trauma the combination of high intakes and an increase in the ambient temperature will be an effective method of reducing the nitrogen losses. High-temperature nursing will clearly be of greater value when a component of energy expenditure such as evaporative heat loss is present after injury, as in severe burns. However, in patients with closed injuries or after major surgery where excessive evaporative heat loss does not occur but where the resting metabolic expenditure may be increased by up to 40 per cent (Kinney, Long, and Duke, 1970), problems of heat distribution might develop within the body. It is important also to determine why some patients could not tolerate the high temperature of their surroundings.

These studies show that the catabolic response to the moderate trauma of abdominal surgery is small in terms of calorie requirements and is not influenced in the first 3 days by changes in ambient temperature. Severe injury, on the other hand, is associated with much greater losses of nitrogen, and the calorie and nitrogen requirements to achieve balance are very great.

Acknowledgements.—We acknowledge gratefully the help of Mrs. D. Weightman from the Department of Medical Statistics. We are also grateful to Mr. Fenton Braithwaite, Mr. J. R. G. Edwards, and Mr. J. K. Stanger for permitting us to study patients under their care; to Staff Nurse C. Walton for assistance with the metabolic balance work; to Mrs. D. S. Adams for secretarial assistance; and to Mr. E. I. Hartshorne and Mr. G. Haldon for biochemical work.

THE EFFECT OF A SINGLE-DOSE PARENTERAL ANTIBIOTIC IN THE PREVENTION OF WOUND INFECTION

A CONTROLLED TRIAL

By A. V. POLLOCK and D. S. TINDAL
SCARBOROUGH HOSPITAL, YORKSHIRE

SUMMARY

In a series of 349 operations a single dose of 500 mg. of ampicillin was given immediately preoperatively to 164 patients selected at random. There was no significant reduction in the wound-infection rate in cases given ampicillin compared with the controls.

THE incidence of postoperative infections in sutured surgical wounds has concerned us for some years (Jackson, Pollock, and Tindal, 1971a, b). We have shown in a series of 921 operations (Jackson and others, 1971a) that the most important determinant of wound infection is the nature of the operation performed. The incidence of infection in clean wounds was 4·4 per cent, in potentially contaminated wounds (largely operations on hollow muscular organs) 14·9 per cent, and in actually contaminated wounds 43·1 per cent. These differences were significant when subjected to χ^2 analysis. Similar results have been reported by other authors (e.g., Jepsen, Larsen, and Thomsen, 1969). In our series a plastic adhesive drape applied before skin incision had no effect in reducing the rate of wound infection.

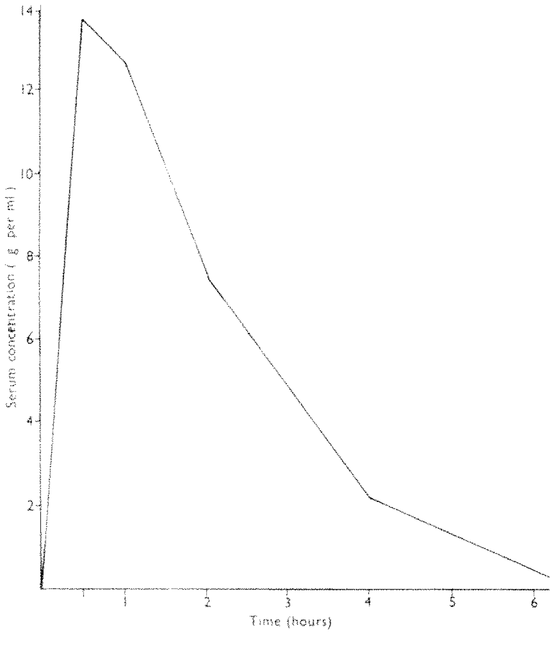

FIG. 1.—Serum concentration following intramuscular injection of ampicillin, 500 mg. (*By courtesy of Beecham Research Laboratories.*) Dr. E. A. P. Croydon of Beecham Research Laboratories has kindly sent us figures for serum concentration after intravenous injection of ampicillin, 250 mg. These show a higher level during the first hour, and thereafter a decline corresponding to the graph after intramuscular injection.

In a second trial (Jackson and others, 1971b) 704 wounds were studied and random cases were sprayed with a bacitracin–polymyxin–neomycin spray. We found that this spray produced no statistically significant improvement in the wound-infection rate.

We then turned our attention to the possibility of reducing wound infections by the prophylactic use of a single parenteral dose of an antibiotic. Our purpose was to flood the tissues with blood containing a high concentration of the antibiotic during the time of possible contamination of the wound (*Fig.* 1). We chose to use ampicillin (500 mg.) as this is a broad-spectrum antibiotic which can easily and safely be injected intravenously by the anaesthetist at the time of induction of anaesthesia.

The use or non-use of the antibiotic was decided by the spin of a coin. All patients were observed for a minimum of a month and wound infections were recorded by one of us, without knowing whether ampicillin had been used or not. We have defined a wound infection as the discharge of pus from the wound and have divided the cases into major and minor wound infections based on the presence or absence of constitutional disturbance, particularly pyrexia, and delay in discharge from hospital.

Each patient was asked about penicillin sensitivity and no one was included in the survey who gave such a history. No patient was excluded on the grounds that antibiotics were already being used, nor was the postoperative use of antibiotics in any way altered. Children under the age of 10 years were excluded.

RESULTS

We stopped the present investigation after 349 operations as we found that the results were not encouraging. In this group there were 172 clean, 155 potentially contaminated, and 22 contaminated operations. In 83 of the clean operations ampicillin was used and 3 wound infections occurred (3·6 per cent). Of these, 2 were minor and 1 was major. In the other 89 clean operations no ampicillin was used and there were 4 wound infections, which were all major (3·4 per cent). The difference is not statistically significant ($\chi^2 = 0{\cdot}085$).

Of 155 potentially contaminated operations, 70 were given prophylactic ampicillin and there were 13 wound infections (18·6 per cent), 11 of which were major. Eighty-five patients were not given ampicillin and 14 wound infections occurred (16·5 per cent), 11 of which were major. The difference is not statistically significant ($\chi^2 = 0{\cdot}118$).

Twenty-two contaminated operations were included, and these were equally divided between the two treatment groups. Six patients who had been given ampicillin and 7 who had had no treatment became infected. The difference is not statistically significant ($\chi^2 = 0{\cdot}188$).

DISCUSSION

The majority of postoperative infections in clean stitched wounds arise as a result of endogenous contamination during the period of operation. When, on the other hand, the wound is left open or is drained, ward infections are probably of greater significance (Davidson and Smith, 1969; Jepsen and others, 1969). The contribution of unsterile instruments, surgeons' hands, or airborne infection during operation has been shown to be of very little significance unless the operating-theatre personnel have obvious symptomatic infections (Todd, 1968; Seropian and Reynolds, 1969).

It should be possible to reduce the rate of wound infection by diminishing the contamination of the open wound from the patient's own sources and by increasing his resistance to infection. Studies are in progress on the latter aspect, but in the present survey we have been concerned only with the possibility of lessening the bacterial contamination of the wound by the use of a prophylactic antibiotic.

There are three ways in which antibiotics may be used: the wound may be sprayed or sprinkled with the active substance, it may be irrigated with a solution of the drug, or the antibiotic may be introduced into the blood-stream whence it will be shed into the new wound. The results of all these methods of prevention have been equivocal. Topical application has been shown to be of value in experimental wounds (Hopson, Britt, Sherman, and Ledes, 1968) and in patients with general peritonitis (Noon, Beall, Jordan, Riggs, and de Bakey, 1967). Our own results with an antibiotic spray failed to show a significant improvement in the rate of wound infection (Jackson and others, 1971b).

The alternative method, using a prophylactic parenteral antibiotic, gives equally controversial results. Fekety, Chiff, Sabiston, Seidl, Smith, and Thoburn (1969) failed to show any effect in cardiac surgery using penicillin and methicillin. Altemeier, Culbertson, and Hummell (1968) suggested that the incidence of wound infection with preoperative or prophylactic antibiotics was greater than the infection rate of wounds in patients not treated with them. On the other hand, Polk and Lopez-Mayor (1969) found a significant reduction in the rate of wound infection in patients undergoing gastro-intestinal operations who were given one dose of cephaloridine before and two immediately after operation. Our own results show that a single preoperative dose of ampicillin affords no protection against wound infections. Further work on antibiotic prevention of wound infection is planned.

A MODIFIED TECHNIQUE OF COLOSTOMY

BY L. R. ABEYATUNGE

MAYDAY HOSPITAL, THORNTON HEATH, SURREY

SUMMARY

A modified technique of colostomy is described which avoids the disadvantages of the more widely used technique employing a glass rod and rubber tube. The use of a rubber drain, instead of a glass rod, which is brought out through two small stab incisions allows the immediate fitting of a bag, thus avoiding contamination of the main incision.

MANY techniques of doing a colostomy have been described (Gabriel and Lloyd-Davies, 1935; Cattell, 1942), each one having its own advantages and disadvantages. Obviously, problems arise with the decompression type of colostomy rather than with the diverting colostomy.

For a colostomy to be effective it must (*a*) decompress the bowel of faeces and flatus adequately, (*b*) be a suitable distance away from the main incision, if any, and (*c*) preferably have a disposable colostomy bag fitted immediately in order to avoid contamination of the main wound.

The most widely used method of colostomy employs a glass rod with a rubber tube connected to its ends to anchor the colon to the abdominal wall. The glass rod is usually kept in position for 7 to 10 days before it is removed, and it is therefore impossible to fit a disposable bag snugly around the colostomy opening. A bulky dressing has to be applied which is very uncomfortable to the patient and also inevitably leads to contamination of the main wound, and occasionally there are attendant complications such as wound dehiscence, incisional hernia, etc.

In 1968 Lee described a method in which he used a sturdy rubber tube instead of a glass rod to anchor the loop of colon. The tube was sutured to the skin at its ends. This method is very effective indeed, except in obese patients where the loop of the colon is under tension and pressure necrosis of the loop of the colonic bridge can occur, leading to retraction of the bowel and the spillage of faeces.

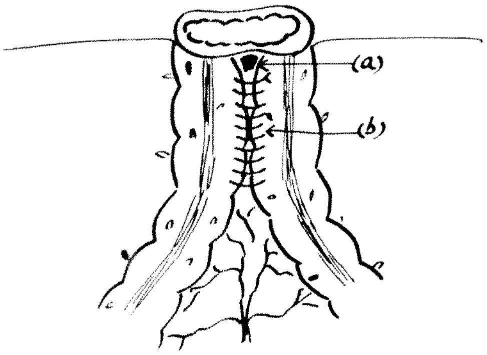

FIG. 3.—a, The site for the rubber tubing through the transverse mesocolon. b, Approximating the taenia coli to form a spur prevents small-bowel inclusion when the enterotome is applied.

The author has found the following modification helpful in overcoming most of the disadvantages of the routine technique.

TECHNIQUE

The loop of colon is brought out of the colostomy incision after separating the omental attachment (in the case of the transverse colon). A 2·5-cm. rubber drain (either a corrugated drain or a Penrose drain) is passed through an avascular area in the mesentery, and is brought out through two small (1·8-cm.) stab incisions on either side of the colostomy incision. This drain traverses a subcutaneous tunnel and is sutured to the stab incisions at either end (*Fig.* 1). The colostomy is opened at the end of the operation. Some surgeons make the incision along the anterior taenia coli, while others make a cruciate incision. Both these methods do not allow a sufficient 'opening-out' of the two stoma, resulting in a wide bridge along which a significant amount of faeces can leak into the distal colon. For this reason the author prefers to make the incision around two-thirds of the circumference of the colon (*Fig.* 2). This allows a more complete 'opening-out' of the stoma, making the bridge narrower (*Fig.* 3). Once this has been done and haemostasis has been achieved there is no real necessity to suture the colon to the skin. With the colostomy thus completed, a disposable colostomy bag can be fitted snugly. The rubber drain is removed in about 7–10 days.

THE LOCAL EFFECTS OF INTRA-ARTERIAL INJECTIONS OF SODIUM TETRADECYL SULPHATE (S.T.D.) 3 PER CENT*

AN EXPERIMENTAL STUDY

By W. A. L. MAC GOWAN, P. D. J. HOLLAND, HYACINTH I. BROWNE, AND DERMOT P. BYRNES
DEPARTMENT OF EXPERIMENTAL SURGERY, ST. LAURENCE'S (RICHMOND) HOSPITAL, DUBLIN, AND DEPARTMENTS OF SURGERY AND PATHOLOGY
ROYAL COLLEGE OF SURGEONS IN IRELAND

SUMMARY

The accidental intra-arterial injection of the commonly used sclerosant sodium tetradecyl sulphate (S.T.D.) 3 per cent during the treatment of varicose veins can affect seriously the blood-supply to the limb, and gangrene may follow.

Intra-arterial injection of S.T.D. into the limb arteries of dogs chemically disintegrates the blood in the slow-moving stream of the capillaries and converts it into a thick sludge which obstructs the circulation locally, resulting in necrosis of the extremity.

THE inadvertent intra-arterial injection of sodium tetradecyl sulphate (S.T.D.) 3 per cent in the treatment of varicose veins can be dangerous. Patients have developed acute ischaemic changes and gangrene of the foot following this accident. For example, a patient aged 20 years developed gangrene of the foot within 2–3 days of injection of S.T.D. into a perforating vein on the medial aspect of the leg. The posterior tibial artery was injected inadvertently, resulting in loss of the forefoot.

An animal investigation was planned to examine the results of injecting the sclerosant S.T.D. into arteries and to determine whether its effect was due to spasm of the artery, to intimal irritation resulting in thrombosis (as in veins), or to denaturing of the blood.

MATERIALS AND METHODS

Greyhound dogs, weighing approximately 25 kg., were used in the experiments. S.T.D. 3 per cent in a sterile aqueous solution containing 2 per cent benzyl alcohol and buffered to *p*H 7·6 was used as a sclerosant (Pharmaceutical Research Limited, Hereford). The effects of 2 per cent benzyl alcohol had already been investigated by Fegan (1967), who found that this substance had no effect when injected intravenously in a similar dosage and situation to the intravenous injection of sodium tetradecyl sulphate. Therefore, it was assumed that the effect of S.T.D. 3 per cent was due to its constituent sodium tetradecyl sulphate, a salt of an alkali metal and a long-chain fatty acid (sodium 1-isobutyl-4-ethyloctyl sulphate).

A total of 18 limbs were examined in 13 dogs; 2·5 ml. of the solution (0·1 ml. per kg. body-weight) were injected into the main femoral artery in the thigh. Arteriograms were performed with 20 ml. of 76 per cent Urografin (Schering) as the contrast medium and using an Elema Schonander cassette changer at a speed of 2 films per second. Arteriograms were carried out immediately after injecting the S.T.D. Further arteriograms were carried out 15 and 30 minutes after the injection of S.T.D. Arteriograms were also performed 1 and 2 weeks after the sclerosant injection. The main arteriographic change noticed was the immediate loss of pad vessels. There was no evidence of narrowing or obstruction in the main lower limb vessels. There was, however, a blurred appearance in the region of the pad (*Fig.* 1). Clinically, the animals who showed loss of pad vessels had limb and paw swelling for up to 2 weeks after the injection.

The animals were killed at 18 hours, 1 week, and 3 weeks after the injection of S.T.D. The complete leg vessels from the site of injection were dissected out with the intact foot pad. Representative areas of the blood-vessels and pad were examined histologically. The most constant histological change was an unusual form of paravascular necrosis of the muscle pad (*Fig.* 2). There was no evidence of any intimal damage or irritation in the vessels, even up to 3 weeks after the injection. This injection, however, did not produce gangrene in the dog's limb. Although the limb became swollen it usually returned to normal in 2 weeks. Even when preliminary compression of the femoral artery for 60 seconds (as suggested by Engler, Freeman, Kanavage, Ogden, and Moretz, 1964) was applied prior to the injection, gangrene was not produced. When the dose of S.T.D. was increased to 4 ml. in one injection, death occurred within 48 hours.

Attempts were made to determine whether the animals could be protected from the local effects of S.T.D. Four dogs were injected intra-arterially with 2·5 ml. S.T.D. followed immediately by 40 mg. of Papaverine HCl solution into the same vessel. The effects were compared with the contralateral limb in which the artery was injected with 2·5 ml. S.T.D. alone. In 2 of the 4 animals there was clinical, histological, and arteriographic evidence that some protection had been achieved.

Lumbar sympathectomy was performed on 2 animals, and on full recovery 2 weeks later 2 ml. S.T.D. were injected into the femoral artery, but again there was limb swelling and obvious pain. Loss of pad vessels was demonstrated on an arteriogram in 1 of the animals. Both animals had recovered fully by 2 weeks. It was not possible to draw any conclusions regarding the value of sympathectomy from these experiments.

---

* Based on a communication to the Surgical Research Society at Hammersmith Hospital, London, in January, 1971.

The results suggested that the lesions were due to occlusion of the smaller vessels of the pad. A further investigation was planned to investigate the effect in small vessels by an experiment *in vivo* using a rabbit's ear chamber. Lop rabbits, weighing approximately 3 kg., on whom a Perspex ear chamber had been inserted 3 months previously were used. The central auricular artery at the base of the ear was injected with 0·3 ml. S.T.D. (based on a dose of 0·1 ml. per kg. body-weight). The events in the ear chamber were observed using a microscope with an oil-immersion lens at low- and high-power magnifications and were filmed in colour. A large arteriole was visualized in the centre of the field. The S.T.D. was seen to enter this vessel. No spasm was noted either in this arteriole or in the capillaries, but within a few minutes the red cells became distorted and broken and formed a central homogeneous thrombus, which appeared to be an intravascular aggregation of destroyed and fragmented red cells without fibrin

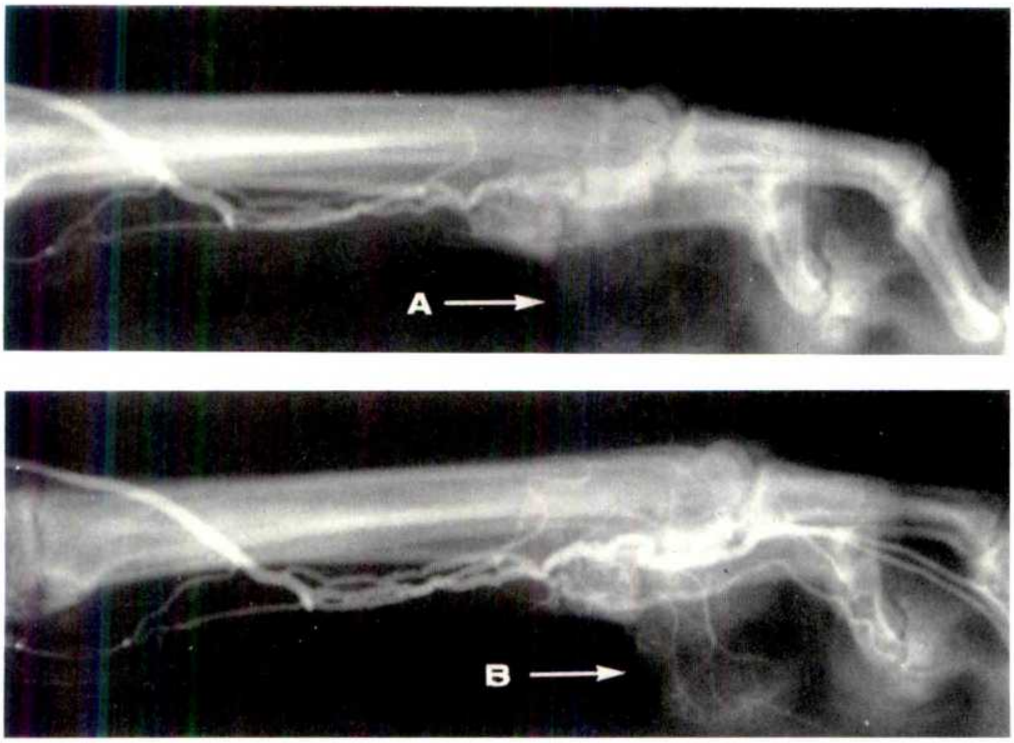

FIG. 1.—Arteriograms of the foot pad of a dog 15 minutes after the injection of 3 ml. S.T.D. Note the blurred appearance of pad A compared with the control B. The major vessels in each case are well filled with contrast medium, with near identical timing following injection.

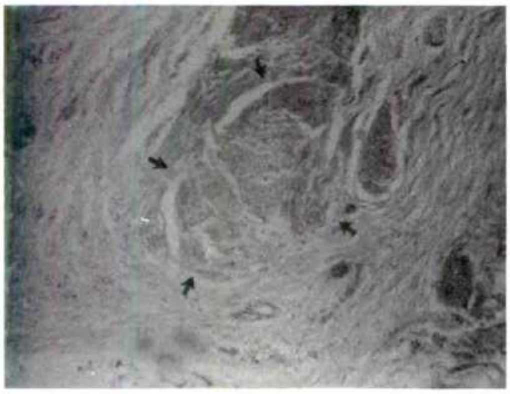

FIG. 2.—Section of the foot pad of a dog 1 week after injection of S.T.D. Necrosis of muscle is visible (arrowed), but there is no change in the vessels.

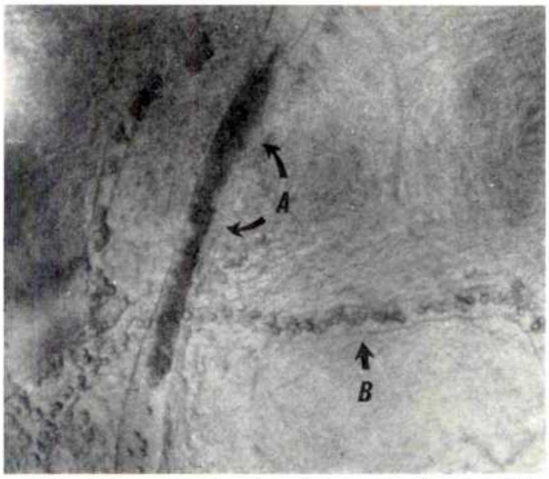

FIG. 3.—Low-power view through the ear chamber of a rabbit during intra-arterial injection of S.T.D. Sludge occupies and occludes the arteriole (A). A normal venule (B) containing blood-cells is seen traversing the field at right-angles.

formation (*Fig.* 3). This thrombus moved slowly down the arteriole into the capillary, where it became impacted. Gradually the whole circulation slowed down with marked stasis in the venules. There was no spasm of the arteriole nor was there any evidence of intimal damage at this stage. An injection of saline moved the sludge up and down the arteriole and capillary. The distal half of the rabbit's ear became blue and cold within an hour of the injection, and subsequently became gangrenous. It was assumed, therefore, that the major effect of the S.T.D. was on the blood-cell mass which it destroyed and converted into an intravascular embolus. It was presumed that secondary thrombosis occurred later owing to stasis and obstruction of the microcirculation and causing gangrene of the ear.

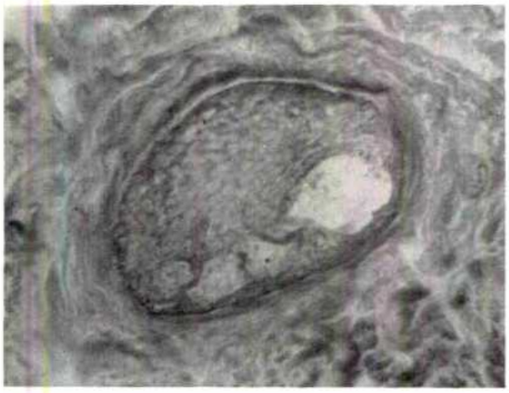

FIG. 4.—Microscopic section of a rabbit's ear 1 hour after an intra-arterial injection of S.T.D. An artery of the ear is blocked by amorphous material or sludge. Note the absence of an inflammatory response in the vessel wall.

Further experiments *in vitro* were performed using S.T.D. and whole normal blood mixed in equal parts. A thick, sticky, homogeneous red lysate was formed which was miscible with water and soluble in fat solvents. All the cellular elements were lysed and fibrin was not formed. On standing for 24 hours the lysate became thicker and more viscid.

The histological details were investigated in 6 New Zealand white rabbits of approximately 3 kg. weight; 0·3 ml. S.T.D. (0·1 ml. per kg.) was injected into the central artery of the rabbit's ear, with a control injection of saline in the opposite ear. If the injection was successful the ear immediately changed in colour and within an hour the distal part of the ear became blue and cold. In 4–5 days gangrenous changes invariably occurred in the distal half of the ear. Two animals were killed, 1 after 1 hour and the other 5 days following injection. Representative histological sections of the ear were made from the site of the injection to the periphery and were stained with haematoxylin and eosin and van Gieson elastin. In the rabbit killed 1 hour after the injection of S.T.D. the main artery and its arterioles were blocked by a yellow amorphous mass of sludge (*Fig.* 4). In the rabbit killed after 5 days the main artery was empty of blood and contained a thin rim of sludge and some proteinaceous material. The smaller branches were blocked completely by the sludge and the surrounding tissues showed coagulation necrosis. The viable tissues outside the affected area showed an acute inflammatory reaction. A section through the main artery proximal to the injection site showed thrombosis without the presence of sludge (*Fig.* 5). There was neither evidence of intimal damage nor thrombosis in the injected vessels distally, even after 5 days, and the perivascular inflammatory reaction that was noted was clearly secondary to the tissue necrosis.

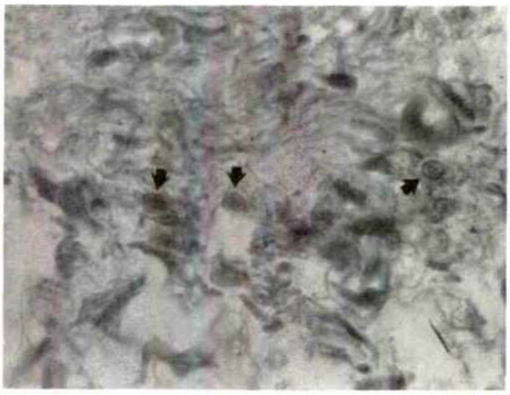

FIG. 5.—Microscopic section of a rabbit's ear 5 days after an intra-arterial injection of S.T.D. This high-power view shows that the small arteries (arrowed) are occluded by sludge. The surrounding collagen shows early necrosis.

DISCUSSION

The results of these experiments indicate that S.T.D., when injected intra-arterially, has little effect on the major vessel and produces no spasm, but is washed into the smaller arteries where it mixes with the blood and denatures it, converting it into a thick lysate or sludge. This sludge or embolus obstructs the microcirculation, causing proximal stagnation, secondary thrombosis, and necrosis. There was no evidence that intimal irritation or damage caused these changes, which appear to be different from the reported effects of S.T.D. on veins, where apparently the intima is denuded immediately with super-added thrombosis (Fegan, 1967).

Many drugs can cause gangrene when injected intra-arterially; besides S.T.D., thiopentone, barbiturate, amphetamine, sodium bromosulphathalein, chlorpromazine, and Ethamolin can all cause similar lesions (Kinmonth and Shepherd, 1959; Engler, Purvis, Kanavage, Ogden, Freeman, and Moretz, 1967). These ischaemic changes are in contrast with the relatively innocuous behaviour of these drugs when injected intravenously. Why the difference? With an intravenous injection, mixing and dilution occur and the material has to pass around the circulation before finally arriving at the distal arterial tree. When injected intra-arterially the irritant material is swept undiluted into the capillaries and arterioles where it exerts its deleterious effects.

How can these effects be prevented? It would seem important to keep to the recommended dosage of 0·5–1 ml. of 3 per cent solution per injection when using S.T.D. for injecting varicose veins, as the effects appear to be dose related. Certainly no more than 8 ml., which is approximately 0·1 ml. per kg. body-weight, should be used at any treatment session. Ethamolin oleate (5 per cent) might perhaps be a more suitable sclerosant, as it appears to cause minimal irritation (Reid and Rothnie, 1968). Special care should be taken when injecting varicose veins near a main artery, particularly in the lower third of the leg where the tibial arteries are relatively superficial and can be entered inadvertently with a needle. Following an intra-arterial injection the patient usually complains immediately of pain in the limb, and within a short time there are obvious colour changes, pallor, and cyanosis. If left untreated the foot can become gangrenous in 3–4 days, with a considerable amount of pain and discomfort to the patient. Heparin should be administered locally and systemically to prevent secondary or spreading thrombosis. Lumbar sympathectomy may help to open up the collateral circulation. The observation that sludge was made to move by forcible injection of saline into the artery of the rabbit's ear suggests that it might be valuable to expose and to cannulate the involved artery in order to dilute and attempt to wash out the sludge with a heparinized saline solution.

Acknowledgements.—We wish to acknowledge the expert assistance of Dr. Sumner Wood, jun., with the experiment which was conducted under his supervision in the Cancer Research Laboratory of the Department of Pathology, The Johns Hopkins Hospital, Baltimore, Maryland. We are grateful to Mr. James Mulvanny, A.I.B.P. (med.), for the photographic illustrations.

GIANT HYDRONEPHROSIS IN A SOLITARY CROSSED ECTOPIC KIDNEY

By A. J. YATES-BELL and D. A. PACKHAM

KING'S COLLEGE HOSPITAL, LONDON

SUMMARY

A case of giant hydronephrosis occurring in a solitary crossed ectopic kidney is presented. This is the seventeenth instance of this renal anomaly, and the first reported in association with a giant hydronephrosis. The diagnosis is discussed, and attention is drawn to the high incidence of genital defects and pathological change associated with solitary ectopic kidneys.

GIANT hydronephrosis has been arbitrarily defined as the presence of more than 1 litre of urine within the collecting system and pelvis of the kidney (Stirling, 1939). A review of the literature by Campbell, Hunsicker, and Marconis (1950) disclosed 100 cases, to which they added a case of their own. Tombari, Power, Harper, and Politano (1968) were able to collect a further 60 cases, and reported the largest hydronephrosis (52 litres) in recent times. However, Glass (1746), a surgeon at Oxford, appears to have documented the most spectacular example, when he described the autopsy findings of a 22-year-old woman, who 'had been remarkable all her life for the preternatural size of her belly'. The circumference of her abdomen was found to be 6 ft. 4 in. (190 cm.), while the distance between the xiphoid cartilage and the os pubis was 4 ft. ½ in. (121 cm.). The autopsy revealed what was clearly a right-sided hydronephrosis, the contents of which were 'found to be not above a pint less than 30 gallons wine measure' (115 litres).

The present case, although not of such extraordinary dimensions, is of interest for the occurrence of a giant hydronephrosis in a solitary crossed ectopic kidney. The subsequent surgical management was complicated further by the posterior rotation of the pelvis.

CASE REPORT

M. F., a 59-year-old man, was admitted with a history of sudden onset of nausea, vomiting, and generalized abdominal pain. He also complained of painless haematuria of 10 days' duration, and thought that his abdominal girth had increased over the past year. A tentative diagnosis of retroperitoneal tumour had been made.

On examination he was found to be pale, sweating, and in severe pain. His temperature was 37·6° C., the pulse-rate was 120 per minute, and the blood-pressure was 140/80 mm. Hg. There was considerable distension of the abdomen by a tense, fluctuant, tender mass. This was central in position, arising out of the pelvis and extending almost to the xiphisternum; it was easily palpable on rectal examination. Bowel-sounds were not audible. There were no obvious abnormalities of the genitalia. Shortly after admission it was evident that the patient was oliguric, catheterization yielding only 100 ml. of blood-stained urine.

Investigations revealed that the haemoglobin was 7·7 g. per cent and the white blood-count was 8700 per c.mm. Examination of the blood-film showed mainly a normochromic anaemia. The blood-urea was 222 mg. per 100 ml., serum sodium 132 mEq. per l., serum potassium 6·2 mEq. per l., and serum bicarbonate 14 mEq. per l. A chest radiograph was normal. A plain radiograph of the abdomen (*Fig.* 1) showed multiple areas of calcification, in particular in the pelvis and medial to the right sacro-iliac joint. An intravenous pyelogram (*Fig.* 2), using 150 ml. of Conray 420, showed opacification of a large mass arising out of the pelvis and reaching up to the level of the second lumbar vertebra.

Following intravenous therapy and resonium enemata the serum potassium level fell to 5·2 mEq. per l., and a cystoscopy was then performed. This revealed that the bladder was indented by an extravesical mass. There was a blood-stained efflux from the left ureteric orifice, while the right ureteric orifice and adjacent ridge were absent. The left ureteric orifice was easily catheterized (*Fig.* 3), and retrograde urography was performed (*Fig.* 4). This showed the left ureter crossing the pelvis to the right side, with a filling defect present in the ureter opposite the right sacro-iliac joint coincidental with the opacity on the plain radiograph. A diagnosis of calculus obstruction of a giant infected hydronephrosis in a solitary crossed ectopic pelvic kidney was made.

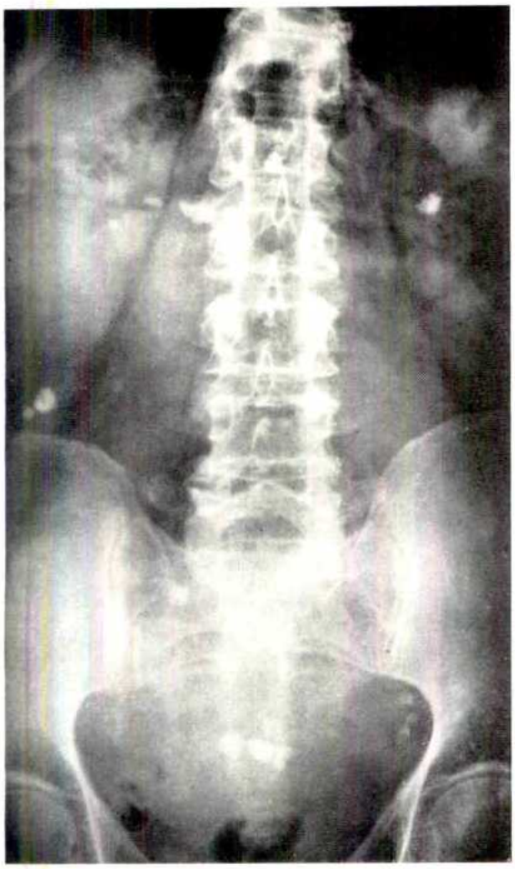

FIG. 1.—Plain radiograph of the abdomen, showing a collection of calculi in the pelvis and a further calculus medial to the right sacro-iliac joint.

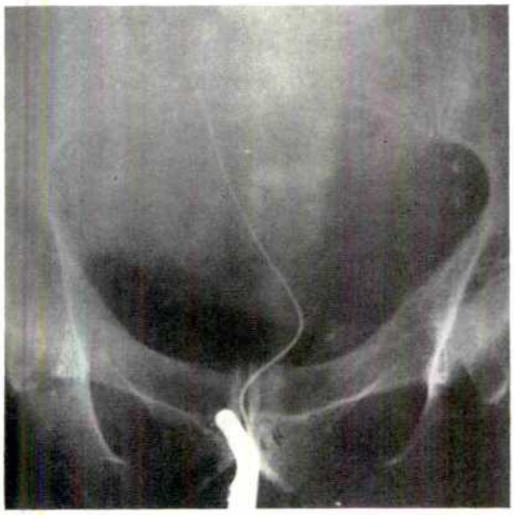

FIG. 3.—Catheter in the left ureter, crossing the pelvis to the right sacro-iliac joint.

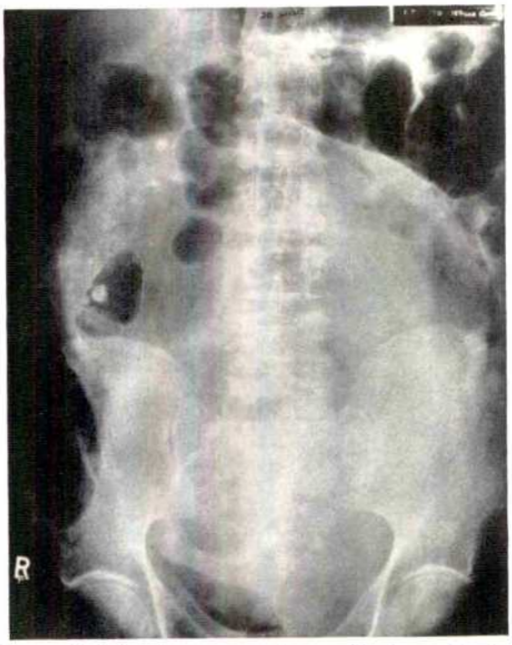

FIG. 2.—High-dose intravenous pyelogram, showing opacification of a large soft-tissue mass, displacing the large bowel.

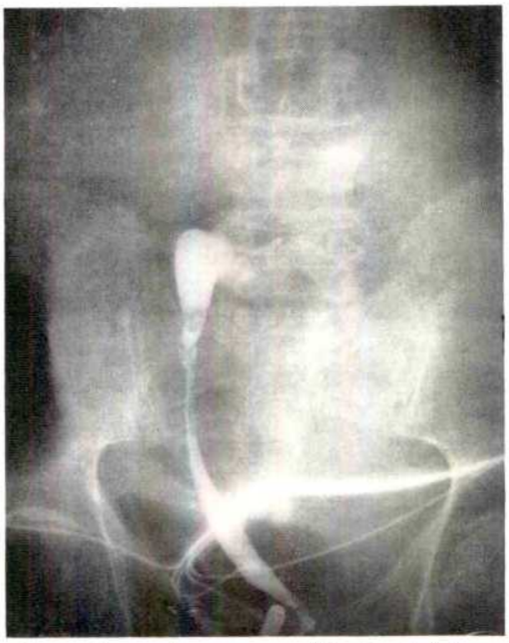

FIG. 4.—Retrograde ureterogram, delineating the left ureter and a filling defect in the pelvi-ureteric junction of the ectopic kidney.

A nephrostomy was performed using a retroperitoneal approach through a low right grid-iron incision, and 4500 ml. of obviously infected urine were drained. Culture yielded a heavy growth of *Escherichia coli*, which was sensitive to ampicillin and cloxacillin, both of which had been administered to the patient preoperatively.

The immediate postoperative course was complicated by a diuretic phase, which required frequent peritoneal dialysis and intravenous fluid replacement over a period of 3 weeks. Six weeks after operation the blood-urea had fallen to 110 mg. per 100 ml., and the creatinine clearance was 9·2 ml. per minute. The patient was discharged for convalescence.

Table I.—DETAILS OF PUBLISHED CASE REPORTS OF CROSSED ECTOPIA OF A SOLITARY KIDNEY

AUTHOR	AGE AND SEX	SIDE OF KIDNEY	NO. OF URETERIC ORIFICES	ABNORMALITIES
Horand (1905)	3½ mth. M.	Left	Two	Patent left ureteric orifice; atrophic left ureter communicating with left vas deferens; absent left seminal vesicle; atrophic right adrenal gland
Lyon-Caen and Marmier (1907)	— —	Left	One, right	—
Day (1924)	32 yr. M.	Left	One, right	Left ectopic testis
Foerster (1934)	— M.	Right	One, left	Undescended testis
Alexander, King, and Fromm (1950)	23 yr. F.	Right	One, left	Anomalies of sacrum, coccyx, and pelvis; hydronephrosis due to vascular band
Blancato (1954)	37 yr. M.	Right	One, left	None
Abeshouse and Bhisitkul (1959)	33 yr. F.	Right	Two	Patent right ureteric orifice; right ureter ending blindly at 4 cm.
Magri (1961)	38 yr. M.	Left	One, right	Absent verumontanum; absent right vas deferens; absent left ejaculatory duct
Purpon (1963)	13 yr. M.	Right	One, left	Pseudohermaphroditism; absent left adrenal gland; short right leg
Irvine and Yaman (1964)	25 yr. F.	Right	One, left	Absent vagina and uterus; atrophic Fallopian tubes; retrocaval ureter
Tabrisky and Bhisitkul (1965)	17 yr. F.	Right	One, left	Absent uterus; vaginal aplasia; anomalous vessels from iliac arteries
Weiss, Maloney, and Beland (1965)	8 mth. F.	Right	One, left	Imperforate anus; anomalies of dorsal spine
Wadskier (1967)	43 yr. M.	Right	One, left	Atrophic left testis and vas deferens; duplication of right thumb; abnormalities of cervical vertebrae
Dworin (1969)	52 yr. M.	Left	One, right	None
Nummi (1969)	41 yr. M.	Right	Two	Patent right ureteric orifice; right ureter ending blindly at iliac crest; left common iliac arterial blood-supply to kidney
Tanenbaum, Silverman, and Weinberg (1970)	7 yr. M.	Right	Two	Patent right ureteric orifice; atrophic right ureter
Present case	59 yr. M.	Right	One, left	Giant hydronephrosis; renal calculi; right common iliac arterial blood-supply to kidney

Two weeks later he was readmitted and laparotomy was performed. This revealed a grossly hydronephrotic solitary kidney lying across the sacrum and extending into the true pelvis and both iliac fossae. The main blood-supply was seen to be derived from the right common iliac artery, and it was clear that the pelvis and ureter lay posterior to the main hydronephrotic mass. Rather than mobilize the kidney and risk compromising the blood-supply, an incision was made in the cortex of the lower pole, and five calculi in the lower calix and a calculus impacted in the pelvi-ureteric junction were removed. The kidney was drained with a nephrostomy tube.

Ten days after operation a nephrostogram demonstrated the greatly distended caliceal system of the kidney, from which a single unobstructed ureter drained into the left side of the bladder. The patient re-established normal micturition following removal of the nephrostomy tube, and at the time of his discharge from hospital, 6 weeks after operation, the urine culture was sterile, the haemoglobin was 10·3 g. per 100 ml., the blood-urea 78 mg. per 100 ml., and the creatinine clearance 11 ml. per minute.

DISCUSSION

Ectopic kidneys have been described in positions from the thorax to the true pelvis. The ectopia may be ipsilateral or contralateral in position. In crossed renal ectopia the anomalous kidney is transposed to the contralateral side with its related ureter crossing the midline to enter the bladder on the correct side. The anomaly is well documented, Abeshouse (1947) in particular reporting a series of 341 cases, and it has been estimated as occurring about once in 2000 autopsies, although Campbell (1970) observed only 4 examples in 51,880 cases. Fusion with the normally situated kidney may or may not occur, non-fusion accounting for 10 per cent of all cases of crossed renal ectopia (Malament and Majnarich, 1960). The varieties of crossed renal ectopia have been classified by Amesur and Singh (1963), crossed fused ectopia with the ectopic kidney in the inferior position being the most common type. Varying degrees of malrotation may occur, with the pelvis tending to overlie the calices, which in turn may point medially.

Crossed ectopia of a solitary kidney is an extremely rare congenital abnormality. The published case reports have been reviewed by Purpon (1963), Dworin (1969), and Tanenbaum, Silverman, and Weinberg (1970). *Table I* represents a continuation of the series with the inclusion of a further example which was reported by Abeshouse and Bhisitkul (1959). The series, including the present report, totals 17 cases, of which 11 are male.

Diagnosis.—The role of radiology, cystoscopy, and ureteric catheterization has been emphasized by Magri (1961). Characteristically, the absence of the ureteric orifice and adjacent trigone on the side of the pyelographically demonstrable kidney is diagnostic of crossed ectopia of a solitary kidney. The position of the anomalous solitary kidney is variable. Although the majority are lumbar in position, Abeshouse and Bhisitkul (1959) and Tabrisky and Bhisitkul (1965) have described examples in which the ectopic kidney was within the confines of the pelvis. In the present case the kidney was probably sacral in position, although the hydronephrosis extended into the pelvis; a further unusual feature was the posterior situation of the pelvis.

Although the ipsilateral ureter is usually absent, it should be observed that there are 4 examples (*Table I*) in which there was a patent ureteric orifice on the same side as the ectopic kidney. In each case the ureter was atrophic and ended blindly, reaching the iliac crest in 1 instance (Nummi, 1969). Clearly, bilateral retrograde urography is indicated in these circumstances in order to clarify the diagnosis.

The recognition of congenital abnormalities of the genital tract may aid or substantiate the diagnosis. The association between anomalies of this system and the probable congenital absence of one kidney is well established, and is reflected in a high incidence of genital abnormalities in conjunction with solitary crossed renal ectopia. Genital defects were present in 6 males and 2 females (*Table I*). Similar findings have been described with the solitary pelvic kidney. Burwell and Kent (1959) reported that 76·9 per cent of females with a solitary pelvic kidney had genital abnormalities with a high incidence of vaginal atresia, while 22·9 per cent of males had associated defects.

Associated Pathology.—Although congenital absence of one kidney is compatible with a normal life-span, the solitary kidney appears to be more prone to disease. Fortune (1927), in an analysis of 422 autopsy cases with solitary kidneys, showed that 22·6 per cent had pathological change of the kidney against the general autopsy average of 15 per cent with renal disease. Campbell (1970) also observed a definitely higher incidence of disease. Furthermore, there is a higher incidence of pathology in the ectopic kidney than in the normally situated organ. In an analysis of 86 cases of solitary ectopic pelvic kidney, Burwell and Kent (1959) disclosed an incidence of 31·4 per cent with pathological change, of which hydronephrosis was a common complication. Abeshouse (1947) found associated renal pathology in 204 of 337 cases of crossed renal ectopia, while Abeshouse and Bhisitkul (1959), in a series of 55 cases of crossed renal ectopia, discovered an associated lesion in 30 (55 per cent). The occurrence of 3 examples of giant hydronephrosis arising in crossed renal ectopia without fusion (Malament and Majnarich, 1960; Pathak, 1965; Hurley, Clery, and Kelly, 1969) is of particular interest in relation to the present case. In each case the crossed ectopia involved the left kidney, which occupied the usual inferior position relative to the right kidney, and stenosis or stricture of the pelvi-ureteric junction was evident as the cause of the hydronephrosis. The present case clearly resembled in position and extent the line drawing of the giant hydronephrosis reported by Hurley and others (1969), except for the higher and posterior situation of the pelvi-ureteric junction in the present example. In addition, a nephrostogram demonstrated an unobstructed ureter, and the hydronephrosis must be attributed to long-standing defective drainage, presenting only when one of the calculi became impacted in the pelvi-ureteric junction.

INHIBITION OF THE GROWTH OF TUMOUR CELLS IN CULTURE BY NOXYTIOLIN

By C. W. JAMIESON

SURGICAL UNIT, ST. MARY'S HOSPITAL, LONDON

SUMMARY

The effect of noxytiolin on the viability of human tumour cells (HeLa) in monolayer culture was determined by vital staining, impairment of plating efficiency, and measurement of concentrations causing inhibition of growth. Concentrations of more than 0·0025 per cent cause significant inhibition of growth. This is much lower than its bacteriostatic concentration, suggesting that its bacteriostatic effect is non-specific.

NOXYTIOLIN (Noxyflex) is a simple compound of low toxicity on systemic administration which has been found to have a wide bacteriostatic effect *in vitro* and some antifungal and protozoal activity (Block, 1967; Horsfield, 1967; Ross, 1967). Its fate *in vivo* is not known nor is its method of action, but it is possible that it acts simply by release of formaldehyde. It has been claimed to be of value in reducing the mortality of faecal peritonitis when instilled into the peritoneum (Browne and Stoller, 1970), and its use as a local adjuvant in the treatment of patients with vesical carcinoma by supervoltage appears, from a controlled trial, to improve prognosis (Garrett, 1969). This study was undertaken to determine the effect of noxytiolin on the viability of human tumour cells in monolayer culture, as there are no existing data of this type to support the claim that noxytiolin has specificity of antibacterial activity.

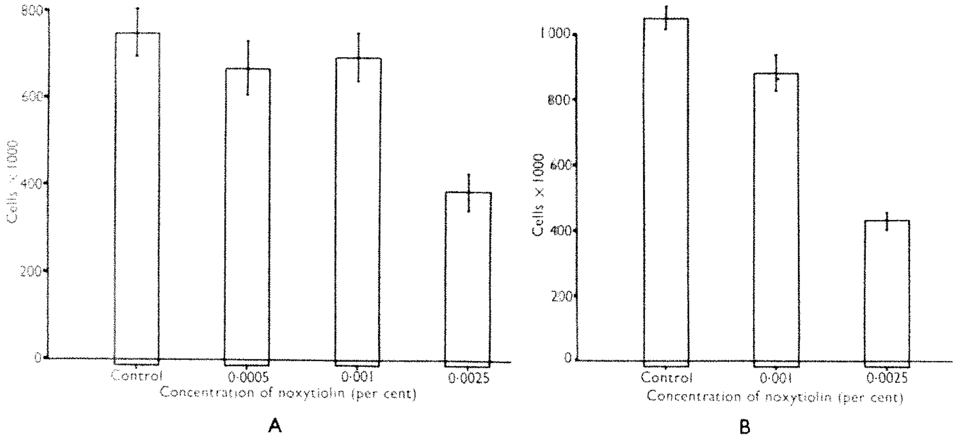

FIG. 1.—Number of cells recovered from groups of ten cultures seeded with 10×10^4 HeLa cells in the presence of varying concentrations of noxytiolin after 48 hours' incubation (mean ± S.E.). Addition of 0·0025 per cent noxytiolin produced significant inhibition of growth.

MATERIALS AND METHODS

The drug was obtained in its pure form and was stored at 5° C. Fresh solutions in Parker's medium 199 were made for each experiment and were sterilized by filtration. The cells used were HeLa (Flow Laboratories) adapted to growth in serial monolayer culture in medium 199 supplemented with 15 per cent foetal calf serum, L-glutamine, penicillin, and streptomycin. The cells were maintained at 37° C. in an atmosphere of air and 5 per cent CO$_2$. In these conditions they have a mean plating efficiency of 75 per cent.

In assessing viability by vital staining, freshly harvested cells were suspended in medium containing varying concentrations of noxytiolin for 4 hours at 37° C. The cells were centrifuged gently and resuspended in equal volumes of medium and 1 per cent trypan blue. After 20 minutes and 4 hours a differential count of the stained and unstained cells was made. In assessing impaired plating efficiency, cells were harvested and several groups of ten cultures were seeded, containing 10×10^4 cells in 4 ml. of medium. Each group contained a different concentration of noxytiolin and one group in each experiment contained no noxytiolin. Hourly observations of the flasks were made for evidence of sheeting of the cells in monolayer culture. In order to assess the growth of the cells, each group was initially fed with normal medium, but after 24 hours, when the cells had entered their exponential growth phase, they were re-fed with medium containing varying concentrations of noxytiolin. Forty-eight hours later the cells were harvested and the number present in each flask was determined using a Model B Coulter counter. Variations in the numbers recovered from each group of flasks reflect variations in growth rate. Control studies were made on the medium containing noxytiolin to ensure that the presence of the drug did not interfere with the counts obtained.

RESULTS

In three experiments exposure for 4 hours to 2 per cent noxytiolin produced significant reduction of viability when measured with trypan blue (viability 44 per cent; control 83 per cent). Exposure to 1 per cent noxytiolin for this period produced no significant decrease in viability.

In four separate experiments, each consisting of four groups of ten cultures, the addition of 0·075 per cent noxytiolin completely prevented sheeting of the cells in monolayer culture.

Seven experiments were performed to measure the growth of HeLa cells in the presence of noxytiolin. Each experiment consisted of five groups of ten cultures containing either no noxytiolin or increasing concentrations of the drug. The results of the two experiments involving critical dose levels are indicated in *Fig.* 1. It can be seen that culture in 0·001 per cent noxytiolin did not significantly affect the growth of HeLa cells, but 0·0025 per cent noxytiolin produced significant inhibition. Greater concentrations produced total inhibition of cell growth.

DISCUSSION

Vital staining is an inaccurate index of cytotoxicity, and the method of assessing cell growth in culture used in this investigation gives an accurate and reproducible index in well-established cell lines such as HeLa (Jamieson, Russin, Benes, DeWitt, and Wallace, 1969). The concentration of noxytiolin producing significant inhibition (0·0025 per cent) is much lower than the effective bacteriostatic concentration of the drug. This study does not, therefore, suggest that this compound has a specific antibacterial effect *in vitro*.

The action and fate of noxytiolin *in vivo* are still unknown but it has been used as a local instillate, in which situation its effects may well be similar to those exhibited *in vitro*. In one series it appeared to offer increased survival when used as a local instillate in cases of advanced bladder tumours, and it is remarkably free of toxic effects (Garrett, 1969, 1970). As it inhibits the growth of tumour cells at very low concentrations it might have a possible value as a local chemotherapeutic agent. It is suggested that this possibility deserves investigation.

Acknowledgements.—The author wishes to thank Mrs. Sheila Siggins for technical assistance and Geistlich Ltd. for supplies of noxytiolin and financial assistance in this investigation.

PERIANAL GAS-PRODUCING INFECTION OF NON-CLOSTRIDIAL ORIGIN

By TERENCE BRIGHTMORE

WESTMINSTER HOSPITAL, LONDON

SUMMARY

Five cases of perianal infection caused by non-clostridial gas-producing organisms are reported. Four were males in their sixth decade, 2 of whom were diabetics, and the fifth was a female in her third decade. Two cases died, and the severity of these infections is emphasized. The diagnosis and treatment of non-clostridial gas-producing infections are discussed.

Perianal infection associated with subcutaneous gas is an uncommon alarming condition which immediately raises the possibility of clostridial infection. The purpose of this paper is to draw attention to non-clostridial gas-producing infections so that an early diagnosis may be made, as the treatment often differs from that of clostridial infections which they may closely resemble. Radical surgery may not be warranted, penicillin may not be the antibiotic of choice, gas-gangrene antiserum is contra-indicated, and hyperbaric oxygen is of equivocal value.

CASE REPORTS

Case 1.—A 51-year-old white male was admitted to St. Thomas's Hospital in January, 1969, with a left ischiorectal abscess, symptoms of which had been developing over 10 days. He had had urinary retention for 1 day prior to admission. During the previous 23 years he had suffered frequent attacks of perianal suppuration. Diabetes, which had been diagnosed in 1959, was well controlled with chlorpropamide, and there were no neurological or vascular complications. His course since 1959 had been punctuated with abscesses of the axillae and buttocks, pus from which had grown penicillin-resistant *Staphylococcus aureus*. There was no other past or family history of relevance.

Under general anaesthesia the ischiorectal abscess was drained. A film of pus revealed pus cells, Gram-negative rods, and Gram-positive cocci. Cultures subsequently grew *Escherichia coli*, *Klebsiella aerogenes*, and proteus, all of which were sensitive to ampicillin (*Table I*).

On the third postoperative day the patient was confused, his temperature was 39·4° C., and the leucocyte count 54,000 (neutrophils 85 per cent). His left upper thigh was painful, hot, red, and swollen. Insulin was then given, although his diabetes had been stable and even in the later stage of his illness was fairly well controlled.

Following the commencement of ampicillin the patient's temperature fell, but his condition deteriorated and by the fifth postoperative day he was jaundiced. The left lower limb was now more painful, oedema and cellulitis had extended in the thigh and leg, and a bulla containing black fluid had developed over the medial malleolus. Subcutaneous emphysema was present in the buttock, thigh, and upper leg, and by the next day it had spread to involve most of the limb. Two bullae were now present on the medial aspect of the calf (*Figs.* 1, 2). Clostridial infection

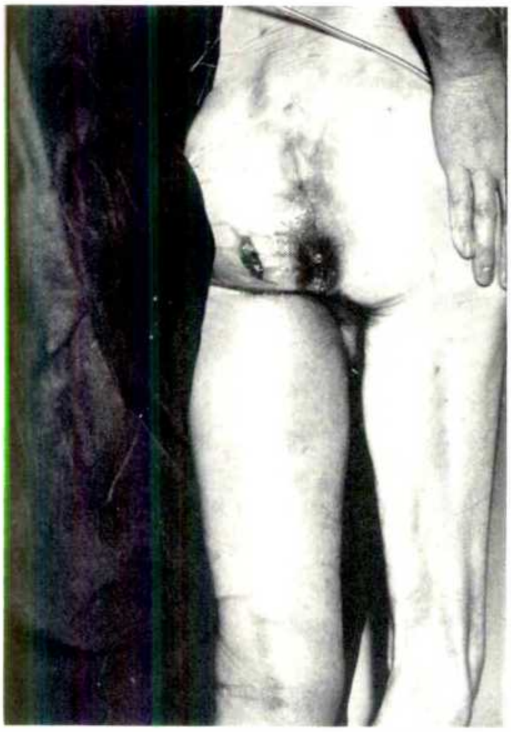

FIG. 1.—*Case* 1. The ischiorectal abscess wound and the swollen left thigh.

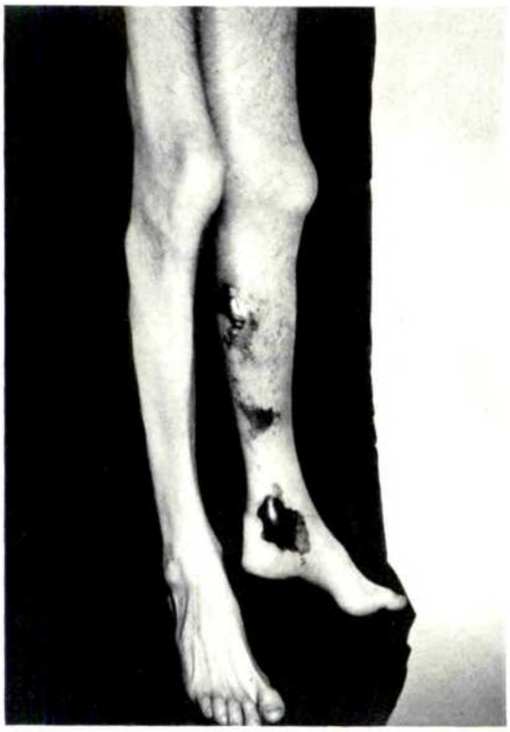

FIG. 2.—*Case* 1. The bullae which were filled with black fluid.

Table I.—THE BACTERIOLOGICAL DATA

5	Right pelvirectal abscess—pus	+	−	−	−	*E. coli* *C. perfringens*
	Right pelvirectal and left ischiorectal abscess—pus	+	+	+	−	*E. coli* *Ps. pyocyaneus* Anaerobic streptococci
	Left groin—pus	+	+	−	−	*Ps. pyocyaneus*
	Loin abscesses—pus	+	+	−	−	*E. coli* *Ps. pyocyaneus*

was suspected, and under general anaesthesia, multiple long incisions were made in the thigh and leg, extending to the deep fascia and exposing grey muscles. Copious amounts of serosanguineous fluid were drained from the oedematous crepitant tissues, and this fluid together with fluid from the bullae and specimens of subcutaneous tissue were sent for bacteriological examination (*Table I*). No Gram-positive rods were seen in the smear, and it was therefore assumed that the infection was non-clostridial. Septicaemic shock was treated with blood, plasma, dextrose, and saline, and benzyl penicillin was added to the ampicillin.

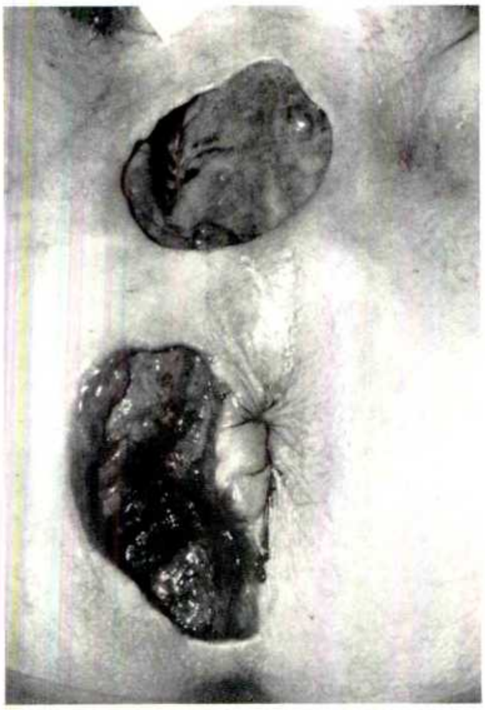

FIG. 3.—*Case* 2. A bridge of skin crosses the perineal wound which anteriorly is very undermined.

The patient lapsed into coma and required intubation. Lumbar puncture was normal. He then rapidly deteriorated: the hepatocellular jaundice deepened, oedema, cellulitis, and crepitus extended to the left flank, and the left lower limb became gangrenous. Four days after his second operation this limb was disarticulated through the hip-joint. There were extensive arterial and venous thromboses in the limb. Postoperatively, a large amount of serosanguineous fluid oozed from the stump, and the patient died the following day.

Post-mortem examination demonstrated a large left ischiorectal abscess, which was excavating behind the ischium but was without communication with the rectum. The amputation wound was infected and the gluteal muscles and surrounding tissues were necrosed.

Case 2.—A 57-year-old white male presented in January, 1968, with a right ischiorectal abscess, symptoms of which had been developing for 2 weeks. Diabetes which had been diagnosed 1 month previously was stable on 10 units of soluble insulin twice daily, and there were no neurological or vascular complications. There was no other personal or family history of relevance.

On examination, cellulitis extended from the right perianal region to the base of the scrotum. Subcutaneous emphysema was present in this area and extended to the right inguinal region. Under general anaesthesia the abscess was laid widely open, and it proved to be a pelvirectal abscess with a fistula into the right lateral wall of the rectum. No Gram-positive rods were seen in pus from the abscess, which subsequently grew coliform organisms and streptococci, both of which were sensitive to ampicillin (*Table I*).

Following transfer to St. Mark's Hospital, the patient's temperature was 40° C., leucocyte count 9100 (neutrophils 61 per cent), and haemoglobin 7·1 g. per cent. The subcutaneous emphysema had extended to the right upper thigh, right iliac fossa and flank, but was not accompanied by oedema or cellulitis in these sites. A large perineal wound extended upwards above the levator ani, posteriorly behind the rectum, and anteriorly under a skin bridge to the base of the scrotum, where the skin was much undermined (*Figs.* 3, 4). The condition of the patient improved with blood transfusion, intravenous fluids, and ampicillin. Six days later sigmoidoscopy under general anaesthesia disclosed the defect in the right lateral wall of the rectum to be about 2·5 cm. in diameter. A sigmoid-loop colostomy was fashioned. Three days after this procedure, chlorpropamide was substituted for insulin, as at no time during the period of admission was the diabetes out of control. The subcutaneous emphysema had by now disappeared. Three weeks later the rectal defect was repaired with catgut sutures, and the perineal wound was laid widely open as it was tending to pocket. The patient was discharged 7 weeks after admission with the wound clean and shallow except for the pararectal extension which was about 8 cm. deep.

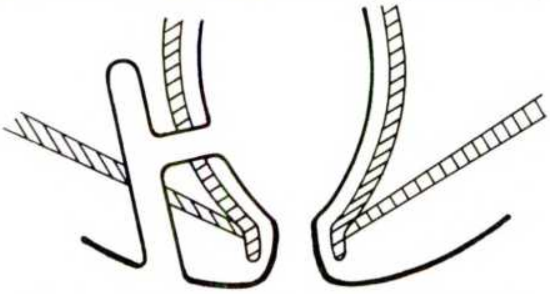

FIG. 4.—*Case* 2. Diagram showing the disposition of the pelvirectal abscess and the fistula into the right lateral wall of the rectum.

Ten months later, i.e., 1 year after presentation, the wound had healed. The colostomy was then closed, and his further course has been uneventful.

Case 3.—A 57-year-old white male presented in June, 1969, with a large anterior perianal abscess, symptoms of which had been present for 2 days. His previous medical history included two myocardial infarctions and a minor stroke. He was taking digoxin, frusemide, Dindevan, and Atromid S. There was no other relevant past or family history.

On examination, the patient's temperature was 38·8° C., and the anterior perineum, including the base of the scrotum, was inflamed. His haemoglobin was 13·5 g. per cent and the prothrombin time was 40 seconds. The abscess was explored under general anaesthesia with penicillin cover. Subcutaneous emphysema was palpated beneath the inflamed area. The abscess was laid widely open, and although the urethra appeared intact there was a large area of perineal necrosis, which was excised (*Fig.* 5). Pus from the abscess contained pus cells, Gram-negative rods, and Gram-positive cocci. It subsequently grew *E. coli* and an anaerobic streptococcus, both of which were sensitive to ampicillin (*Table I*). Because of the extensive tissue necrosis associated with the subcutaneous emphysema the clinical diagnosis was gas gangrene, despite the absence of Gram-positive rods. The patient was immediately transferred to Westminster Hospital where he received 2 hours of hyperbaric oxygen at a pressure of 2 atmospheres.

The abscess cavity bled excessively and the patient's haemoglobin fell to 9 g. per cent. Dindevan was temporarily reversed with Konakion. Blood, plasma, saline, and massive doses of penicillin and ampicillin were given to combat shock. Within a few hours he had recovered sufficiently to tolerate a further 2 hours of hyperbaric oxygen. The following day there was still subcutaneous emphysema of the cellulitic scrotum (*Fig.* 6), but this disappeared over the next 3 days. He rapidly improved, but his further course was complicated by a minor stroke which caused a transient left hemiparesis. At his own request he was discharged 2 weeks after admission and he returned to South Africa where he has been lost to follow-up.

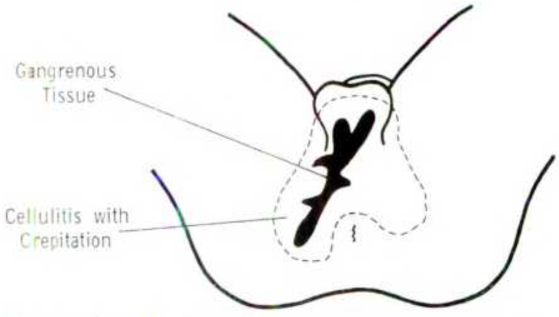

FIG. 5.—*Case* 3. Diagram of the areas of gangrene and cellulitis.

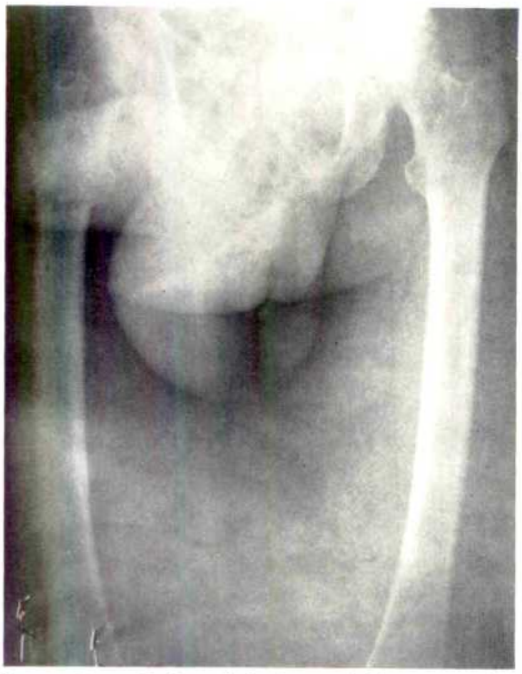

FIG. 7.—*Case* 4. Radiograph showing gas in the scrotum and in the grossly oedematous penis.

Case 4.—A 52-year-old white male was admitted to hospital in November, 1968, with a 1-week history of perianal pain which had become progressively more severe. Three weeks prior to admission he had had an acute anal fissure. There was no other personal or family history of relevance.

On examination, the patient's temperature was 38·8° C., and there were oedema and cellulitis of the perineum and perianal region. He was given intramuscular penicillin, but within 18 hours, oedema and cellulitis had extended to the scrotum. The penis was grossly swollen, with ecchymoses and vesicles, and crepitus was palpated in the shaft. No pus cells or Gram-positive rods were seen in the offensive, amber-coloured fluid which was aspirated from the penile vesicles, but coliform organisms and an anaerobic streptococcus were later grown (*Table I*). Ampicillin and kanamycin were given in addition to the penicillin. The presumptive diagnosis was gas gangrene and the patient was transferred to Whipps Cross Hospital.

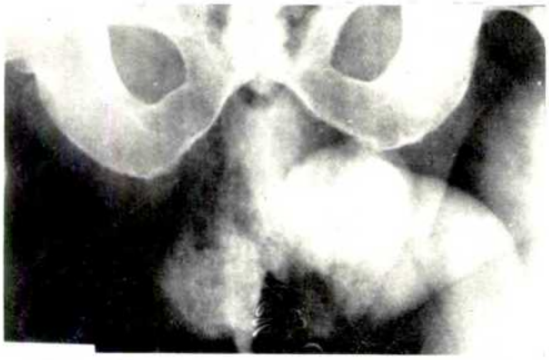

FIG. 6.—*Case* 3. Radiograph depicting gas in the scrotum.

On admission, his leucocyte count was 9000 (neutrophils 64 per cent) and the haemoglobin was 14·4 g. per cent. Oedema, cellulitis, and crepitus were present in the perineum, scrotum, and penis (*Fig.* 7). On the dorsum of the shaft of the penis there was a pregangrenous area of skin. The suprapubic region was tender, inflamed, and indurated, but crepitus was not elicited. The patient improved during the day of admission following the administration of cephaloridine and two treatments of hyperbaric oxygen. On the next day he received one treatment with hyperbaric oxygen, and following this, incisions were made under general anaesthesia in the gluteal regions, the perineum, and the penis to evacuate gas and watery pus, which subsequently grew coliform organisms, bacteroides, and an anaerobic streptococcus (*Table I*). Although there had been no difficulty in micturition, a suprapubic catheter was inserted as a precautionary measure. The patient received hyperbaric oxygen on the 4 subsequent days, during which time his general condition improved, although abscesses had now formed in both loins. On the fifth day after admission both loin abscesses were drained, the suprapubic wound was laid more widely open, and necrotic skin was removed from the dorsum of the shaft of the penis. Hyperbaric oxygen and antibiotics were stopped after 3 more days of treatment, but within 2 days the penis became infected and hyperbaric oxygen was given daily for the following 9 days. The suprapubic catheter was then removed. The glans button-holed through the skin defect in the dorsum of the penis, but this rapidly epithelized.

Nine weeks after presentation all wounds had healed and the patient was discharged home. His further course has been uneventful.

Case 5.—A 21-year-old white female was admitted to hospital in August, 1970, with a right ischiorectal abscess, symptoms of which had been present for 2 weeks and which had discharged spontaneously 1 week prior to admission. Apart from a doubtful allergy to penicillin there was no past or family history of relevance.

On examination, the patient's temperature was 38·8° C., the leucocyte count was 21,000 (neutrophils 89 per cent), and haemoglobin was 12·5 g. per cent. The perineum was inflamed, and the right ischiorectal abscess was discharging thick pus. No Gram-positive rods were seen in the pus, which later grew *E. coli* and *Clostridium perfringens* (*Table I*). The patient was given Septrin, but 3 days later abscesses appeared in the left ischiorectal fossa, the left groin, and the lower abdominal wall. Cellulitis and oedema, which had been limited to the gluteal regions and the perineum, had now spread to the lower abdomen, the left groin, and both upper thighs. Crepitus was present in these inflamed oedematous areas (*Fig.* 8). Clostridial infection was suspected and polyvalent gas-gangrene antiserum administered, but this provoked a widespread urticarial reaction.

Under general anaesthesia both ischiorectal fossae were laid widely open, and on the right side the abscess proved to be pelvirectal. No Gram-positive rods were seen in the thick pus from these abscesses, and *E. coli*, *Pseudomonas pyocyaneus*, and an anaerobic streptococcus were later grown (*Table I*). An incision in the left inguinal region allowed drainage of thick pus and gas from this region and also from the lower abdominal wall. No Gram-positive rods were seen in the pus from this area and the only organism which was cultured was *Ps. pyocyaneus* (*Table I*). Despite intensive treatment, including blood transfusion, cephaloridine, and tetracycline, the patient's condition deteriorated, and 2 days after the drainage procedures she was transferred to Whipps Cross Hospital.

On admission, the patient was critically ill with a temperature of 39·7° C. and a leucocyte count of 25,600 (neutrophils 84 per cent). Hyperbaric oxygen was given on the day of admission and on the 4 succeeding days. She continued to deteriorate, and on the fifth day, abscesses of both loins were drained under general anaesthesia. The abscess in the left loin extended inferiorly to the left iliac fossa, superiorly under the diaphragm, posteriorly to the vertebral bodies, and anteriorly to within 5 cm. of the midline, and sloughing in this area resulted in a large defect. No Gram-positive rods were seen in the pus from these abscesses and subsequent growth revealed *E. coli* and *Ps. pyocyaneus* (*Table I*). Hyperbaric oxygen was given over the next 3 days and she then gradually improved. One month after admission to Whipps Cross Hospital all wounds were clean and the left loin defect was skin-grafted. However, on the next day the patient's temperature rose to 40·5° C., and 5 days later she died suddenly. Postmortem examination demonstrated an empyema and extensive pulmonary suppuration.

DISCUSSION

The causes of tissue gas may be physical, chemical, or infective. Physical causes include skin penetration and perforation of an air-containing cavity. Chemicals which generate gas on contact with body tissues include hydrogen peroxide, benzine, and certain magnesium compounds. Organisms causing gas-producing infections may be classified as follows:—

1. Clostridial.
2. Non-clostridial.
    - *a.* Aerobic.
        - i. *E. coli* and *K. aerogenes.*
        - ii. Haemolytic streptococcus.
    - *b.* Anaerobic.
        - (i) Streptococcus.
        - (ii) Bacteroides.

1. Clostridial Infections.—Although usually associated with trauma, especially involving lacerated or crushed muscle, clostridial infections of the perianal region may follow anal fistula and perianal or ischiorectal abscesses (Berkow and Tolk, 1923; Campbell, 1929; Thomas, 1946; Sterling, Ong, Klaus, and Goldsmith, 1954; Boskovic, 1962; Ahmed, 1965; Colwill and Maudsley, 1968; Duff, McLean, and MacLean, 1970).

The diagnosis of clostridial infections is essentially clinical, although occasionally there may be difficulty in making an early diagnosis as the distinguishing features (*Table II*) may not be present in the earlier stages. MacLennan (1962) emphasizes that the most important features of clostridial myonecrosis are local pain and swelling, severe toxaemia, muscle necrosis, and jaundice with haemoglobinuria and haemoglobinaemia. If there is any doubt about whether a lesion is gas gangrene, then it is almost certainly not.

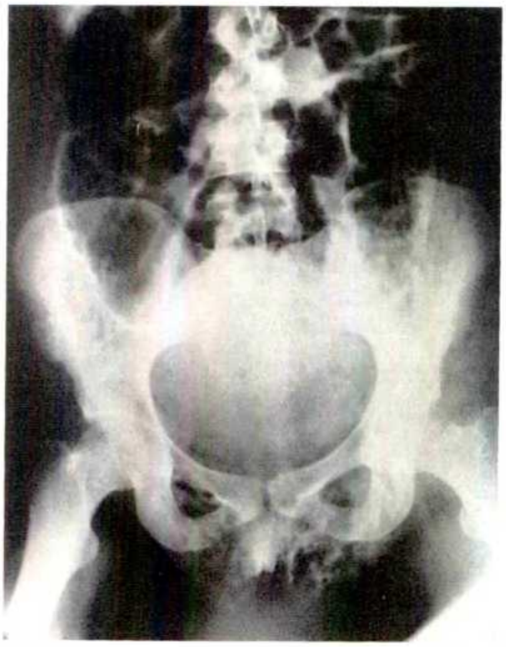

FIG. 8.—*Case* 5. Radiograph in which gas is seen in the perineum and in the lower abdominal wall.

Surgery in clostridial cellulitis is usually limited to the provision of adequate drainage, whereas in myonecrosis all infected tissue must be excised. Penicillin is the antibiotic usually given. It has been claimed that with hyperbaric oxygen treatment, early and radical operations, apart from relieving incisions, are rendered unnecessary (Colwill and Maudsley, 1968), and that gas-gangrene antiserum is of no additional value (Van Zyl, 1967).

2. Non-clostridial Infections.—Chiari (1893) was the first to describe a non-clostridial gas-forming infection. This was due to a colon bacillus and occurred in the gangrenous lower limb of a diabetic patient. Most of the recorded cases of non-clostridial gas-producing infections have occurred in diabetics who had neurological or vascular complications of their diabetes, which was usually out of control (Spring and Kahn, 1951; Wills and Reece, 1960). The 2 diabetics reported in the present series were both well controlled prior to their infection, and even during their illness the diabetes was easily managed. Neither had neurological nor vascular complications of the diabetes, and the extensive thrombosis in *Case* 1 followed the infection. Nearly all the reported cases have originated in the lower limbs, and only 2 cases have followed perianal infection. Terrel (1940) recorded a case of non-clostridial crepitant cellulitis which originated from an anal fistula, and Altemeier and Culbertson (1948) noted a similar infection which originated from a perirectal abscess.

Non-clostridial gas-forming infections are not uncommon in war-time (MacLennan, 1962) and, as in peace-time, the most frequent organisms isolated have been the coliforms.

Table II.—CLINICAL FEATURES OF THE COMMON AEROGENIC INFECTIONS*

CRITERION	CLOSTRIDIAL CELLULITIS	CLOSTRIDIAL MYONECROSIS	STREPTOCOCCAL MYOSITIS	COLIFORM INFECTION
Onset	Gradual	Acute	Insidious	Gradual
Pain	Absent	Severe; first symptom	Usually severe	Variable; often first symptom
Swelling	Slight	Marked	Marked	Marked
Skin reaction	Little change	Marked; tense, bronzed, or erythematous	Marked; often coppery tinge	Marked; erythema
Muscles	No change	Marked change	Oedema initially	Variable
Gas	Abundant	Rarely pronounced except terminally	Slight	Abundant
Exudate	Serous	Serous	Seropurulent	Purulent
Smell	Foul	Sweet	Sour	Foul

* Modified from MacLennan (1962).

a. Aerobic Infections.—

i. E. coli *and* K. aerogenes: The frequency of infection with these organisms has increased since the introduction of antibiotics (Altemeier, 1966). Diabetics with ischaemic or gangrenous extremities are particularly prone to gas-producing infection with these organisms (Chiari, 1893; Hitschmann and Lindenthal, 1899; Warren, 1938; Gillies, 1941; Spring and Kahn, 1951; Wills and Reece, 1960). Reasons for this include: excessive amounts of tissue carbohydrate which may enhance gas production by *E. coli*; decreased body resistance to infection because of neurological and vascular lesions; and ischaemia may also be a contributory factor in that any gas produced may not be absorbed. Infections with these organisms usually involve subcutaneous or epifascial tissue, but may involve muscle and thus simulate clostridial myonecrosis. The first symptom is usually pain which is less severe than in clostridial myonecrosis and precedes swelling or erythema by 1–3 days (Altemeier and Culbertson, 1948). The absence of pain in the 4 cases of aerobic cellulitis reported by Wills and Reece (1960), all of which were fatal, was ascribed to neurological complications of diabetes. Within 24 hours the temperature is raised to about 38·3–40° C. The pulse and respiratory rates are also raised, although less than with clostridial infection. Necrosis and crepitation occur within 2–5 days of onset, gas being maximal in the fascial layers. With increased swelling there is increased pain and tenderness. The tempo is slower than with clostridial lesions and toxicity is therefore of later onset. Dysuria and urinary retention are common with perineal infections (Altemeier and Culbertson, 1948).

Microscopical examination of the exudate reveals pus cells and a number of different organisms. Muscle biopsy exhibits an oedematous, contractile muscle of normal colour.

The condition is usually not correctly diagnosed till a late stage is reached, and the uncertainty as to the best method of treatment and, in particular, the choice of antibiotic is complicated by the uncertainty of the causative organism, as the infection is usually polymicrobic.

Both *E. coli* and *K. aerogenes* are normal inhabitants of the gastro-intestinal tract, the various members of which exhibit marked synergistic activity (Altemeier, 1941, 1942). *K. aerogenes* is, however, the more resistant organism. The gas produced by both these organisms consists of carbon dioxide and hydrogen, which *E. coli* produces in equal volumes, whereas with *K. aerogenes* the ratio is 2 : 1 (Harden, 1901, 1905; Harden and Walpole, 1906).

ii. *Haemolytic streptococcus*: This organism may produce an epifascial, spreading gangrene in which thrombosis of the skin vessels is prominent. It occurs particularly in the extremities, the perineum, and the face. Pain and swelling are prominent at the wound site, and later cellulitis and bullae appear. The temperature and the pulse are elevated, and in the later stages the patient is toxic. Only rarely is crepitation present.

b. Anaerobic Infections—

i. *Streptococcus*: Although sporadically reported (Bingold, 1914; Marwedel and Wehrsig, 1915; Bérard, Lumière, and Donet, 1918; Bell and Gaebe, 1926; Meleney, 1936) the rare condition of streptococcal myonecrosis was first studied by MacLennan (1943a, b). Superficially, it may resemble clostridial myonecrosis. Pain, however, is of late onset, although it then rapidly becomes severe and may produce a toxic type of reaction. According to MacLennan (1962) there is usually no systemic reaction, but Slack, Hanson, and Chew (1969) observed that their patients were flushed, sweating, had temperatures of 38·8° C. or more, and were critically ill within 24 hours of onset. Cutaneous erythema is more pronounced than with clostridial myonecrosis, and gas, which is invariably present although rarely pronounced, is not as extensive as in clostridial myonecrosis. Oedema, which is moist rather than gelatinous, progresses diffusely and is not very haemorrhagic unless haemolytic streptococci are involved. Large quantities of seropurulent fluid with a peculiar sour odour are discharged from the wound. The muscles which at first are pale and soft are later more haemorrhagic than in clostridial myonecrosis. They then become bright red and later dark purple, and eventually become gangrenous. Microscopical examination of the exudate and the muscle smear is important and is of great help in differentiating the condition from clostridial myonecrosis. Mixed infections are rare and the characteristic picture is of pus cells and long chains of streptococci, which are smaller than aerobic streptococci.

Although still not fully classified (Topley and Wilson, 1964) the anaerobic streptococci have been subdivided on their growth characteristics into nine groups (Thomas and Hare, 1954). They are obligate anaerobes and are encountered in the normal female genital tract, mucosae, and skin, and they have been isolated from brain abscesses, wounds, and muscle. In fluid culture, abundant gas is produced, provided that sulphur is present. The commonest potential pathogen, *Streptococcus putridus*, is the only well-documented member and has been recognized for over 60 years (Schottmüller, 1910).

ii. *Bacteroides*: These have only very rarely been incriminated in crepitant infections involving subcutaneous and retroperitoneal tissues and muscle (Altemeier, 1966), and they are always part of a mixed flora. The spread is local and slow. Thrombosis of the skin vessels is prominent, the tissues appearing brown or black (Altemeier and Culbertson, 1948) and foul-smelling pus being produced. They are normal inhabitants of the respiratory, gastro-intestinal, and genital tracts. Being strict anaerobes, usually Gram-negative, very pleomorphic, and non-spore-bearing, they are difficult to culture and are avirulent for animals, as are the anaerobic streptococci (Altemeier, 1940).

THE DIAGNOSIS OF NON-CLOSTRIDIAL GAS-PRODUCING INFECTIONS

Clinically, the presence of gas in infected tissues may be denoted by swelling, bubbling from a wound, and most commonly by crepitation, although this sign will not be elicited in a subfascial structure unless the fascia has disintegrated. With auscultation, Hunnicutt (1965) diagnosed crepitus earlier than by palpation, and he also detected the presence of gas 2–5 cm. beyond the extent which was delineated radiologically.

When confronted with a gas-producing infection it is important to distinguish between clostridial and non-clostridial infection, because the treatment of these conditions differs. Differentiation is primarily on clinical grounds (*Table II*), but help may be gained from bacteriological and radiological examinations.

Clostridial infections are characterized by extensive tissue necrosis without significant suppuration, and microscopical examination of any discharge reveals Gram-positive, square-ended rods, numerous red blood-cells, and usually no pus cells, although if these are present they are very few and degenerate. The necrosis resulting from non-clostridial infections is usually less extensive, and the discharge, which is purulent, does not contain Gram-positive, square-ended rods, but there are numerous pus cells. Aerobic and anaerobic cultures should be set up. Both clostridial and non-clostridial discharges usually contain a variety of organisms, and members of one group may be present as contaminants in infection caused by an organism or organisms of the other group and thereby perhaps cause confusion as to the true nature of the infection. The stormy clot test (Altemeier, 1944) which was designed to be specific for *Clostridium perfringens* (*welchii*) is also positive for *Clostridium septicum* and *E. coli* and is therefore of no help in differentiating between clostridial and non-clostridial infections. Because the isolation of a particular organism does not prove that it is the culprit the diagnosis must be based on the clinical picture.

Radiologically, tissue gas presents as translucent bubbles, pockets, or linear streaks and is best demonstrated by lateral views with the suspected area uppermost. In cases of clostridial myonecrosis, gas is seen within muscle bundles as multilinear streaks, whereas in clostridial cellulitis and non-clostridial infections the gas is never intramuscular. Multilinear streaks similar to those seen in clostridial myonecrosis may be seen in the elderly as a result of increased fat deposition and also following buttock injury in obese people (Kemp, 1945).

In the 5 cases of non-clostridial gas-producing infection reported here the initial lesions were a perianal abscess (*Case* 3), anal fissure (*Case* 4), ischiorectal abscess (*Case* 1), and pelvirectal abscesses (*Cases* 2 and 5), symptoms of which had been present for between 2 days and 2 weeks. There was a 23-year history of perianal infection in *Case* 1. Two cases were well-controlled diabetics (*Cases* 1 and 2) without neurological or vascular complications, and during their illness they presented little problem as regards the management of the diabetes. All the patients were very ill, with temperatures of 38·8° C. or more and with leucocyte counts varying from 9000 to 54,000. The infections were purulent and were accompanied by varying amounts of tissue necrosis. Subcutaneous gas was clinically prominent, and radiologically there was no evidence of intramuscular gas. Gram-positive rods were not seen in any of the smears. In *Case* 5, *C. perfringens* (*welchii*) was cultured from the thick pus from a pelvirectal abscess, but on retrospect this must have been a contaminant. No clostridia were cultured from the other cases. In order of frequency the non-clostridial gas-producing organisms cultured were coliforms, anaerobic streptococci, bacteroides, and a haemolytic streptococcus. These organisms were sensitive to ampicillin, except the bacteroides, which was sensitive to tetracycline.

THE TREATMENT OF NON-CLOSTRIDIAL GAS-PRODUCING INFECTIONS

Treatment may be considered under the headings of surgery, antibiotics, antiserum, and hyperbaric oxygen. The administration of intravenous fluids, blood transfusion, renal dialysis, and other measures will depend on individual circumstances.

Surgery.—In the absence of peripheral arterial disease, surgery can usually be limited to decompression, evacuation of pus, and excision of necrotic material. If infection occurs in an ischaemic limb this may well require amputation, as in *Case* 1. In cases of clostridial myonecrosis involving the perineum there is often a reluctance to remove all of the infected tissue because of the subsequent functional disabilities, and this most probably accounts for the high mortality-rate of these cases (MacLennan, 1962). In non-clostridial infections the approach may be more conservative.

Antibiotics.—The most commonly used antibiotic in these infections has been penicillin. In the present series all non-clostridial organisms, except the tetracycline-sensitive bacteroides, were sensitive to ampicillin. This drug was used alone (*Case* 2), with penicillin (*Cases* 1 and 3), and with penicillin and kanamycin (*Case* 4). The fifth case was treated with Septrin, cephaloridine, and tetracycline. Slack and others (1969) found no response to intramuscular penicillin or ampicillin and recommended cephaloridine. Guidance will, however, be obtained from sensitivity tests.

Gas-gangrene Antiserum.—There is no indication for its use in non-clostridial infections, and even in cases of doubtful clostridial infection its administration is to be condemned, as hypersensitivity reactions are common (Rifkind, 1963). Polyvalent gas-gangrene antiserum provoked a widespread urticarial reaction in *Case* 5.

Hyperbaric Oxygen.—Hyperbaric oxygen at 2 atmospheres is toxic for aerobes and anaerobes *in vitro* and *in vivo*, and bacteria differ in their susceptibility (McAllister, Stark, Norman, and Ross, 1964; Ross and McAllister, 1964). Although of value in clostridial lesions, Slack and others (1969) observed that it was less effective in non-clostridial infections. They noted that if there was no clinical improvement after 3 hours of treatment a crepitant infection was unlikely to be clostridial. Until there are further reports of the use of hyperbaric oxygen in the treatment of non-clostridial infections its value must remain in doubt.

Non-clostridial gas-producing infections, although uncommon, must be differentiated from clostridial infections, and early and adequate treatment instituted. Despite intensive treatment, 2 of the 5 cases reported here died from overwhelming infection (*Cases* 1 and 5), and the experience with these 5 cases suggests that these infections warrant a reputation as sinister as that of clostridial infections.

Acknowledgements.—I am grateful to Mr. H. E. Lockhart-Mummery and Professor H. Ellis for their comments. My thanks for permission to publish cases who were admitted under their care are due to Mr. H. E. Lockhart-Mummery (*Cases* 1 and 2), Mr. F. A. d'Abreu (*Case* 3), and Dr. W. K. Slack (*Cases* 4 and 5). The illustrations were prepared by the Departments of Medical Photography at St. Thomas's Hospital (*Figs.* 1, 2), St. Mark's Hospital (*Fig.* 3), and Westminster Hospital (*Figs.* 4, 5, 6, 7, 8).

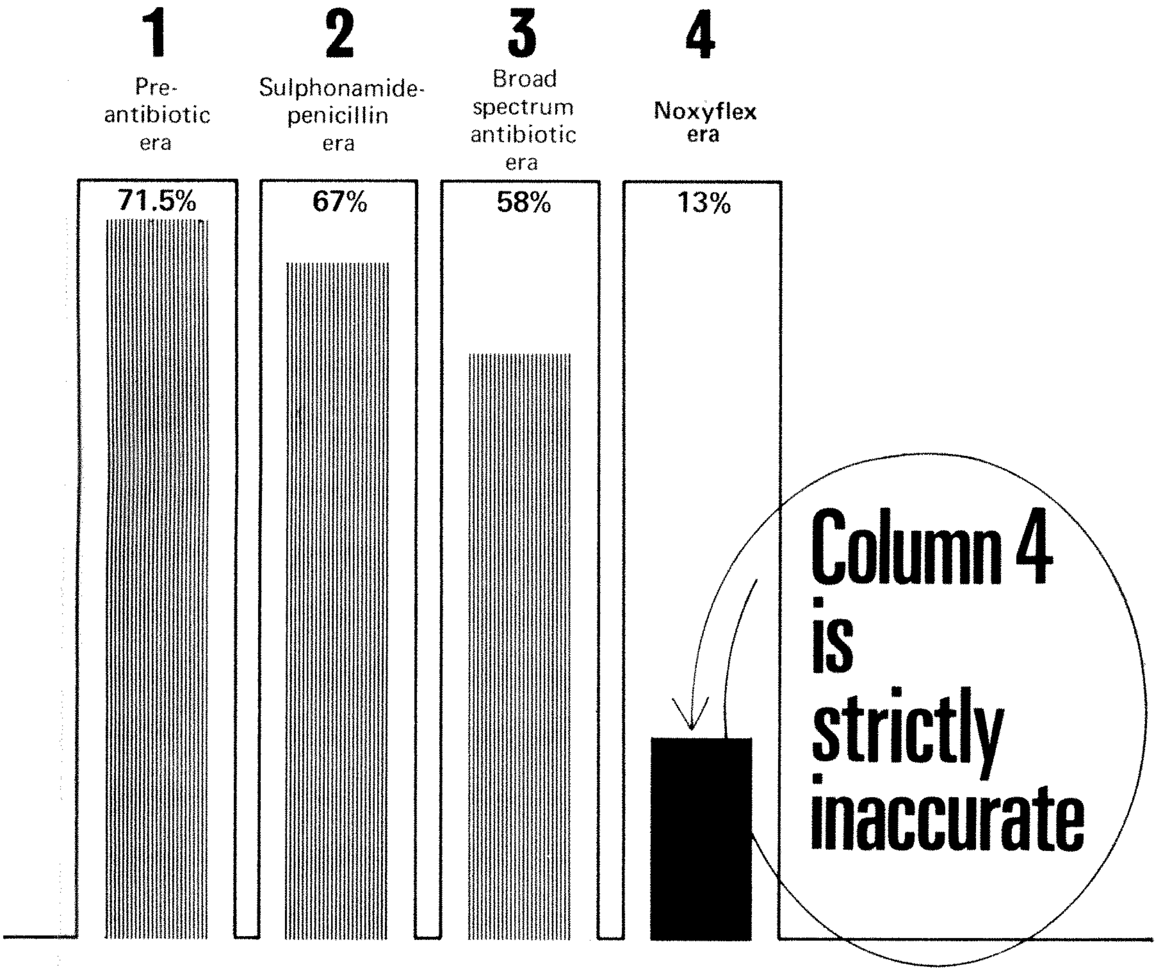
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Column 4 is strictly inaccurate

Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

When bacterial contamination of the peritoneum is diagnosed or suspected: Noxyflex

DICONAL TABLETS

for relief of severe pain when morphine injection would normally be given

DICONAL* is indicated in conditions where potent analgesics such as morphine would normally be used.

DICONAL Tablets contain dipipanone, which has a morphine-like action. The inclusion of the anti-nauseant and anti-emetic cyclizine enables the drug to be given by mouth.

Each tablet contains Dipipanone Hydrochloride, BP. 10 mg and Cyclizine Hydrochloride, BP, 30 mg.
DICONAL is subject to the DDA.

Full information is available on request.

PRIMARY SKIN-GRAFTING IN THE TREATMENT OF CHRONIC OSTEOMYELITIS

BY A. NAYLOR AND D. J. CROCKETT

BRADFORD ROYAL INFIRMARY AND WOODLANDS ORTHOPAEDIC HOSPITAL, RAWDON, NEAR LEEDS

SUMMARY

Attention is called to the value of primary split-thickness skin-grafting, as opposed to secondary grafting, used in conjunction with radical excision of avascular, sclerotic bone in the treatment of chronic osteomyelitis.

Nine cases treated by this method are described. These have remained healed following this procedure after periods of recurrent infection and disability varying from 28 to 2 years, 6 patients having recurrent osteomyelitis for over 10 years before operation. Five cases have remained healed for periods varying from 3 to 5 years following operation, the more recent remaining cases being asymptomatic for 1½–3 years subsequently.

THERE is general agreement that the radical treatment of chronic osteomyelitis requires excision of all avascular bone and fibrous tissues, but there are varying views concerning the method of subsequent closure. Whilst closure may be obtained in many cases by direct suture, such a method involves the risk of leaving undrained pockets and cavities with subsequent sinus formation and recurrent infection. This is particularly prone to occur in the tibia, where obliteration of the cavity by a pedicled muscle-graft may not be possible. Whilst split-skin closure of the cavity has been advocated it is infrequently practised, and adherents of this method (Lord, 1902; Kelly, Rosarty, and Murray, 1945; Knight and Wood, 1945; Evans and Davies, 1969) describe a two-stage procedure of bone excision with secondary skin-grafting 4–7 days later, after the formation of a layer of granulations over the bony walls of the cavity. It is the aim of this paper, by a study of 9 cases who were treated by a one-stage, immediate, primary skin-grafting procedure, to show that the two-stage, delayed, secondary grafting procedure is unnecessary, subjecting the patient to an additional procedure and being liable to hide an inadequate excision of avascular bone. The primary grafting, one-stage procedure is considered to be preferable.

MATERIAL

Over a period of 6 years 9 cases of chronic osteomyelitis have been treated by a one-stage procedure of excision of all avascular infected bone and immediate closure with split skin-grafts.

TECHNIQUE

Radiological examination of the affected part, using different penetrations, projections, and tomography, will help to delineate the probable extent of the excision of bone required, but it is no substitute for direct vision at the time of operation.

Bacteriological examination of any discharge is made and appropriate chemotherapy is instituted some days prior to operation. If no sinus is present, reference to the bacteriological state at previous examinations when a sinus was discharging will assist a decision regarding appropriate chemotherapy, but where such information is not available, ampicillin or tetracycline is administered.

At operation a tourniquet is used in the immediate gross excision of scar tissue and sclerotic bone. It is then removed to allow further excision of any dense or evident avascular bone to be completed. The walls and floor of the cavity should then consist of healthy bleeding bone, and their contours are shaped to form a shelving cavity with no residual irregularities or pockets. Bleeding is arrested with packs and by elevation of the limb throughout the operation. A generous area of free-hand skin-graft of intermediate thickness is prepared. A completely successful take of a graft depends on achieving intimate contact with every contour of the cavity; tenting across the depths will lead to failure in that area. Therefore, separate sheets of graft are sutured to the two margins of the defect and draped into the cavity so that one overlays the other. The cavity is packed very firmly with acriflavine emulsion wool, the two sheets of graft sliding over each other so as to adapt to every detail of the walls and floor. The procedure is completed with a pressure dressing and the patient is nursed with the leg elevated. The wound is examined 7 days later when the sutures are removed and the overlapping skin-graft is cut away. Any small areas which have not taken indicate underlying dead bone which must be further excised and skin-grafted. As a corollary to this, successful take of grafts is certain proof that the underlying bone is living.

A Blue-line bandage is worn when the patient is allowed up and is retained for 3 months. The skin-graft increases in thickness from about 0·5 mm. at the time of application to nearly 3 mm. and it attains considerable stability.

CASE REPORTS

Case 1.—S. C., aged 50 years. In 1954 this patient had fallen down a ship's hold, sustaining a compound fracture of the right femur. A Steinmann's pin had been used to treat the fracture and the pin track had subsequently become infected. Since that time the patient had had recurrent episodes of discharge and pain at the site of insertion of the Steinmann pin.

The patient was admitted to hospital on 6 Aug., 1965, with a discharging ulcer on the medial aspect of the upper end of the tibia. A radiograph of this area showed a chronic bone abscess with ring sequestra (*Fig.* 1). Bacteriological examination showed the infecting organisms to be staphylococcus, which was sensitive to cloxacillin and Ceporin, and resistant to penicillin, tetracycline, and erythromycin, and proteus, which was sensitive to cloxacillin, Kanomycin, and Ceporin.

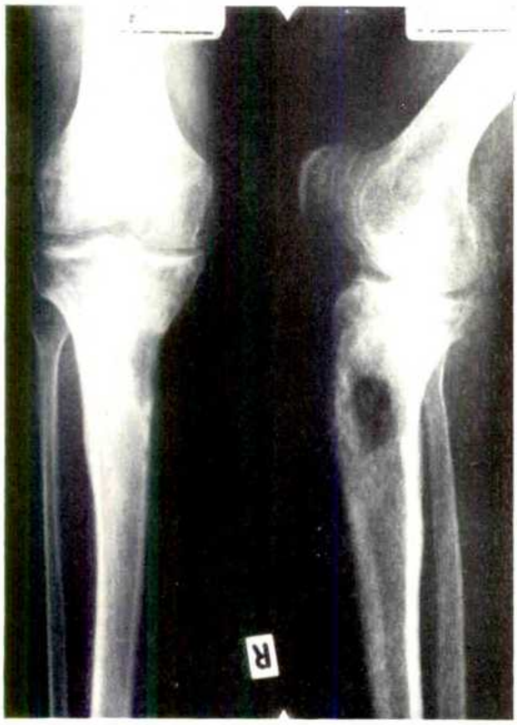

FIG. 1.—*Case* 1. Radiographs showing chronic bone abscess.

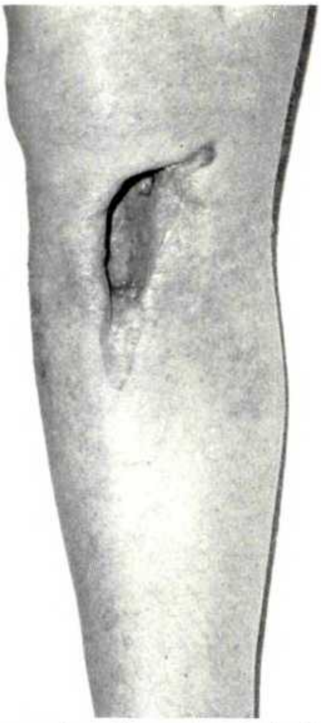

FIG. 2.—*Case* 1. Bone cavity surfaced with split grafts.

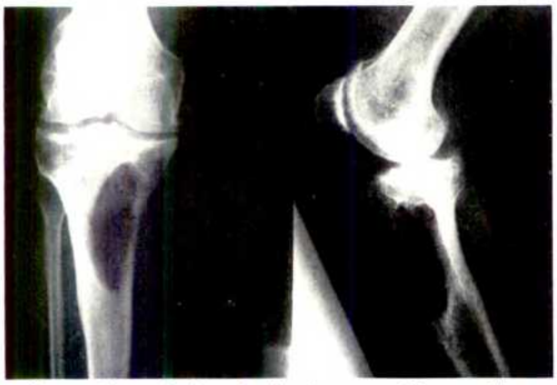

FIG. 3.—*Case* 1. Radiographs showing extent of bone excision.

On 16 Aug. the sinus was excised together with sequestra and sclerotic bone. The wound was revised. Old scar-tissue granulations were excised and a split graft was placed on to exposed cancellous bone, resulting in an 85 per cent take.

There was still some discharge persisting on 16 Sept., and therefore resaucerization of the cavity with further split grafts was carried out.

On 21 Oct. some areas of dead bone were removed by curetting with a Volkmann's spoon and the cavity was regrafted to give 100 per cent cover.

On 12 March, 1966, radiographs showed osteo-arthritic changes in the knee. No sequestra were present. The patient was able to start light work, and on 6 May he returned to work as a heavy labourer, the graft having healed satisfactorily.

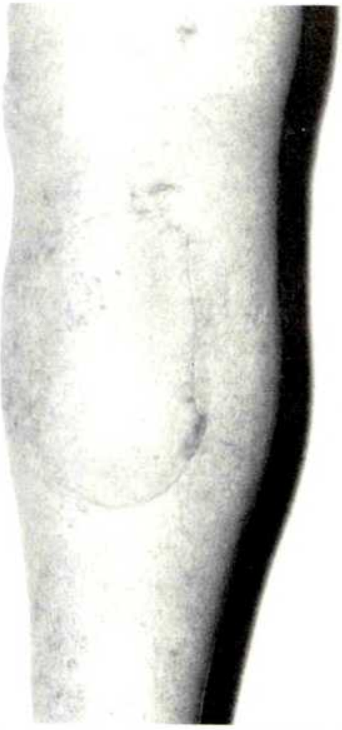

FIG. 4.—*Case* 1. Split grafts replaced with full-thickness, tube-pedicle graft.

On 14 Nov. one area in the upper part of the cavity, 1 cm. in diameter, reopened. A small area of dead bone was present (*Fig.* 2). On 6 Dec. curettage was performed and a split graft, 1 cm. in diameter, was applied. A tube pedicle was later raised from the abdomen, was transferred via the left wrist, and was inserted with fat to fill the cavity after the lining had been excised. The graft had healed by 13 Dec., and to date (August, 1971) remains satisfactory (*Figs.* 3, 4).

COMMENT.—This case demonstrates the value of the split-graft technique in revealing remaining areas

Table I.—SUMMARY OF CASE RECORDS

CASE NO.	AGE (years) AND SEX	HISTORY	DURATION OF INFECTION (years)	INFECTING ORGANISMS AND SENSITIVITY*	ANTIBIOTICS USED	RADIOGRAPHIC APPEARANCES	PERCENTAGE INITIAL TAKE OF GRAFT	RESULT
1. S. C.	50 M.	Open fracture of right femur in 1954. Treated by traction with Steinman's pin in upper third of tibia. Recurrent discharge and pain from pin-track	11	*Staph. aureus* R. Penicillin Tetracycline S. Cloxacillin Proteus S. Cloxacillin	Cloxacillin	Chronic bone abscess with ring sequestrum	85	Remains healed 5 years after operative treatment. No symptoms
2. E. C.	61 M.	Brodie's abscess in upper third of tibia excised in 1954. Closure by suture. Recurrent flares of infection	11	*Staph. aureus* R. Penicillin Ampicillin S. Tetracycline Erythromycin Cloxacillin	Cloxacillin	Sclerotic osteitis of upper third of tibia	80	Remains healed 4 years after treatment. No symptoms
3. T. A.	56 M.	Gunshot wound with open fracture of tibia in 1944. Recurrent infection. Excision and bone-chip grafting in 1957 failed to heal	23	*Staph. aureus* R. Penicillin S. Ampicillin Proteus S. Ampicillin Penicillin	Ampicillin	Sclerotic osteitis of upper third of tibia	90	Remains healed 3 years after treatment. Deep-vein thrombosis followed cross-leg reconstruction
4. T. D.	20 M.	Tibia kicked by horse in 1962. Recurrent osteomyelitis with discharging sinuses	6	*Staph. aureus* S. Penicillin Ampicillin Streptococcus R. Cloxacillin Penicillin S. Ampicillin	Ampicillin	Sclerotic osteitis of upper third of tibia	100	Remains healed and free of symptoms 3 years after treatment
5. S.M.	43 M.	Osteomyelitis in lower third of tibia at age of 15. Pain and pyrexia for 1 month	28	*Staph. aureus* S. Cloxacillin R. Penicillin	Cloxacillin	Ankylosis of ankle. Osteitis with abscess cavity of lower third of tibia	95	Remains healed and free of symptoms 2 years after treatment
6. G. P.	34 M.	Open comminuted fracture of upper tibia in 1960. Recurrent infection and sinus formation	9	*B. pyocyaneus* S. Colomycin	Colomycin	Sclerotic osteitis of upper tibia	95	Small sequestrum extruded 1 year after treatment. Remained healed since
7. V. B.	17 F.	Recurrent osteomyelitis of tibia since age of 6	11	*Staph. aureus* S. Penicillin	Penicillin	Sclerotic osteitis of midshaft of tibia	100	Remains healed
8. J. G.	27 M.	Open fracture of left tibia after parachute jump in Spanish Army in 1968. Treated by intramedullary nail. Infected. Recurrent sinus formation	2	No growth on culture	Cloxacillin	Sclerotic osteitis with sequestra in middle third of tibia	50; 50 per cent lost because of haematoma; 100 per cent take on regrafting	Remains healed
9. S. C.	12 M.	Sickle-cell anaemia. Recurrent sinus from bilateral tibial osteomyelitis for 4 years. Stiff left hip and knee	4	Haemolytic streptococcus S. Cloxacillin Ceporin R. Penicillin Ampicillin *Staph. aureus* R. Ampicillin S. Cloxacillin	Cloxacillin	Diaphysis of each tibia with extensive chronic osteitis	Right leg: all grafts lost due to infection; regraft 1 week later; 95 per cent take. Left leg: 100 per cent take	Remains healed 4½ years after treatment

* R = Resistant, S = Sensitive

of dead bone. With other methods of closure these would have led to more extensive chronic infection.

Case 2.—E. C., aged 61 years. In 1954 this patient had had a Brodie's abscess with sequestrum in the upper one-third of the tibia. The cavity had been drained, curetted, and filled with bone chips. The wound had healed approximately 2 months later. Subsequently the patient had had recurrent flares of infection, the infecting organism being *Staphylococcus aureus*, which was sensitive to tetracycline, erythromycin, and cloxacillin, but resistant to penicillin and ampicillin.

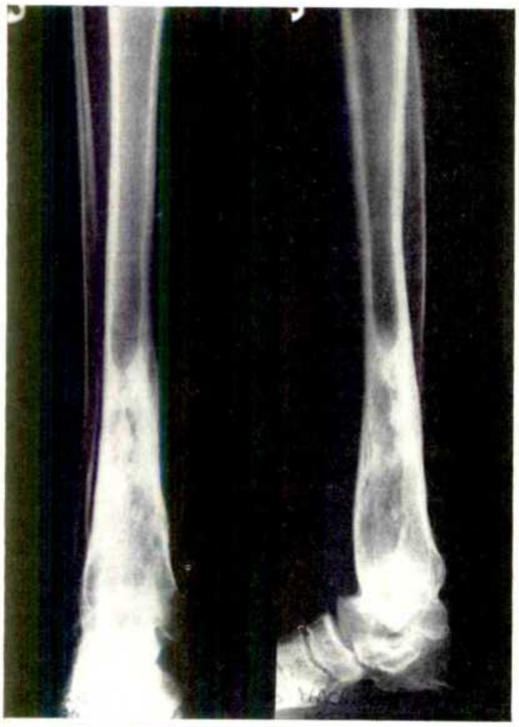

FIG. 5.—*Case* 5. Radiographs of tibia, showing ankylosed ankle, abscess cavities, and sclerotic bone.

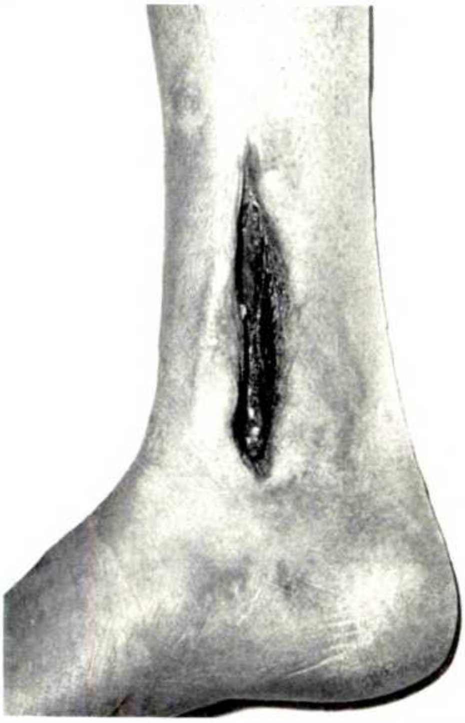

FIG. 6.—*Case* 5. Stable, healed, primary, split-skin grafts line the cavity remaining after excision.

At the present admission in February, 1967, skin, scar tissue, and sclerotic bone were excised and split grafts were applied. On 3 March, 1967, an 80 per cent take of the graft was noted, and excision of a small fragment of necrotic bone was carried out. Following this procedure the grafts took satisfactorily (23 March). On 13 April a further small fragment was removed and a small graft was applied.

The graft remains dry and soundly healed in August, 1971.

Case 3.—T. A., aged 56 years. This patient had sustained a gunshot wound in his left leg with a compound fracture of the midshaft of the left tibia in 1944. The scar tissue had been excised and the wound had been closed by secondary suture in July, 1948. On 14 Aug., 1957, he had been to hospital with a Brodie abscess. The abscess with the sclerotic bone had been excised, and the cavity had been packed with iliac chips. The wound had been closed, and had healed satisfactorily, although recurrent infection in July, 1959, had required drainage of a localized abscess. In 1964 an adherent scar had been excised and resurfaced by split grafts to the periosteum. The patient has had recurrent flares since then, the last being in early 1967, when it was evident that sclerotic avascular bone was still present.

The old scar was excised on 19 Sept., 1967. The infecting organisms were found to be proteus, which was sensitive to ampicillin but resistant to penicillin, and *Staph. aureus*, which was sensitive to both ampicillin and penicillin. All the sclerotic bone was excised over a wide area until healthy bleeding bone was exposed. Split grafts from the right thigh were used to cover the left tibia, and the graft healed satisfactorily. In view of the patient's type of work, further protection by full-thickness skin cover was thought to be advisable. This was carried out in several stages.

On 5 Oct. a first-stage cross-leg flap was raised, and on 19 Oct. the cross-leg flap was elevated and sutured over the tibia after excision of the split-skin grafts, which had taken fully. The flaps were separated and reinserted on 1 Nov. The patient was discharged on 2 Dec., and he returned to work on 20 Feb., 1968. The graft remained soundly healed in August, 1971.

COMMENT.—Initial inadequate excision of infected and sclerotic bone and direct suture over the cavity resulted in further scarring and recurrent episodes of infection. Primary grafting at that time would have revealed areas of necrotic bone still to be present. A more radical excision and primary skin-grafting should have been undertaken in 1957. The bone chips could then have been inserted at the time of a cross-leg-graft reconstruction if necessary.

Case 4.—T. D., aged 20 years. This patient had been kicked by a horse 6 years previously and had since had recurrent osteomyelitis of tibia. On examination on 4 Jan., 1968, there was an adherent scar in the upper part of the left tibia with a discharging sinus, 2·5 × 1·8 cm. The infecting organisms were *Staph. aureus*, which was sensitive to penicillin, and streptococcus, which was sensitive to ampicillin but resistant to cloxacillin, penicillin, and tetracycline. A radiograph showed old osteitis at the upper end of the left tibia.

On 19 Jan. the scar, the sclerotic tissue, and the sclerotic bone were excised. The cavity was saucerized and split grafts were applied, with 100 per cent take. A cross-leg flap was raised. On 1 March, 1968, the cross-leg flap was raised and was inserted into the graft area after excision of the split grafts.

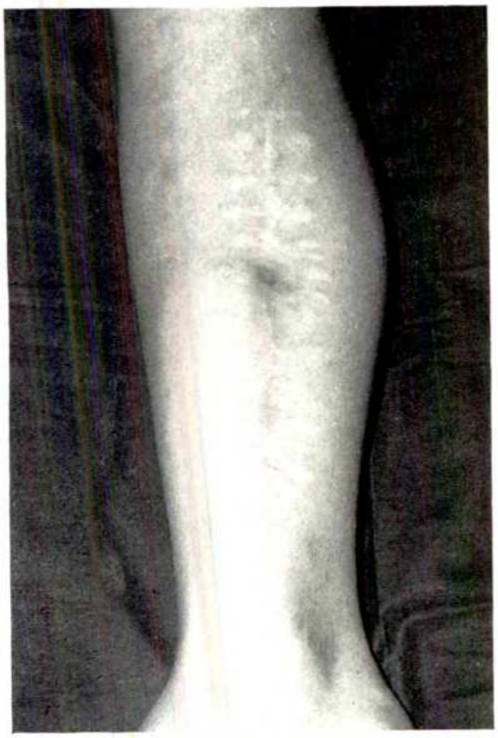

FIG. 7.—*Case* 7. Unstable scar and sinus overlying sclerosed infected bone.

The patient resumed working on 11 June, and the graft remains satisfactory to date (August, 1971).

Case 5.—S. M., aged 43 years. The patient presented on 12 Feb., 1969, with a 2-week history of pain in the right ankle. The ankle was ankylosed, the patient having had osteomyelitis at 15 years of age. Radiographs showed complete obliteration of the ankle-joint (*Fig.* 5), and there were abscess formation and sclerosed bone in the lower third of the tibia. The infecting organism was *Staph. aureus*, which was sensitive to cloxacillin, streptomycin, and erythromycin, but resistant to penicillin and tetracycline.

Sequestrectomy and saucerization were carried out on 14 March. Pus under tension was evacuated, and a primary split graft was applied. On 21 March a good take of 95 per cent was recorded. On 27 March a small strip of graft in the base, 1·8 cm. wide, had not taken. Furacin and a compression bandage were applied, and on 17 April the graft appeared to be healed (*Fig.* 6). The patient returned to work on 9 Sept. and the leg has remained satisfactory.

COMMENT.—Primary grafting succeeded in the presence of an infection where pus was under tension.

Case 6.—G. P., aged 34 years. This patient had sustained a compound comminuted fracture of the upper end of the left tibia and fibula on 7 Feb., 1960. The fracture had been treated by wound excision and plaster immobilization, the leg remaining in plaster until 7 Oct. when the fracture had been clinically firm.

On 26 Jan., 1961, the patient had had manipulation of the knee to improve knee movements. He had been seen again in 1961 with some discomfort at the fracture site, and again in May, 1964, with a recurrent discharging sinus over the upper end of the tibia in the original wound. No localized sequestra had been seen but sclerotic bone had been evident. Local dressings had been applied, antibiotics had been given, and the sinus had healed.

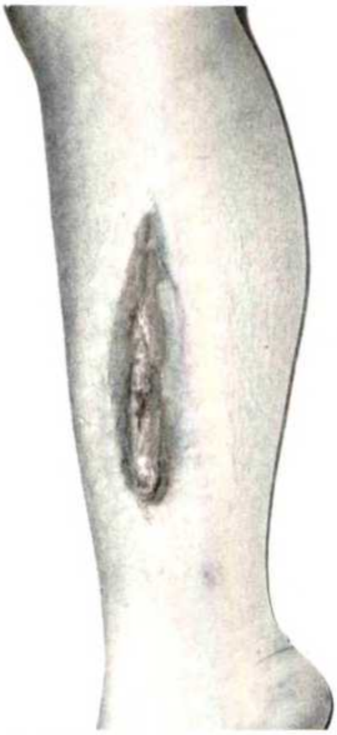

FIG. 8.—*Case* 7. Stable skin cover after excision of necrotic and sclerotic bone.

The patient presented on 17 July, 1969, with recurrent pain in the left knee and the sinus had reopened. On 31 Oct., 1969, the infecting organism was shown to be *Bacillus pyocyaneus*, which was sensitive to colomycin.

On 17 Oct. the scarred area was excised. The necrotic bone was cut away, but there was a ring of dense bone at the fracture site and it could not all be removed without weakening the tibia. A primary skin-graft was applied and it took satisfactorily (95 per cent). One small area in the upper angle of the wound, less than 0·6 cm. in diameter, has discharged a little intermittently since.

On 30 June, 1970, radiographs revealed a very small sequestrum to be present which was coincident with the area which had not healed. The sequestrum was removed and a small split-skin graft was applied. The wound has remained healed since.

COMMENT.—This case illustrates the limitations of the method of primary skin-grafting, i.e., it must be possible to remove all the necrotic bone without disturbing the structural stability of the affected bone.

Case 7.—V. B., aged 17 years. This patient had had recurrent osteomyelitis of the right tibia since initial treatment as a child at the age of 6. The primary infection had been *Staph. aureus*, which had been sensitive to penicillin.

Examination on 13 Feb., 1970, revealed a broad, ugly, unstable scar over the lower half of the tibia. A radiograph showed some sclerosis of the midshaft of the

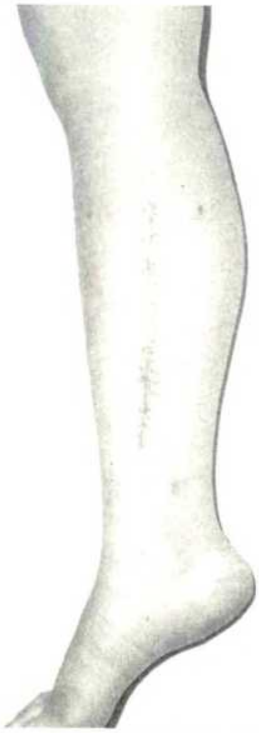

FIG. 9.—*Case* 7. Full-thickness skin cover after excision of split-skin grafts.

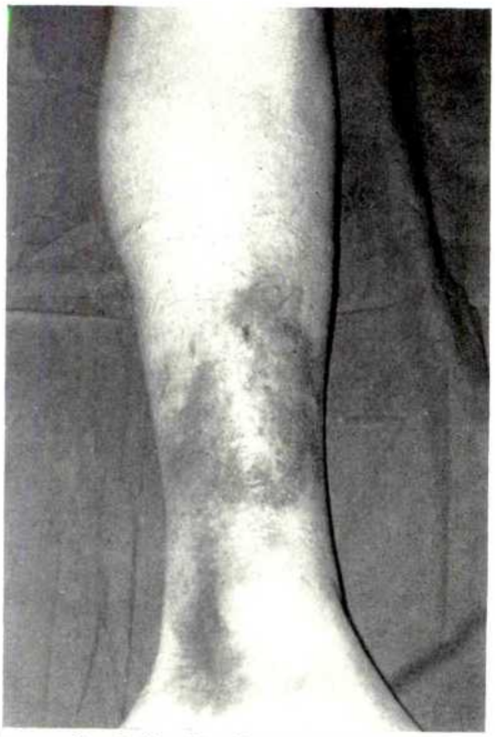

FIG. 10.—*Case* 8. Unstable adherent scar and sinus overlying necrotic bone.

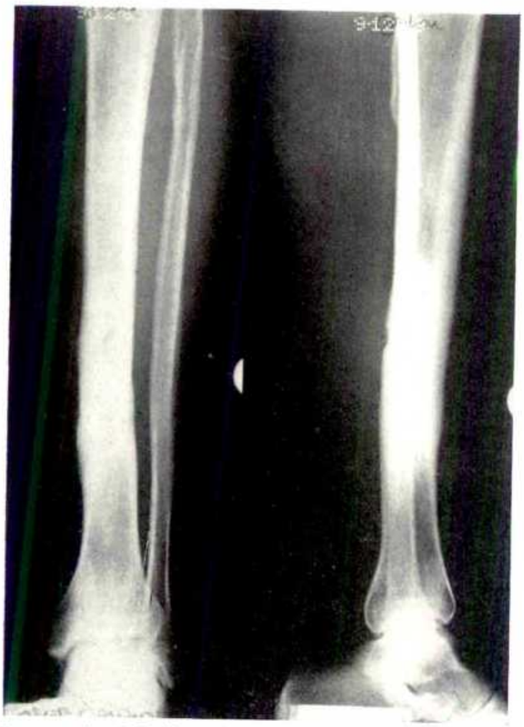

FIG. 11.—*Case* 8. Radiograph showing dense sclerotic bone with a small sequestrum separating posteriorly.

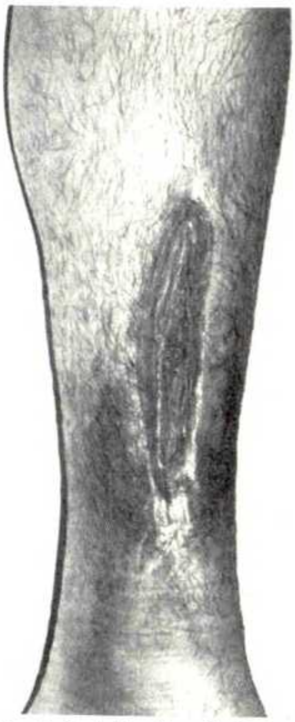

FIG. 12.—*Case* 8. Cavity lined by split-thickness grafts.

tibia (*Fig.* 7). The old scars were excised, and a large area of thick sclerotic bone was removed from the mid-shaft of the tibia until healthy bone was exposed. Very small sequestra were present in the granulation tissue. The infecting organisms were *Staph. aureus* and *Staph. albus*, which were sensitive to penicillin. A primary split-skin graft from the same thigh was applied, and it took satisfactorily (100 per cent). A sound, stable split-skin cover was noted on 13 April (*Fig.* 8). In June the graft was replaced with full-thickness skin by local resuture in order to produce a cosmetically acceptable scar. The split grafts were excised and local resuture was performed in September. The area remains healed at the present time (*Fig.* 9).

Case 8.—J. G., aged 27 years. This patient had sustained a compound fracture of the left tibia when he had been a parachutist in the Spanish Army in 1968. The wound had been excised and 5 days after the injury he had had an intramedullary nail inserted into the tibia. Four weeks later this had to be removed because of infection. Another plaster had been applied and the wound had gradually healed. The patient had had a further operation in Sept, 1969, in Spain for a sinus.

On examination on 9 Dec., 1969, a small discharging sinus 7·5 cm. above the ankle in the midst of a large area of excoriated skin was present. Clinical alinement of the tibia was good. A radiograph showed a united fracture of the tibia with some sclerosis at the fracture site. A small cavity and sequestrum were visible (*Figs.* 10, 11).

The patient was admitted to Woodlands Orthopaedic Hospital on 13 Feb., 1970. At operation an incision was made along the original scar, including the sinus in the incision. The bone was very sclerotic and was marble hard. The bone was saucerized using a gouge and chisel. There was a small amount of pus deep in the cavity, from where the small sequestrum was removed. The sinus track was dissected out and removed. An inlay skin-graft was taken from the same thigh and was inserted into the cavity.

A 50 per cent take of the graft was noted on 9 March. There was loss of graft from the lateral side and the floor of the cavity owing to a haematoma. The necrotic graft was removed on 10 March and the defect was covered by new grafts from the left thigh. On 19 March the dressing was removed in the operating theatre under general anaesthetic. One hundred per cent take of the graft was noted (*Fig.* 12).

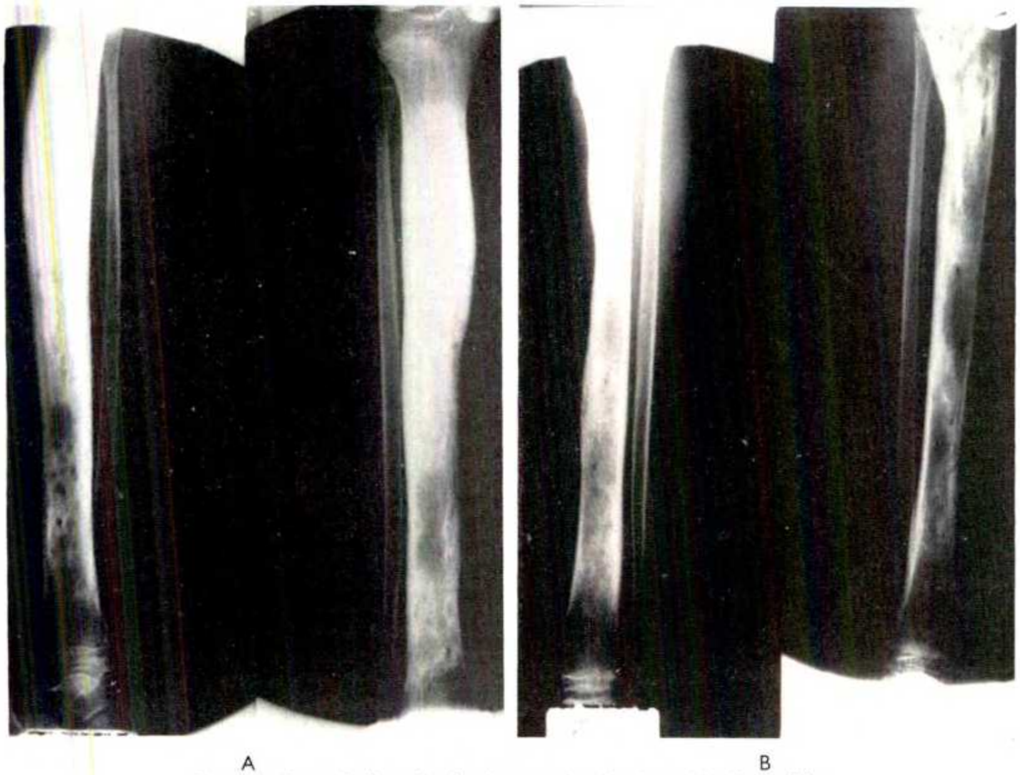

FIG. 13.—*Case* 9. Radiographs showing extensive chronic osteitis of both tibiae.

When the donor area had healed, the patient was allowed up, with a Blue-line bandage on the leg. He was discharged from hospital on 29 March.

At review on 27 Oct., 1971, the graft had healed soundly, and the patient was able to work.

COMMENT.—Inadequate haemostasis produced a partial take of the primary grafts. Regrafting of the unhealed area, after removal by curettage of any granulations, produced 100 per cent take.

Case 9.—S. C., aged 12 years. This patient had had recurrent osteomyelitis of both tibiae for 4 years. The left knee and hip had been stiff for at least 2 years.

On examination, in November, 1966, there were multiple scars and sinuses over both tibiae, chiefly on the subcutaneous surface from the knee to the ankle, and healed scars over the lower end of the left femur. Left knee movement was 180–160°, while the right knee movement was full. Full ankle movements of both legs were present. There was left hip flexion to 90°, and rotation to half range. Radiographs showed chronic osteomyelitis with multiple dense areas extending throughout the whole of the diaphyses of each tibia. The left hip showed evidence of avascular necrosis in the epiphysis of the head of the left femur (*Fig.* 13). Blood examination showed a negative test for 'sickling'. In Singer's test less than 2 per cent of the haemoglobin resisted alkali denaturation. Electrophoresis of the haemoglobin at *p*H 8·9 revealed a single haemoglobin band of similar mobility to that of haemoglobin C. Red-cell morphology was strongly suggestive of haemoglobinopathy. The haemoglobin was 69 per cent, W.B.C. 10,000, polymorphs 5300, lymphocytes 4000, and eosinophils 300. A study of the red-cell morphology revealed anisocytosis, target cells + + +, polychromasia + +, hypochromia + +, and 3 per cent reticulocytes.

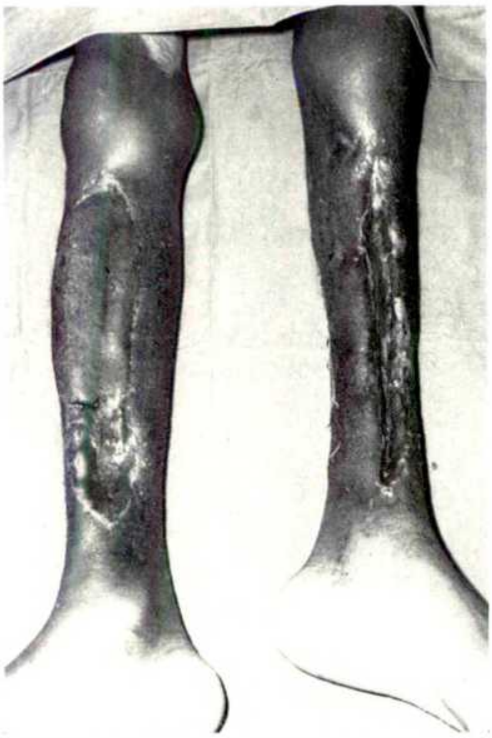

FIG. 14.—*Case* 9. One-hundred per cent split-skin cover of both legs. The upper half of the right leg has been replaced by a full-thickness cross-leg flap.

A swab taken from the wounds cultured *Staph. aureus*, which was coagulase positive and resistant to penicillin and ampicillin but sensitive to cloxacillin, Ceporin, erythromycin, and Tetracycline, and haemolytic streptococcus, group A, which was sensitive to penicillin, ampicillin, cloxacillin, and erythromycin.

Cloxacillin was begun 2 days prior to operation on 10 Dec., 1966. The diaphysis of the right tibia was guttered from end to end. Split-skin grafts were sutured into the cavity. Two pints of blood were transfused during the operation, which was performed without a tourniquet. Removal of the dressings of the right leg on 15 Dec. revealed total failure of the grafts. A further swab confirmed that haemolytic streptococci were still present. The wound was packed. On 5 Jan., 1967, excision of the sclerotic bone and guttering of the left leg was performed. Split grafts were applied. Granulations were stripped from the wound of the right leg and the area was regrafted. On 12 Jan. the right leg had 100 per cent take and the left leg had a 95 per cent take of the grafts (*Fig.* 14). On 26 Jan. a long abdominal tube pedicle graft, 21·8 × 7·5 cm., was raised. A cross-leg flap of the left leg was also raised, and a Thiersch graft was used to cover this. A series of procedures were undertaken in order to transfer these tubes to cover the defects in both the legs. By 12 June all the flaps and both the thighs had healed with full-thickness skin cover (*Fig.* 15). The patient was then allowed to take his full weight on both legs. Both tibiae have remained healed and free from symptoms since.

COMMENT.—The initial operative procedure was undertaken too soon before control of the streptococcal infection by antibiotic therapy. When the infection had been controlled, primary grafting direct to the bone succeeded.

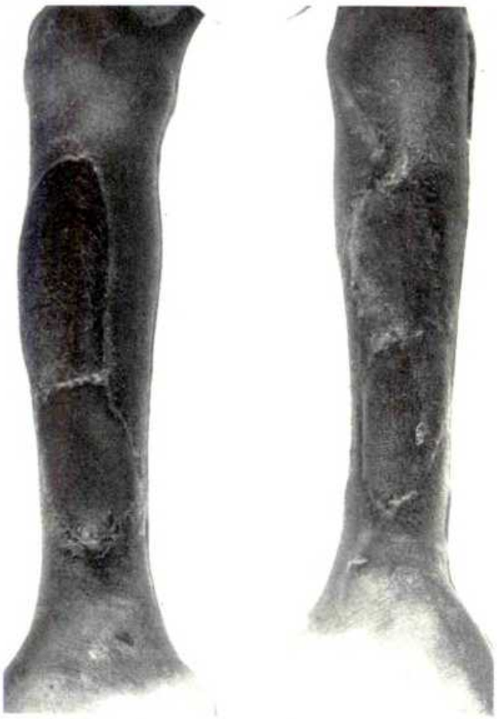

FIG. 15.—*Case* 9. Complete full-thickness skin cover obtained.

DISCUSSION

Chronic osteomyelitis is synonymous with the persistence of infected, avascular bone accompanied by soft-tissue fibrosis and, in many cases, by dense, adherent, superficial scarring, and is characterized by acute phases of pyrexia, pain, loss of function, and often recurrent sinus formation.

Whilst rest and antibiotic therapy may produce subsidence of such an acute episode, frequent recurrences require a more radical procedure. A radical excision of all avascular bone, scar tissue, and unstable skin is essential and is common practice, but there is still some variation in the subsequent methods of closure and repair. After radical excision a cavity is left which must be obliterated if a haematoma is not to ensue with resulting recurrence of infection and scarring, and yet direct suture and closure without obliteration are often practised with |subsequent failure to eradicate the infection. Obliteration by granulation and epithelization under a plaster cast by the Winnett Orr method often results in prolonged hospitalization, chronic sinuses, and unstable, adherent, ugly scars. The cavity in many cases can be obliterated by the use of a pedicled muscle-flap which because of its vascularity is highly resistant to infection, and adequate skin closure without tension may then be possible. There are many situations, however, for example, the tibia and lower end of the femur, where such an obliteration is difficult or impossible and where an adequate skin closure cannot be made by simple suture. These cavities can be very satisfactorily closed with adequate skin cover by means of a primary, inlay, split-skin graft, as shown by Robertson and Barron (1946), yet the treatment of chronic osteomyelitis by such a method has failed to receive the general adoption its effectiveness indicates. Where skin-grafting has been advocated (Lord, 1902; Armstrong and Jarmon, 1936; Kelly and others, 1945; Knight and Wood, 1945; Kelly, 1946; Evans and Davies, 1969), grafting as a secondary procedure 4–7 days after excision and saucerization is the recommended procedure. Primary grafting at the time of saucerization as a one-stage procedure is preferable, with one contra-indication, to a secondary-grafting procedure, and it has been the aim of this paper to recall and to stress the advantages of this method. Secondary grafting has been recommended by other authors because it was thought that a layer of granulations on the floor and walls of the cavity was essential for skin-grafts to take on cortical bone, or that grafts would not take in the presence of infection. This belief is erroneous. A split graft will take on cortical or cancellous bone, provided that the bone is adequately vascularized. Where small areas of the skin-graft do not take, it is therefore evident that the saucerization procedure has been inadequate and that sclerotic bone has been left in the walls of the cavity on which the grafts will not survive. Such areas can then be locally excised and small grafts can be applied to complete the closure, or they may close by direct epithelization. With the exception of infection with haemolytic streptococcus, the split graft will take in the presence of infection. The presence of haemolytic streptococcus at the time of operation is the one contra-indication to the use of primary grafting.

A further advantage of the primary one-stage procedure is that the risk of development of secondary infection after the saucerization procedure, which is liable to occur in a two-stage procedure, is considerably reduced. The split grafts remain quite stable and they thicken to 3 mm. Survival of the grafts indicates that the radical excision of avascular infected bone has been complete, thus eliminating any further risk of recurrence of the infection. If there is a risk of further local trauma a full-thickness skin replacement may be undertaken later, either by local direct suture or by rotation of local flaps or by cross-leg-flap or tube-pedicle procedures.

The method is equally applicable to the treatment of open, infected fractures, particularly when union is delayed.

HYPERKALAEMIA FOLLOWING TEMPORARY OCCLUSION OF THE PORTAL VEIN AND HEPATIC ARTERY

By R. R. HALL

DEPARTMENT OF SURGICAL SCIENCES, ROYAL COLLEGE OF SURGEONS OF ENGLAND

SUMMARY

Temporary occlusion of the hepatic artery and the portal vein during operations on the liver has been considered a safe procedure provided that the period of ischaemia is not extended beyond 20–30 minutes. Measurement of serum potassium in the portal and systemic circulation of dogs which were subjected to 20 minutes' hepatic ischaemia reveals a transient hyperkalaemia of sufficient degree to cause cardiotoxicity. It is concluded that even this short period of inflow occlusion to the liver is inadvisable.

Haemorrhage is a hazard that complicates liver surgery (Stone and Saypol, 1952; Madding and Kennedy, 1965). A variety of surgical techniques have been described that minimize such bleeding (Wangensteen, 1945; Nakayama, 1957; Balasegaram, 1968), including temporary occlusion of the portal vein and the hepatic artery to arrest blood-flow through the liver while resection is being performed. This method was described by Duchinova in 1926 and by Wangensteen in 1951, and was subsequently recommended by Brunschwig (1955) and by Madding and Kennedy (1965).

Patients have been subjected to hepatic circulatory arrest for 30–45 minutes at normal body temperature without apparent harm (Brunschwig, 1955; Anastasia, Williams, and Byrne, 1967), but by no means all patients have survived this operative procedure

(Wangensteen, 1951), and there has been considerable speculation concerning the maximum time that the blood-supply to the liver may be safely interrupted.

Raffucci and Wangensteen (1951) found that 20 minutes was the maximum period of continuous occlusion of the hepatic artery and portal vein that was tolerated by normal dogs without showing evidence of hepatic necrosis. This was confirmed by Goodall, Hyndman, and Gurd (1957). Longer periods of ischaemia are usually fatal (Bernhard, McMurrey, and Curtis, 1955) but are tolerated if a portacaval shunt (Jolly and Foster, 1963) or hypothermia (Bernhard, Cahill, and Curtis, 1957) is employed.

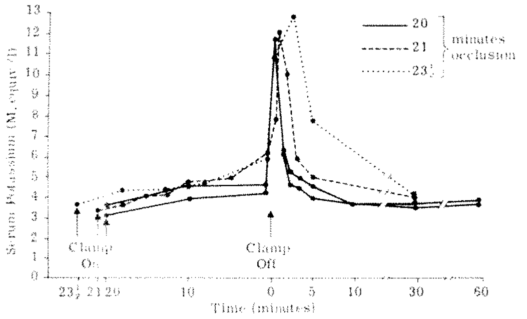

FIG. 1.—Serum potassium levels in the pulmonary artery before, during, and following arrest of the hepatic circulation for 20, 21 and 23½ minutes.

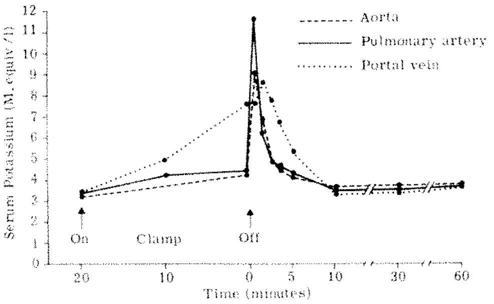

FIG. 3.—Serum potassium levels in the pulmonary artery, the portal vein, and the aorta before, during, and following 20 minutes' hepatic circulatory occlusion.

The mortality and morbidity resulting from longer periods of hepatic inflow arrest have been variously ascribed to hypovolaemic shock (Elman and Cole, 1934; Brunschwig, 1955), release of a vasodepressor material (Shorr, Zweifach, and Furghott, 1945; Buckberg, Hiromichi, Joseph, Tocornal, Fonkalsrud, and Longmire, 1968), acidosis (Barnett, Turner, and Walker, 1958), and anaerobic bacteriaemia (Markowitz, Rappaport, and Scott, 1949; Battersby, Balderson, Winch, and Burnett, 1971).

Hyperkalaemia has been noted with interest by several observers but has been discounted as a cause of death (Backlund, Stevens, Hamit, and Jordan, 1965; Stewart, Potter, Hubbard, and Anderson, 1953). These authors agree that the serum potassium level in the hepatic veins rises progressively while the hepatic circulation is arrested for periods longer than 20 minutes, but it falls promptly to normal when the circulation is restored. Jolly and Foster (1963), and Bengmark, Hafström, Hultin, Jagenburg, and Vosmik (1969), however, observed a rise in serum potassium when the circulation was restored following 2 hours' liver ischaemia. This could be dangerous, for circulatory hyperkalaemia is cardiotoxic causing a variety of arrhythmias (Blake, 1839; Ewy, Karliner, and Bedyner, 1971) and cardiac arrest (Ringer, 1883), and could account for some of the morbidity or mortality of temporary arrest of the hepatic circulation.

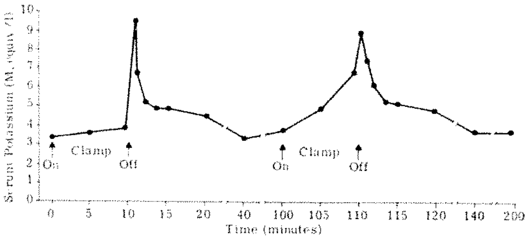

FIG. 2.—Serum potassium levels in the pulmonary artery before, during, and following two 10-minute periods of hepatic circulatory arrest.

Ischaemic liver cells are known to release large amounts of intracellular potassium (Flink, Hastings, and Lowry, 1950; Abouna, Skillen, Hull, Hodson, and Kirkley, 1969). If the amount of potassium is sufficient to allow detection in the hepatic veins and the suprahepatic vena cava while the hepatic bloodflow is at a standstill, it is to be expected that the accumulated potassium would be flushed out of the liver on restoration of the circulation and would cause an increase rather than a decrease of serum potassium levels in the hepatic veins and the systemic circulation. A simple experiment has been undertaken to investigate this hypothesis, and the results are reported here.

MATERIALS AND METHODS

Five dogs weighing 14–16 kg. were anaesthetized with intravenous Nembutal and the pulmonary artery and descending aorta were catheterized via the femoral vein and artery respectively. Upper midline laparotomy was performed and the main portal vein was cannulated via the splenic vein. These catheters enabled constant recording of pressure and intermittent sampling of blood for serum potassium estimation from the portal vein, pulmonary artery, and aorta. Blood was sampled from the pulmonary artery rather than from the suprahepatic vena cava because samples from the pulmonary artery would indicate the true potassium concentration of the mixed venous blood returning to the heart. An electrocardiogram using standard limb leads was monitored.

The blood-supply to the liver was then interrupted by means of a clamp applied across the hepatoduodenal ligament to occlude the portal vein and hepatic artery as they entered the porta hepatis. In 4 dogs hepatic circulatory arrest was maintained for 20 minutes, this being the accepted maximum 'safe period' for normothermic ischaemia of the liver in dogs. The fifth dog was subjected to two 10-minute periods of hepatic ischaemia which were separated by a recovery period of 90 minutes.

Blood samples were collected before, during, and immediately following the period of hepatic circulatory arrest. The animals were sacrificed at the conclusion of the experiment.

RESULTS

Serum Potassium.—*Fig.* 1 shows the serum potassium levels of blood in the pulmonary artery before, during, and following hepatic circulatory arrest. The period of hepatic ischaema in 4 dogs was 20, 20, 21, and 23½ minutes respectively.

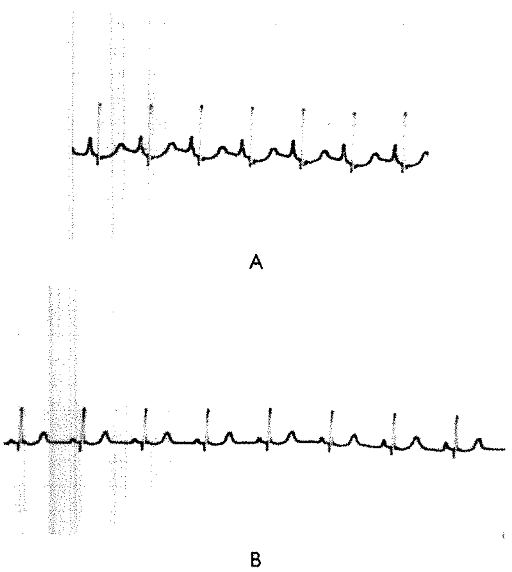

FIG. 4.—The electrocardiogram (lead II) (A) before and (B) 30 seconds following 10 minutes' hepatic circulatory arrest.

There was a small rise in serum potassium during the period of hepatic ischaemia, from 3·4 to 5·2 mEq. per l. On restoring the circulation there was a very rapid rise to high peak levels (10·8–12·7 mEq. per l.) within ½–2½ minutes. These were not maintained, however, and fell to normal limits within 5–10 minutes, remaining so for 1 hour. From this three factors emerge:—

1. The circulating serum potassium rose rapidly to cardiotoxic levels immediately following 20 minutes' stasis of the hepatic circulation.
2. This hyperkalaemia was transient and would have been missed if sampling were delayed by 5 minutes.
3. Hyperkalaemia was more marked and of longer duration following the longer period of hepatic ischaemia.

Fig. 2 shows the potassium levels (pulmonary artery) for two 10-minute periods of ischaemia which were separated by a 90-minute period for recovery. Severe but transient hyperkalaemia is again demonstrated and, in addition, there is a more marked rise during rather than following the second period of ischaemia. This suggests two further factors:—

1. Ten minutes' arrest of the liver circulation, i.e., half of the recommended 'safe period', produced hyperkalaemia of a potentially dangerous degree.
2. One and a half hours was insufficient for full recovery of the liver, the latter releasing almost twice the quantity of potassium during the second ischaemic phase.

Fig. 3 compares the serum potassium levels in the portal vein, the pulmonary artery, and the aorta of the 2 dogs which were subjected to identical 20-minute periods of hepatic stasis. Potassium increase in the portal vein was considerable while the blood-flow was occluded, but that in the systemic circulation was negligible. On releasing the clamp there was no immediate potassium increase in the portal vein at ½ minute, as was seen in the pulmonary artery, but

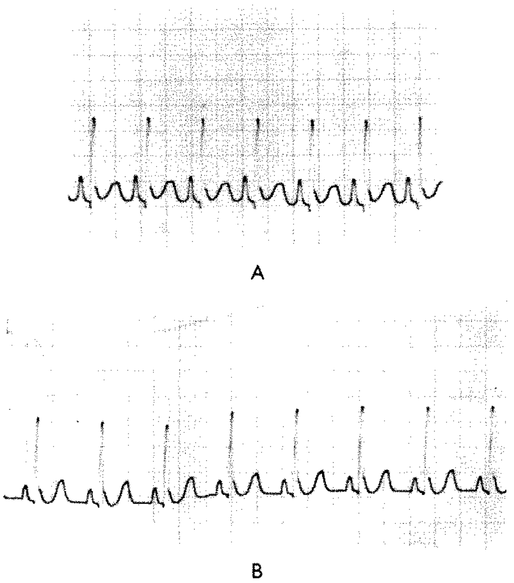

FIG. 5.—The electrocardiogram (lead II) (A) before and (B) 1 minute following 20 minutes' hepatic circulatory arrest.

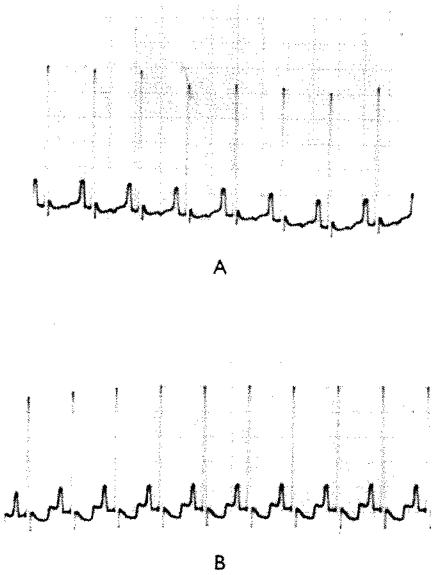

FIG. 6.—The electrocardiogram (lead II) (A) before and (B) 5 minutes following 21 minutes' hepatic circulatory arrest.

a peak followed at 1½ minutes. This sequence of events suggests that the secondary peak in the portal vein was a reflection of the systemic hyperkalaemia which was delayed by the normal circulation time from the heart to the liver. Of greater importance is the contribution of the portal venous potassium accumulation during stasis to the systemic hyperkalaemia.

Pressure in the portal vein rose from 1–8 mm. Hg to 46–95 mm. Hg when it was occluded. The intestines became congested, and 2 of the 4 dogs developed extensive petechial haemorrhages in the mesentery and small bowel. Blood samples from the portal vein during this period (and from the pulmonary artery on release of the clamps) showed variable degrees of haemolysis. (The haemolysis was of no significance to the potassium estimation because the potassium content of red cells in the dog is negligible (Stewart and others, 1953).) Jolly and Foster (1963) and Grana, Saldana, Donnellan, and Swenson (1968) have shown that intestinal congestion may be avoided by a portacaval shunt, but this does not diminish the potassium concentration in the hepatic veins. Flink and others (1950) showed, in addition to the release of potassium by ischaemic liver cells, the immediate uptake of potassium by the same cells when they were reoxygenated. Thus, it is unlikely that the portal hyperkalaemia contributes significantly to that of the systemic circulation which has been described.

The peak potassium level which was measured in the abdominal aorta was lower than that in the pulmonary artery. This was to be expected as a result of dilution during pulmonary circulation, the potassium concentration of the blood perfusing the coronary vessels lying between the two levels.

Electrocardiographic Changes.—Complete electrocardiogram (E.C.G.) records (*Figs.* 4, 5, 6) were available in 3 of the 5 experiments, each of them showing features of hyperkalaemia: reduced P wave, tented T wave, increased Q–T interval, and loss of U wave (*Fig.* 4), and diminished P wave, 'tented' T wave, and S–T depression (*Fig.* 6). These changes developed a few seconds after restoring the hepatic circulation and persisted for approximately 10 minutes. It should be noted that the changes in *Fig.* 4 occurred after only 10 minutes' ischaemia.

Tanturi, Mejia, Canepa, and Gomez (1960) investigated the electrocardiographic changes resulting from the temporary occlusion of the portal vein of the dog, and they reported marked signs of cardiac ischaemia but failed to mention any signs of hyperkalaemia. In the experiments reported here some cardiac ischaemic changes were seen while the hepatic circulation was arrested, but the E.C.G. reverted to normal on restoring the blood-flow and then developed the signs of raised potassium a few seconds later.

CONCLUSION

It is clear that temporary occlusion of the hepatic artery and portal vein in the dog causes transient but severe hyperkalaemia of a sufficient degree to cause cardiotoxicity, even when the duration of circulatory arrest is only 10 minutes. It has not been possible to undertake similar measurements on patients who have been subjected to this operative procedure, but it would be reasonable to expect a similar effect.

Thus, the suggestion of Anastasia and others (1967) that the currently accepted limits of hepatic ischaemia be extended cannot be endorsed. Rather, an alternative method of haemorrhage control should be sought.

Acknowledgements.—I am grateful to Lord Brock, Director of the Department of Surgical Sciences, Royal College of Surgeons of England, for providing the facilities for this investigation. I would also like to thank Miss M. Jacques and Mr. J. Manders for their technical assistance, the staff of the Clinical Pathology Department, Royal Marsden Hospital, for performing the potassium estimations, and Mr. D. M. Wallace, Consultant Surgeon, Royal Marsden Hospital, for his encouragement.

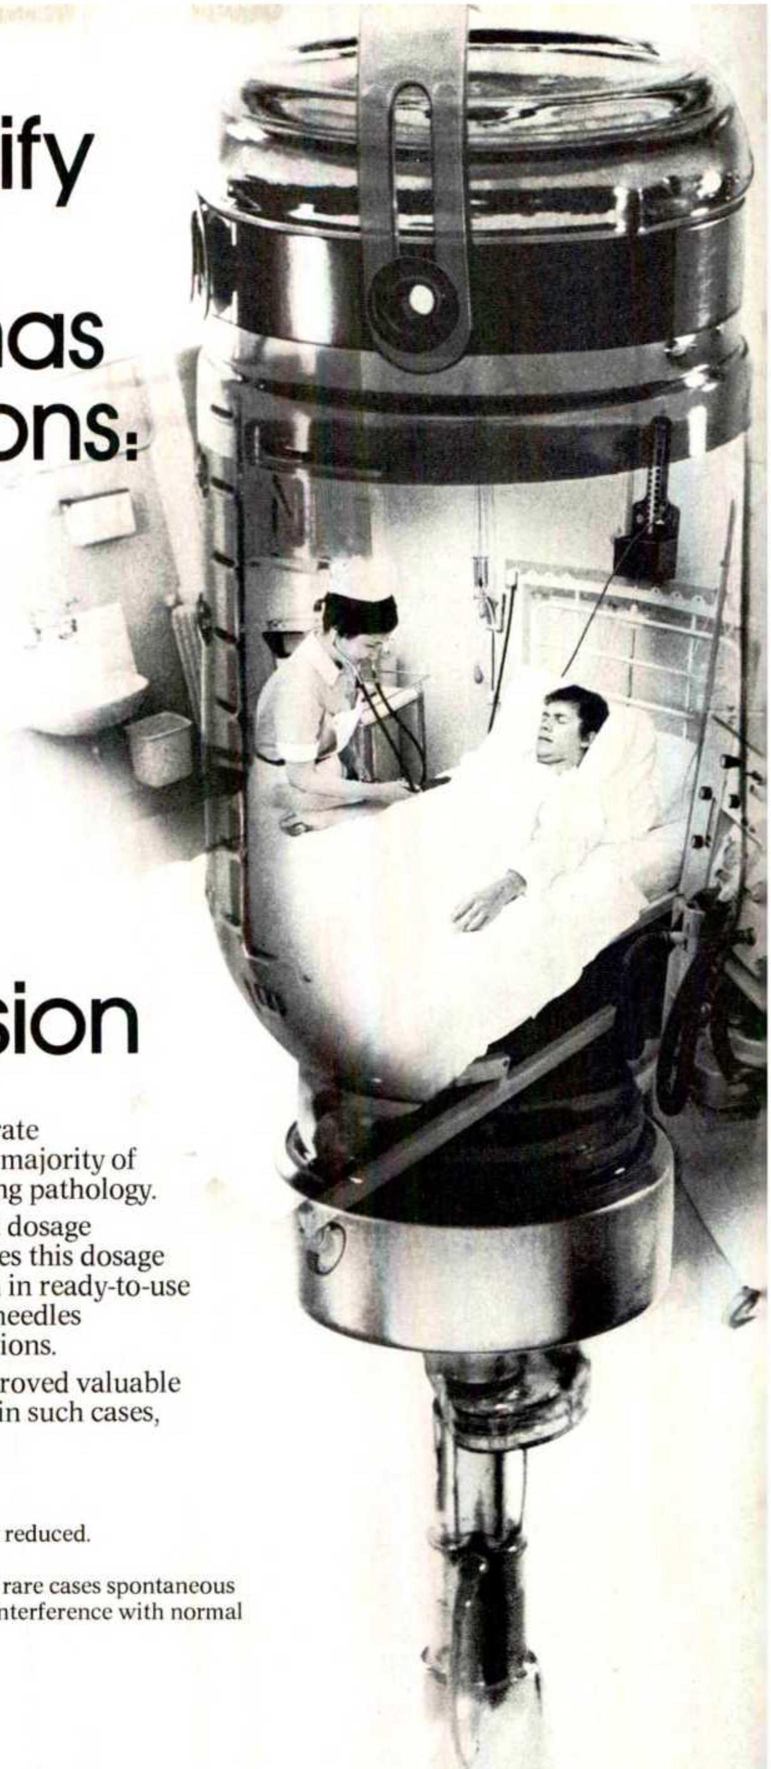
Now, to simplify treatment of pseudomonas chest infections:



Pyopen infusion

n the published papers, Pyopen's success rate n chest infections is 65% even though the majority of he patients described had severe underlying pathology.

The best results have been achieved with a dosage of 20-30G. I.V. daily. Pyopen infusion makes this dosage simpler to administer by providing Pyopen in ready-to-use nfusion bottles with diluent and transfer needles or the easier preparation of infusion solutions.

Pyopen is, of course, a penicillin, and has proved valuable n patients with known renal impairment: in such cases, however, dosage should be reduced.

dult dosage: 20-30G. I.V. daily.
n patients with renal impairment dosage should be reduced.
ontra-indications: Penicillin hypersensitivity.
ide-effects: As with other injectable penicillins. In rare cases spontaneous kin and mucous membrane haemorrhages due to interference with normal lotting mechanisms have been reported.

Pyopen

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

morphine without vomiting

CYCLIMORPH* provides the benefits of morphine without the distressing side-effect of vomiting because, in addition to morphine, it contains the rapid-acting anti-emetic cyclizine.

CYCLIMORPH is indicated whenever the benefits of morphine are required, especially where nausea and vomiting would be harmful, as in myocardial infarction, pre-operative medication, post-operative pain and debilitated patients.

Cyclimorph

CYCLIMORPH Injection is subject to the DDA. It is issued in two strengths:
CYCLIMORPH 10 containing Morphine Tartrate (10mg) and Cyclizine Tartrate (50mg);
CYCLIMORPH 15 containing Morphine Tartrate (15mg) and Cyclizine Tartrate (50mg).
Full information is available on request.

OMENTAL REINFORCEMENT OF INTESTINAL ANASTOMOSES

AN EXPERIMENTAL STUDY IN THE RABBIT

By D. C. CARTER, D. H. R. JENKINS,* and H. N. WHITFIELD†
DEPARTMENT OF CLINICAL SURGERY, UNIVERSITY OF EDINBURGH

SUMMARY

1. A series of end-to-end everting colonic anastomoses were performed in 95 rabbits in order to assess the value of omental reinforcement. The animals were divided into three groups: (*a*) control animals, (*b*) animals with anastomoses reinforced by a free omental graft, and (*c*) animals with anastomoses reinforced by an omental pedicle.

2. Reinforcement with a free omental graft carried a prohibitive increase in mortality. The use of an omental pedicle appeared to strengthen the anastomosis against forced disruption in the immediate postoperative period but it did not improve the survival rates and it may carry long-term dangers. The explanation for these findings is discussed.

3. It is our view that there is no place for omental reinforcement in colonic surgery.

THE natural protective powers of the omentum are well recognized. As Freeman (1916) observed: 'a well known function of the omentum is its almost intelligent ability to seek out and attach itself to raw or inflamed surfaces, wrapping itself around them in such a way as to afford a maximum of protection'. The artificial use of the omentum in the deliberate reinforcement of end-to-end intestinal anastomoses was first advocated by Tietze (1876), and the majority of subsequent reports have favoured the use of free or pedicled omental grafts in hazardous areas of gastro-intestinal surgery (Senn, 1888; Scudder, 1908; Sweet, Chaney, and Wilson, 1915; Finton and Peet, 1919; Bothe, 1929; Devine, 1946; Chester, Bell, and McCorkle, 1949). Nevertheless, sporadic reports have appeared which conflict with this majority view. Springer (1906) could find no special advantages in the use of free omental grafts to reinforce small intestinal anastomoses in the dog and could envisage no indications for their use in practical surgery. Wilkie (1911) was unfavourably impressed by the propensity of free grafts to form extensive adhesions, while Lexer (1924) concluded from extensive clinical and experimental observations that necrosis of the transplanted tissue was inevitable and that free transplantation of the peritoneum should not be performed either within or outside the peritoneal cavity. On the other hand, Pettet, Judd, and Woolner (1956) considered that free grafts will usually survive and provide some reinforcement of an anastomosis, although they agreed that their use within the peritoneal cavity was limited by dense adhesion formation. Kleinsasser, Cramer, and Warshaw (1950) found no particular advantage in omental reinforcement of end-to-end anastomoses in the oesophagus of the dog, while Goldsmith, Andrew, and Randall (1968) found omental pedicles to be of value in this experimental situation and worthy of further clinical trial.

While there may be little ground for concern as to the security of end-to-end anastomoses in viable small intestine in human surgery, the same cannot be said to apply to large-bowel anastomoses. Goligher, Graham, and de Dombal (1970) and Goligher, Morris, McAdam, de Dombal, and Johnston (1970) have drawn attention to the frequency with which leakage may occur in the latter situation, in some cases with fatal results and at least a significant increase in morbidity.

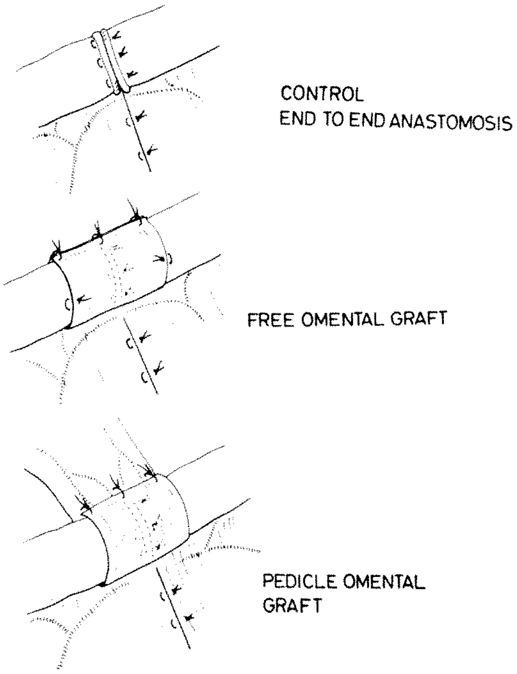

FIG. 1.—Technique of anastomosis and omental reinforcement.

It is valuable, therefore, to re-examine the whole problem of free and pedical omental grafts in an animal model where leakage from a colonic anastomosis might be anticipated, and in this way to determine the relative value of the techniques and their possible role in human surgery.

MATERIALS AND METHODS

Experiments were performed on a total of 95 rabbits of the New Zealand white strain. The animals were not starved prior to operation and no attempts were made to sterilize the bowel lumen or to achieve purgation of the intestinal contents. Anaesthesia was induced by intravenous Nembutal (24 mg. per kg. body-weight) and was maintained by nitrous oxide (1·5 litres per minute), halothane (0·5 per cent), and oxygen (0·75 litre per minute), using an open circuit.

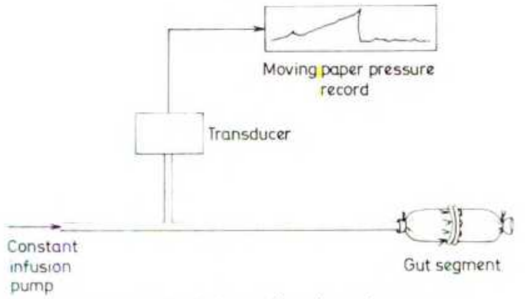

FIG. 2.—Method of recording disruption pressure.

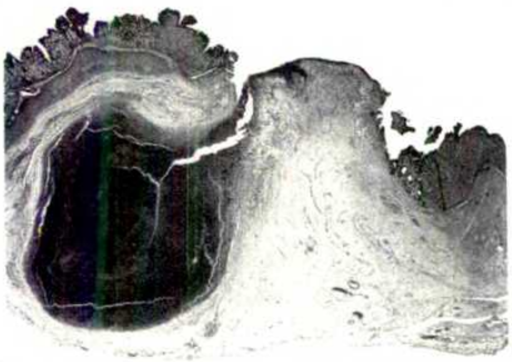

FIG. 4.—Peri-anastomotic abscess as seen at 7 days (free-graft group). H. and E. (× 5·7.)

The abdomen was opened through a longitudinal midline incision and the ascending colon was identified. The marginal artery was ligated at two points, 1 cm. apart, on either side of the proposed line of anastomosis, and the bowel was then divided transversely between occlusion clamps. An end-to-end everting anastomosis was performed using interrupted sutures of 00000 silk (*Fig.* 1). The occlusion clamps were removed and any gross defects in intestinal continuity were closed by additional sutures. No drains were led down to the anastomosis and no topical or systemic antibiotics were used.

The animals were then allocated to one of three groups in a sequential manner:—

Control Group (26 Rabbits).—On satisfactory completion of the anastomosis the mesenteric defect was closed with interrupted 00000 silk sutures and the abdomen was closed with a double layer of 000 continuous chromic catgut.

Free Omental Graft Group (41 Rabbits).—Prior to closure of the mesenteric defect a strip of the free border of the greater omentum was removed between haemostats and was applied around the anastomosis (*Fig.* 1). Adherence between the omentum and the intestinal serosa was reinforced by interrupted sutures at the proximal and distal margins of the graft, care being taken not to enter the bowel lumen while placing these additional sutures. Closure was then instituted as in the control group.

Omental Pedicle Graft Group (28 Rabbits).—The anastomosis was reinforced in this group of animals by wrapping the free border of the greater omentum around the anastomosis, as shown in *Fig.* 1, without interruption of the omental blood-supply. Closure was carried out as in the control group.

ASSESSMENT OF RESULTS

Histological Assessment.—One animal in each group was sacrificed at 6 hours, and 1, 3, 7, 14, and 21 days after completion of the anastomosis, solely for histological assessment with light microscopy using standard histological techniques.

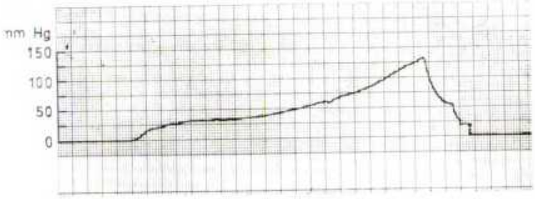

FIG. 3.—Typical disruption tracing.

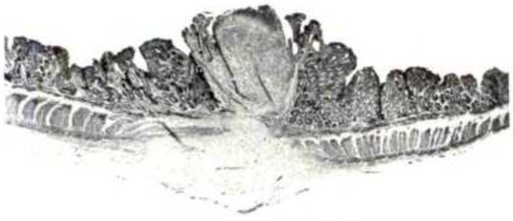

FIG. 5.—Restoration of mural continuity by fibrous tissue as seen at 21 days (pedicle-graft group). H. and E. (× 10.)

Pressure Studies.—Three animals in each group were sacrificed at 1, 3, 7, 14, 21, and 28 days after completion of the anastomosis. A standard 10-cm. length of bowel including the anastomosis was removed, surrounding adhesions being preserved by an *en bloc* removal of neighbouring adherent structures where necessary. The distal end of the colon was sealed by a ligature and an open-tipped catheter was tied into the proximal end. The catheter was connected to a Harvard constant-infusion pump (Model 901, infusion rate 3·82 ml. per minute), and by an open three-way connexion to a Sanborn Differential Pressure Transducer No. 267BC (*Fig.* 2). Disruption of the anastomosis resulted in visible leakage of the contents of the intestine and was reflected by a sudden fall in pressure in the transducer and its associated pen recorder (*Fig.* 3). The mean bursting pressure for the three values recorded on each day within the three groups was then calculated.

Deaths.—The success or failure of omental reinforcement was judged ultimately by the number of deaths occurring within each experimental programme. To provide the necessary number of animals for pressure and histological studies, additional experiments were performed in each group to replace animals dying before the appointed day of sacrifice.

RESULTS

Histological Assessment.—The potential gap between the everted ends of anastomoses in the control animals was plugged by fibrinous exudate within 6 hours of operation, and by 24 hours the sealing thrombus became covered by a layer of cells of serosal appearance. The characteristic changes of acute inflammation were observed in all animals. Although both the free and pedicle grafts remained viable in the material examined, partial degeneration of the graft with destruction of the omental fat invariably occurred around the anastomosis. This increased the inflammatory reaction and delayed the rate of subsequent organization in the reinforced groups. Occasional giant cells were seen in later sections from all groups but only in the vicinity of suture material.

Table II.—NUMBER OF DEATHS

SURVIVAL	CONTROL	FREE OMENTAL GRAFT	OMENTAL PEDICLE GRAFT	TOTAL
Deaths	2	17	4	23
Survivors to day of sacrifice	24	24	24	72
Total	26	41	28	95

Table III.—TIMING OF DEATHS

TYPE OF ANASTOMOSIS	POSTOPERATIVE DAY OF DEATH	TOTAL NO. OF DEATHS
Control	5, 8	2
Free omental graft	2, 3, 3, 3, 5, 5, 6, 7, 7, 7, 8, 9, 10, 10, 11, 26, 27	17
Omental pedicle graft	5, 5, 6, 12	4
All methods	—	23

Peri-anastomotic abscesses were noted in all three groups (*Fig.* 4) but were more extensive in the presence of an omental barrier. Exuberant granulation tissue was a constant feature of the organization process, and new vessel formation was not noticeably increased in animals with reinforcement by an omental pedicle. The resulting fibrous tissue bridge had restored the continuity of submucosa and muscle layers by the third week (*Fig.* 5), although regeneration of the muscle layers was not detected in the material examined. The mucosa showed an initial contraction from the suture-line in all the animals, and although reconstitution of the mucosal lining became evident the process was far from complete in all the sections taken within 21 days of operation.

Pressure Studies.—The results are set out in *Table I* and are shown diagrammatically in *Fig.* 6, where each point represents the mean of three bursting-pressure readings. The control anastomoses were slow to gain strength and on day 7 were significantly weaker than anastomoses reinforced by either free omental grafts ($t = 11{\cdot}13$, $n = 4$, $P < 0{\cdot}01$) or omental pedicles ($t = 3{\cdot}928$, $n = 4$, $P < 0{\cdot}05$). Thereafter, the bursting pressures approximate in all three groups, and the apparent superiority of the free-graft technique at 14 days is not statistically significant (free versus control group: $t = 2{\cdot}278$, $n = 4$, $P > 0{\cdot}05$; free versus pedicle group: $t = 2{\cdot}103$, $n = 4$, $P > 0{\cdot}10$).

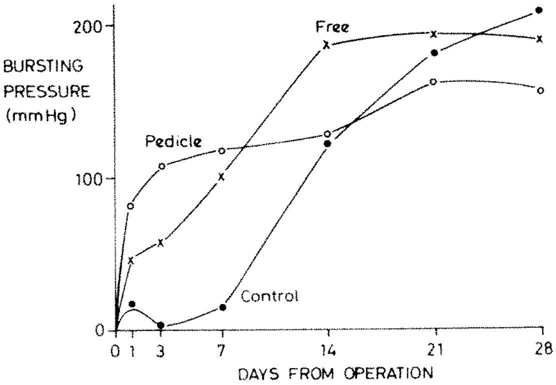

FIG. 6.—Mean anastomotic disruption pressures.

Deaths.—In order to obtain the 24 animals required for histological and pressure studies on the predetermined postoperative days a total of 26 animals had to be used in the control group. Similarly, 41 animals were needed in the free omental graft group, and 28 in the omental pedicle group (*Table II*). The number of deaths occurring in the free omental graft animals before the appointed day of sacrifice is significantly greater ($\chi^2 = 8{\cdot}93$, $P < 0{\cdot}01$) than the number of deaths in the control group. *Table III* shows the number of days elapsing between operation and the number of deaths in all three groups. In all the animals anastomotic leakage appeared to make a major contribution to death. Adhesion formation was difficult to assess at autopsy but was noticeably lacking in the immediate postoperative period in the free omental graft group. Of the 2 animals dying on the twenty-sixth and twenty-seventh postoperative days within this group, both showed extensive adhesion formation, and in 1 animal this had resulted in intestinal obstruction.

DISCUSSION

Despite an initial impression favouring the use of everting intestinal anastomoses (Getzen, 1966; Getzen, Roe, and Holloway, 1966; Healey, McBride, and Gallagher, 1967) the weight of surgical opinion has remained in favour of conventional inverting techniques. The recent publication from Goligher, Morris, and others (1970) has reinforced the conclusions reached in later animal experiments (Hargreaves and Keddie, 1968; Gill, Fraser, Carter, and

Hill, 1969; Garner, Hargreaves, and Keddie, 1969; McAdams, Meikle, and Medina, 1969; Rusca, Bornside, and Cohn, 1969) and leaves little doubt that everted anastomoses carry a higher risk of morbidity and even mortality from anastomotic leakage. For this reason a single-layer everting anastomosis was adopted in the present experiment and the possibility of leakage was increased further by the deliberate avoidance of bowel preparation in any form.

The most striking feature of the present experiment is the high mortality observed in the free omental graft group, despite an increased resistance to forced disruption in the immediate postoperative period in those animals surviving to the specified day of sacrifice. Contrary to the conclusions of Lexer (1924), we would agree with Bothe (1929) and Pettet and others (1956) that death of the transplanted tissue is not inevitable and at least part of the graft remains viable. However, survival is invariably offset by an intense inflammatory reaction and necrosis. Thus, while an omental graft might confer an added mechanical protection against forced disruption of the suture-line, it is unlikely that the graft, itself partially degenerate, could mount an effective biological response to major anastomotic leakage, should this occur.

In a series of animal experiments Laufman and Method (1948) reported that the absorbable materials, geletin sponge and oxidized cellulose, were deleterious to survival when applied around colonic anastomoses and suggested that the materials acted as an isolated bacteriological culture medium. Similarly, Trowbridge and Howes (1967) found that urethane-foam-reinforced anastomoses in the dog colon withstood lower disruption pressures than controls, unless the material was impregnated with neomycin. Canalis and Ravitch (1968) have shown conclusively that wrapping an everted intestinal anastomosis with an inert material such as polyethylene film or Silastic is almost invariably followed by anastomotic leakage, which leads on to abscess formation, generalized peritonitis, and death of the animal. Mellish, Ty, and Keller (1968) found that an inert silicone rubber membrane produced little or no adhesive reaction when applied around unopened bowel in the rat. When the membrane was sutured around an everting small-bowel anastomosis all 20 animals died from generalized peritonitis, the anastomoses failing to heal and there being no adhesion formation. Even in a similar group of membrane-wrapped inverting anastomoses the technique carried a prohibitive mortality, 8 out 19 animals succumbing to generalized peritonitis. All of these experiments indicate that any method of preventing adhesion formation by separating the anastomosis from the peritoneal cavity results in a serious impairment of the normal healing process and a definite increase in anastomotic breakdown and generalized peritonitis.

Although the degree of adhesion formation is difficult to quantify, it is our impression that in the immediate postoperative period a free omental graft behaves to some extent as an inert membrane, in that the biological defences contained in peritoneal adhesions may be denied adequate early access to the immediate suture-line. Thus, in the presence of significant anastomotic leakage a major infection could develop behind the omental barrier, protected from the natural defence mechanisms until established and in many cases overwhelming. The eventual destruction of the omental graft would release large quantities of contaminated material into the peritoneal cavity. Even if the animal survives the postoperative period, the presence of extensive adhesions within the peritoneal cavity could now only be detrimental to long-term survival. This sequence of events would explain the observations of Wilkie (1911) and Pettet and others (1956) on the long-term dangers of adhesion formation in association with free omental graft reinforcement of intestinal anastomoses.

In our experience the marginal strengthening of colonic anastomoses attributable to free omental grafts in surviving animals is far outweighed by the attendant mortality and potential long-term dangers of extensive adhesion formation.

The use of an omental pedicle appears much less dangerous in the present experiment and also results in an increased resistance to forced disruption in the immediate postoperative period (*Fig.* 6). While persistent viability of the pedicle seems assured, the attractive theoretical advantage of an immediate increase in blood-supply to the area of the suture-line was not apparent in our survival figures. As shown in *Table II*, the omental pedicle group of animals ultimately fared no better than the control animals in this respect. In the absence of any striking effects on survival, the omental pedicle does not appear to be a useful adjunct to routine colon surgery and could conceivably predispose to intestinal obstruction.

While the present experiment might be criticized in its failure to examine the problems arising from omental reinforcement of anastomoses performed in the conventional inverting manner, it seems unlikely that the events following leakage from an inverted anastomosis would differ markedly from those reported here. It is probable that free omental grafts would again fail in exactly the group of patients that they are designed to protect, namely, patients with significant anastomotic leakage. Again the experiment might be criticized in its failure to investigate the problems of distal colonic surgery. While this may justify a further experimental series, it seems certain that if omental grafting fails to improve the results of right-sided colonic surgery, its effects on more distal colonic anastomoses will be even more disastrous. We believe that the natural protective powers of the omentum are best left undisturbed by operative interference and that omental reinforcement is unjustified in any area of colonic surgery at the present time.

THE ROUTINE USE OF ULTRASOUND FOR THE DIAGNOSIS OF POSTOPERATIVE DEEP-VEIN THROMBOSIS IN A DISTRICT GENERAL HOSPITAL

By R. F. McILROY*

SURGICAL REGISTRAR, KENT AND CANTERBURY HOSPITAL, CANTERBURY, KENT

SUMMARY

The results of 6 months' experience in routine screening for deep-vein thrombosis in all postoperative patients in a district general hospital are presented. Clinical methods and ultrasound diagnosis are compared. Ultrasound was found to be easy and safe to use and to be more accurate than clinical methods. A case is made for the use of ultrasound as a routine method of screening postoperative patients for deep-vein thrombosis.

The diagnosis of postoperative deep-vein thrombosis is a problem that continues to tax all those involved in the care of surgical patients. In 1951 McLachlin and Patterson reviewed venous thrombosis and pulmonary embolism. They stated: 'A clinical test which may help in the detection of thrombi in this area is urgently needed.' Twenty years later the need is still as urgent, and up until now has not been fully met.

There is almost universal agreement that the classic clinical signs of an elevated temperature on the tenth postoperative day, pain in the calf, calf tenderness, ankle oedema, and a positive Homan's sign can no longer be regarded as diagnostic, and often the first sign of deep-vein thrombosis is pulmonary embolism.

Routine use of ultrasound offers a convenient and accurate method of diagnosing deep-vein thrombosis. Using this technique, it was decided to examine daily all postoperative cases in a district general hospital with two aims:—

1. To ascertain the incidence of deep-vein thrombosis.
2. To see if it was feasible in terms of time and workload to examine routinely all patients in this way.

MATERIALS AND METHODS

The machine used was a Sonicaid D.205 (*Fig.* 1). This has the advantage of simplicity of operation, as well as being portable, inexpensive, and totally safe to the patient. The machine consists of a transmitter operated at 2 MHz, a receiver, an audio-amplifier, and a loudspeaker contained in a case approximately 30 × 20 × 7·5 cm. and weighing 9–13·5 kg. which can easily be carried from bed to bed. A transducer containing two ceramic crystals, one of which emits ultrasound and the other acting as a receiver, is connected to the case by a detachable lead. Usually the examiner listens for a 'whooshing' sound, although, if desired, permanent recordings can be obtained by connecting a lead from a pen-recorder to the transmitter, or, alternatively, if he does not wish the patient to hear the sound, the examiner can listen through a set of headphones.

The femoral artery is first located with the transducer by the characteristic pulsatile sound of major arterial flow, and the transducer is moved medially over the femoral vein, the calf is squeezed, and venous flow is detected by the presence of a roar. This is the so-called 'augmentation' or 'A-wave', described by Sigel, Popky, Wagner, Boland, Mapp, and Feigl (1968a). Similar observations can be made with the transducer over the inferior vena cava, the iliac veins, the femoral vein in the adductor canal, or the popliteal vein, thus localizing the site of any obstruction. Obstruction is indicated by the absence of a sound, although with practice one could recognize diminished sound compared with the other leg or with what is recognized as normal values. For the purposes of this study, thrombosis was only diagnosed by the absence of sound.

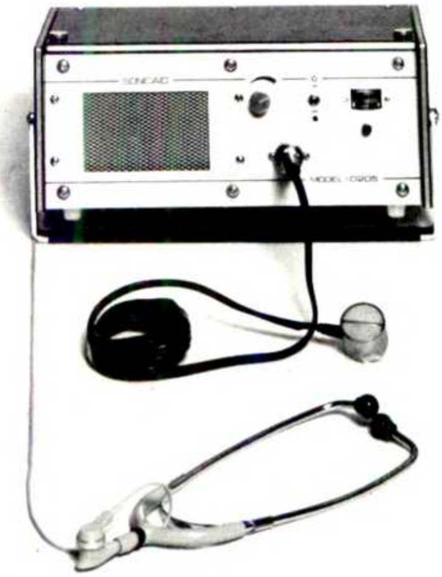

FIG. 1.—The ultrasound apparatus which was used, with probe and headphones.

Table I.—THE DIAGNOSIS OF DEEP-VEIN THROMBOSIS BY CLINICAL AND ULTRASOUND METHODS IN 322 LEGS

CLINICAL DIAGNOSIS	ULTRASOUND DIAGNOSIS		
	Normal	Positive	Total
Normal	299	9	308
Positive	7	7	14
Total	306	16	322

RESULTS

Over a 6-month period, 322 legs were examined. Only those patients undergoing surgery were included in the study. Patients who spent less than 48 hours in hospital for minor surgical procedures were excluded.

It takes only 2–3 minutes to examine patients who are sitting in bed, and this can readily be fitted into the daily round. With practice in this technique it was found that the patients in a ward with 20 beds could be examined in 30–40 minutes, and the procedure did not interfere with ward routine or add much to workload.

Table I shows that of 14 legs thought to have thrombosis on clinical grounds, only 50 per cent were confirmed by ultrasound, but a further 9 legs thought to be clinically negative were positive on ultrasound. Thus, the overall incidence of deep-vein thrombosis on routine screening of all postoperative patients was 5·19 per cent.

There were 4 patients in the series who had pulmonary emboli confirmed by clinical examination, chest radiographs, and electrocardiograms. *Table II* indicates that all of these patients were shown to have had a deep-vein thrombosis by ultrasound, whereas 2 were thought to have been negative on clinical grounds.

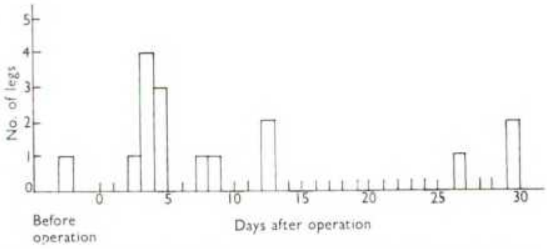

FIG. 2.—The stage at which ultrasound shows deep-vein thrombosis to be present.

Table II.—THE CORRELATION BETWEEN ULTRASOUND AND CLINICAL DIAGNOSIS IN PATIENTS DEVELOPING PULMONARY EMBOLISM

CLINICAL DIAGNOSIS	ULTRASOUND DIAGNOSIS	NO. OF PATIENTS
Positive	Negative	None
Positive	Positive	2
Negative	Positive	2

Fig. 2 shows that 50 per cent of the patients who developed deep-vein thrombosis did so on or before the fourth postoperative day. It is significant that 50 per cent of the patients who had a pulmonary embolus were in this group.

There were 4 deaths in the series, 2 from pulmonary embolism, both of whom had deep-vein thrombosis diagnosed by ultrasound. The presence of deep-vein thrombosis was confirmed at post-mortem examination in both cases. One other death was due to carcinomatosis and the fourth to a myocardial infarct. The cause of death was confirmed by post-mortem examination and neither was shown to have had deep-vein thrombosis either by ultrasound or at post-mortem examination.

DISCUSSION

It is agreed that deep-vein thrombosis presents a considerable problem in diagnosis by clinical methods. The correlation between an operative procedure and pulmonary embolism is well documented. Morrell and Dunnill (1968) reviewed the post-mortem incidence of pulmonary embolism and found that 63 per cent of postoperative deaths had had a recent pulmonary embolus compared with 45 per cent of other deaths. In their series the majority of post-operative pulmonary emboli occurred in the first week.

Deep tenderness was advocated by Murley (1950) as the most constant indication of a deep-vein thrombosis. Lowenburg (1954) stated that a sphygmomanometer cuff could be inflated to a pressure of 250 mm. Hg before discomfort was noted in a normal individual, whereas in one with deep-vein thrombosis discomfort would be experienced at 150 mm. Hg or less. However, Makin (1968) concluded that Lowenburg's test was of no value in the prediction of the likelihood of deep-vein thrombosis, or in the early diagnosis of the condition, as the response was too variable.

Phlebography (Kakkar and Flanc, 1968) and isotopic studies (Flanc, Kakkar, and Clarke, 1968; Atkins and Hawkins, 1968) have been advocated as the methods for routine screening for postoperative deep-vein thrombosis. Both methods involve the use of sophisticated and expensive equipment and require highly skilled technical staff and time. They, therefore, have certain disadvantages for routine use in a busy district general hospital.

Strandness, Schultz, Sumner, and Rushmer (1967) suggested the use of ultrasound for the diagnosis of venous disease, an idea which was expanded by Sigel and others (1968a, b) in America, and by Evans and Cockett (1969) in this country.

These two papers showed ultrasound diagnosis to be far superior to clinical diagnosis of deep-vein thrombosis, and Sigel and others (1968b) confirmed their findings by phlebography, post-mortem examination, or operation. In those with proved thrombosis, ultrasound was 86 per cent accurate compared with a clinical accuracy of 57 per cent. They also found that where clinical diagnosis and ultrasound diagnosis were at variance, ultrasound was accurate in 84 per cent of cases compared with 16 per cent for clinical diagnosis.

Evans and Cockett (1969) compared ultrasound and clinical diagnosis with phlebography or isotopic studies. Of 19 legs thought clinically to have deep-vein thrombosis, 8 were positive by ultrasound compared with 10 positive by radiographic or isotopic studies. In 19 clinically normal legs, 2 were positive by ultrasound compared with 3 positive by radiographic or isotopic methods. Similar results were obtained by Evans (1970) in a series in which there were no false-positives, and he advocated ultrasound as the routine method for screening those at risk of deep-vein thrombosis.

In the present series only half of the patients who were thought to have deep-vein thrombosis on clinical grounds were shown to have a positive deep-vein thrombosis by ultrasound. More significantly, however, over 50 per cent of those who were shown to have a deep-vein thrombosis by ultrasound were judged clinically to be negative. The overall incidence of deep-vein thrombosis on routine screening was found to be 5·19 per cent. These results correlate closely with previously reported series.

It is again emphasized that deep-vein thrombosis occurs much earlier than the classic tenth postoperative day. Of those who had a positive deep-vein thrombosis, 50 per cent were positive on or before the fourth postoperative day. It is this group that is largely clinically negative and it is in this group that half of those who developed pulmonary embolism are found.

The routine use of ultrasound causes the minimum of inconvenience to the patient, and there are no contra-indications to its use to exclude deep-vein thrombosis in even seriously ill patients. The technique described takes little time to learn and the interpretation of results is simple, the presence of a venous roar or A-wave when the calf is squeezed signifying normal flow and the absence of sound indicating a thrombus. To examine postoperative patients takes little more time than would normally be spent in assessing such patients each day, and can readily be fitted into the daily routine.

Thus, after 20 years it would seem that the answer to McLachlin's plea for a simple clinical test to help in the detection of deep-vein thrombosis has been found in ultrasonics. Certainly it is time that this procedure became part of the routine management of all postoperative patients.

Acknowledgements.—I would like to thank Mr. M. R. Williams and Mr. B. G. A. Lilwall of the Kent and Canterbury Hospital for permission to investigate their patients. I would also like to thank Dr. R. J. C. Hall and Dr. A. W. Burrows for help in testing patients, and Mr. R. W. Lloyd-Davies for helpful criticism in the preparation of this paper.

The ultrasound machine was purchased with a research grant from the South East Regional Metropolitan Hospital Board.

EXTRAHEPATIC BILIARY DRAINAGE IN EXPERIMENTAL LIVER INJURY

By IRWIN FARIS*

DEPARTMENT OF SURGERY, MONASH UNIVERSITY, MELBOURNE

SUMMARY

A case has been made by many authors for the routine drainage of the biliary tract in patients with liver injuries, and this case is summarized. To test the logic of such treatment the outcome of a standard lethal injury in dogs was studied and was found not to be influenced by drainage of the common bile-duct. Survival was improved by excision of the damaged tissue. The experimental evidence does not support the practice of routine drainage of the extrahepatic biliary tract.

LIVER necrosis, subphrenic abscess, and bile fistula cause morbidity and mortality after liver injuries. Merendino, Dillard, and Cammock (1963) suggested that routine decompression of the extrahepatic biliary tree might lessen complications by decreasing the leakage of bile through the damaged liver tissue. This idea gained rapid and wide acceptance, especially in the United States, so that drainage of the common bile-duct or gall-bladder became regarded as an important part of the treatment of liver injuries (Byrne, 1964; Longmire, 1965; Madding and Kennedy, 1965; Williams and Byrne, 1966; Mays, 1971). A summary of the arguments for and against extrahepatic biliary drainage has been given by Lucas (1970). Perry and La Favre (1964) extended this concept when they suggested that extrahepatic biliary drainage might remove the need for other external drainage. Experimental support for this idea followed when Lane, Johnson, and Walker (1967) and Wasowski (1968) reported that extrahepatic biliary drainage improved the results in their experimental preparations. Lane and others (1967) suggested that tube drainage of the common bile-duct in dogs produced a significant improvement in survival over control animals.

It remains to be shown that extrahepatic biliary drainage confers any advantage over, or in addition to, formal excision of a liver injury. The latter is soundly based on established surgical principles and is more frequently possible because of adequate resuscitation and an understanding of liver surgery. This paper compares drainage and excision.

MATERIALS AND METHODS

Adult mongrel dogs, weighing 10–15 kg., were used. General anaesthesia was induced by an intravenous injection of 5 per cent thiopentone sodium and was maintained with nitrous oxide and oxygen through an endotracheal tube. Cannulae were inserted into the femoral artery and femoral vein—one for pressure measurement and the other to permit bleeding and reinfusion. The method of study employed the standard injury described by Lane and others (1967), in which a rat-trap is allowed to spring closed across the chosen lobe of the liver. In their hands (Lane and others, 1967) the injury was always lethal, but our preliminary experiments with this model resulted in the death of only 4 of 18 dogs. A combination of liver injury and bleeding was then used (a pattern that incidentally more closely resembles that of human liver injury) which without treatment was lethal.

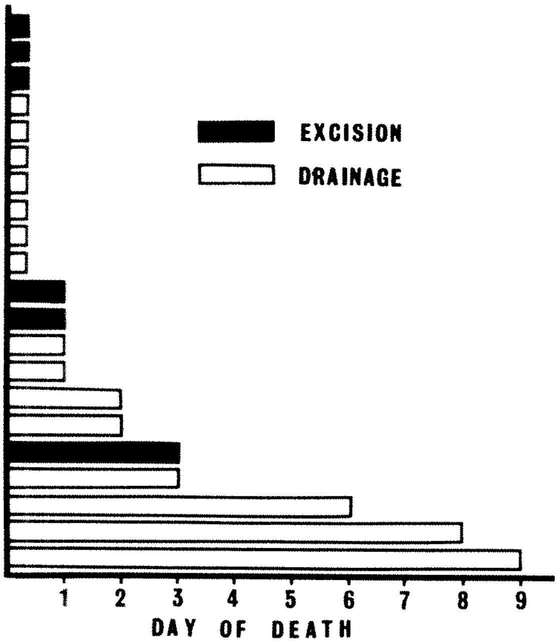

FIG. 1.—Day of death of animals, showing method of treatment. The uppermost 10 animals all died within 8 hours of operation.

Through an upper midline incision the left lateral lobe of the liver was delivered into the wound, was placed on the base of a fully opened rat-trap, and was submitted to six blows. The effect of the injury was to leave the lobe of the liver hanging by a few strands of tissue which contained blood-vessels. Bleeding was profuse initially, but soon stopped. Directly after injury, blood was run from the femoral vein cannula at a rate of 50 ml. per minute (Ehrlich, Kramer, and Watkins, 1969) until the systolic blood-pressure fell to a level of 73 ± 25·5 mm. Hg. After 1 hour an equal volume of Hartmann's solution was reinfused and the animal was randomly allocated for treatment either by drainage of the common bile-duct or by excision of the damaged tissue.

---

* Address for reprints: Department of Surgical Studies, Middlesex Hospital, London.

In those animals which were treated by drainage a Portex nylon cannula (external diameter, 2·75 mm.) was placed in the supraduodenal part of the common bile-duct. Damaged tissue was excised after clamping and ligating those structures which remained in the line of the liver wound. Good haemostasis was secured in this way. The laparotomy wound was closed and the animal was allowed to recover. Antibiotics were not given. Animals alive after 10 days were classed as survivors.

RESULTS

The outcome of these experiments is shown in *Table I*. There is a significant ($P < 0{\cdot}05$) difference between the animals which were treated by excision and those which were treated by drainage when the results are analysed using Fisher's test (Langley, 1970).

Table I.—RESULTS OF TREATMENT

TREATMENT	NO. OF ANIMALS TREATED	NO. OF ANIMALS SURVIVING
Excision	13	7
Drainage	16	1

Table II.—COMPARISON OF THE EFFECTS OF BLEEDING

TREATMENT	INITIAL BLOOD-PRESSURE (mm. Hg systolic)	BLOOD-PRESSURE AFTER BLEEDING (mm. Hg systolic)	RATIO
Excision	172 ± 25·7	78 ± 25·6	2·49 ± 0·98
Drainage	175 ± 33·4	68 ± 23·9	2·89 ± 0·79
	t	0·97	1·19
	P	$0{\cdot}40 > P > 0{\cdot}30$	$0{\cdot}30 > P > 0{\cdot}20$

Because the only objective measurement of the severity of the injury was the level to which the blood-pressure fell, this decrease has been compared between the two groups both directly and by expressing the ratio of the initial systolic blood-pressure to the systolic blood-pressure after bleeding. Student's t-test was applied to these figures and the results confirm that the groups were similarly treated (*Table II*).

The time of death of the animals is shown in *Fig.* 1, which indicates that only 1 death in an animal which was treated by excision occurred later than 24 hours after operation. In contrast, 5 deaths in the group which was treated by drainage occurred in the period from 24 hours to 9 days following operation.

We consider that these results confirm the hypothesis that drainage would not be preferable to excision as a method of treatment for liver injury.

DISCUSSION

As a treatment option in this model, excision is clearly superior to drainage, converting a lethal injury into one which has about an equal chance of death. Excision is particularly effective in preventing deaths which occur later than 24 hours after operation. This conclusion differs from that of Lane and others (1967) and Wasowski (1968). The results of Lucas, Lenaghan, and Walt (1969), although they could not be statistically analysed, support our findings; the injury that they inflicted on their animals was not lethal, but extrahepatic biliary drainage did not influence the mortality or the rate of abscess formation. However, their most important observation was that extrahepatic biliary drainage did not produce a significant fall in the extrahepatic pressure, even when the common bile-duct had been ligated. Thus, it seems unlikely on theoretical grounds that drainage will have anything to offer, a conclusion borne out by the present results.

The results described do not show whether drainage could better the outcome after excision. However, in view of the failure of drainage to reduce intrahepatic biliary pressure and the preliminary results of these two treatment options in man (Lucas and Walt, 1970), it seems unlikely that synergism would occur.

We conclude that drainage of the common bile-duct as part of the standard treatment for liver injuries is not justified.

Acknowledgement.—I am indebted to Professor Hugh Dudley for his advice and encouragement during this study.

A TECHNIQUE FOR DETECTING REJECTION EPISODES IN HUMAN TRANSPLANT RECIPIENTS USING RADIOACTIVE FIBRINOGEN*

By JOHN R. SALAMAN

CARDIFF ROYAL INFIRMARY AND WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF, WALES

SUMMARY

Radioactive ^{125}I-labelled human fibrinogen was given to 32 patients who had received renal transplants. In each case radioactivity was measured over the transplant and expressed as a percentage of the value recorded over the heart. Recipients that were experiencing rejection episodes had higher levels of radioactivity over their transplants when compared with patients who were free of rejection at the time. It is suggested that this technique could be of value in the diagnosis of rejection episodes, particularly in those recipients who remain oliguric after transplantation.

It is well recognized that fibrinogen is deposited as fibrin in the vessels of kidney transplants that are undergoing rejection. Such deposits have been found in sections taken from rejected kidney transplants (Porter, 1967; Dammin, 1968; Lindquist, Guttman, and Merrill, 1968; McKenzie and Whittington, 1968; Busch, Braun, Carpenter, Corson, Galvanek, Reynolds, Merrill, and Dammin, 1969), and fibrin degradation products have been detected in the urine of transplanted patients at times of rejection (Braun and Merrill, 1968; Antoine, Neveu, and Ward, 1969; Colman, Braun, Busch, Dammin, and Merrill, 1969; Carlsson, Hedner, Nilsson, Berkentz, and Ljungqvist, 1970; Clarkson, Morton, and Cash, 1970).

The use of ^{125}I-fibrinogen has become popular recently as a method of detecting deep-vein thrombosis in the lower limbs, and the labelled product is now freely available. In a previous report (Salaman, 1970) experiments were described in which ^{125}I-fibrinogen was given to a small group of patients with renal transplants in order to determine whether the labelled fibrin would be concentrated in the kidney at times of rejection. It was found by external scintillation counting that radioactive fibrin was indeed retained by renal transplants that were undergoing rejection, and it was suggested that this finding might be of use as a test for rejection. A larger group of patients has now been studied and the results obtained are presented here.

MATERIALS AND METHODS

Thirty-two renal transplant recipients were studied on one or more occasions after transplantation and all had consented to receiving radioactive material. Two kidneys had been obtained from living related donors and the remaining 30 were from cadavers. Details of the techniques that were used have already been published (Salaman, 1970). For each test 90–130 μc. ^{125}I-labelled human fibrinogen were injected intravenously, and counts were recorded 6 hours later and then daily from over the patient's heart, renal transplant, bladder, contralateral iliac fossa, and liver. Uptake of radioactive iodine by the thyroid was blocked by administering 50 mg. of potassium iodide daily for 2 weeks, commencing on the first day of the test. Surface radioactivity was measured in the early experiments with a semi-portable detector linked to a linear amplifier and scaler, but in later experiments a small transistorized rate-meter (Pitman Model 235) was used. On each day of the test the counts registered over the transplant were expressed as a percentage of the counts recorded over the heart. A value greater than 120 per cent was regarded as evidence that radioactive fibrin had been deposited within the kidney.

Of the 32 patients studied, 5 were investigated on two occasions and 1 was tested three times. The results will be considered in four groups.

The tests in group 1 were performed on recipients with well-functioning transplants showing no evidence of rejection. In group 2 the tests were conducted in recipients who had had good renal function previously, but who were showing signs of rejection at the time that the test was performed. These rejection episodes were diagnosed from a renal biopsy result or from an observed deterioration in renal function in the absence of any other cause. In groups 3 and 4 the tests were undertaken in recently transplanted patients who were oliguric as a result of ischaemic tubular necrosis. It could be shown from renal biopsy and other evidence that the recipients in group 3 were free of rejection, whereas those in group 4 were experiencing a rejection episode during this early postoperative period.

RESULTS

The injection of ^{125}I-fibrinogen was uncomplicated and no patient became jaundiced. Radioactivity levels in the body declined rapidly after the injection owing to the short biological half-life (±3 days) of the labelled fibrinogen (*Fig.* 1). As a result, scintillation counting became difficult and somewhat inaccurate when continued for more than 5 days, and only those readings obtained within this period have been evaluated. The highest level of 'percentage radioactivity' that was recorded for each renal transplant during this interval is that given in *Tables I–IV*.

Group 1: Functioning Transplants with No Rejection.—The results of the nine tests that were performed in this group of patients are given in *Table I*. In 5 cases the transplant radioactivity remained below that of the heart throughout the period of testing (maximum transplant radioactivity

---

* Based on a paper read to the Surgical Research Society at Cambridge on 3 July, 1970.

< 100 per cent). The readings that were obtained for *Case* 5 are shown in *Fig.* 1. In 2 patients the transplant radioactivity exceeded marginally that of the heart, and maximum values of 108 per cent were obtained. In the 2 remaining patients much higher values were found (140 and 290 per cent), although neither was thought to be undergoing rejection. Both patients had developed painful swellings in the region of their transplants at the time that the tests were performed, and it was thought likely that in each case these high readings were caused by a haematoma that had formed around the transplant. One transplant (*Case* 8) was explored subsequently and a haematoma was found.

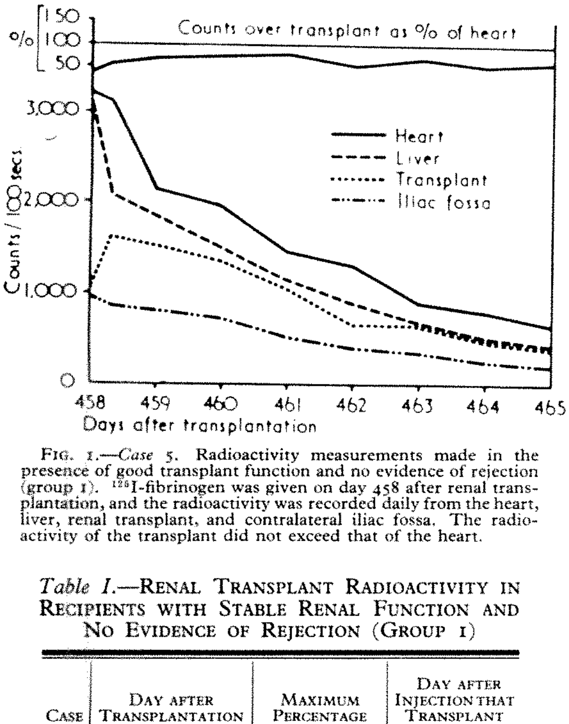

FIG. 1.—*Case* 5. Radioactivity measurements made in the presence of good transplant function and no evidence of rejection (group 1). ^{125}I-fibrinogen was given on day 458 after renal transplantation, and the radioactivity was recorded daily from the heart, liver, renal transplant, and contralateral iliac fossa. The radioactivity of the transplant did not exceed that of the heart.

8	9	140*	3
9	9	290*	2

* Patients with wound haematomata (*see* text).

Group 2: Functioning Transplants with Rejection.—The tests in this group were conducted in 11 patients who were suspected of having rejection at the time. In 7 patients there was a rapid rise in the percentage radioactivity of the transplant, and values greater than 120 per cent were recorded within 48 hours of the injection (*Table II*). These patients were given antirejection therapy, and renal function recovered in 4. Three patients failed to respond and a rejected kidney was removed a few weeks later from 2 of them. A typical result (*Case* 10) is shown in *Fig.* 2.

The 4 other patients in this group showed little or no rise in renal transplant radioactivity. One of these was receiving anticoagulant drugs at the time of the rejection episode, and the 3 others were experiencing a much more gradual deterioration in renal function that had progressed despite treatment with prednisone, antilymphocyte globulin, and graft irradiation. Histological changes in these kidneys were those of an obliterative vascular rejection in 2 and recurrent nephritis in the third.

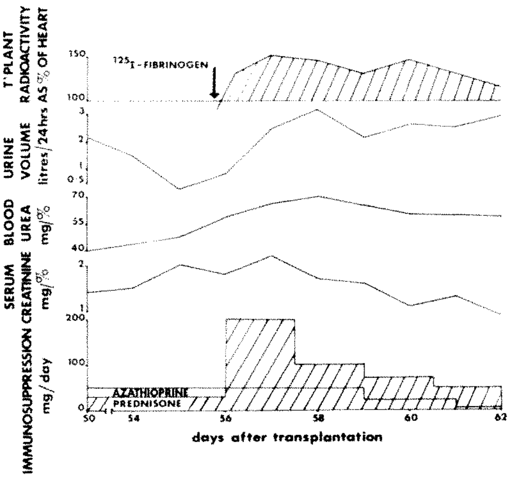

FIG. 2.—*Case* 10. Transplant radioactivity measured during an episode of acute rejection (group 2). Renal function started to deteriorate on the fifty-fifth day after transplantation and ^{125}I-fibrinogen was given on the following day. A rapid rise was observed in the percentage radioactivity of the transplant, which reached a maximum of 150 per cent in 24 hours. The rejection episode was treated successfully.

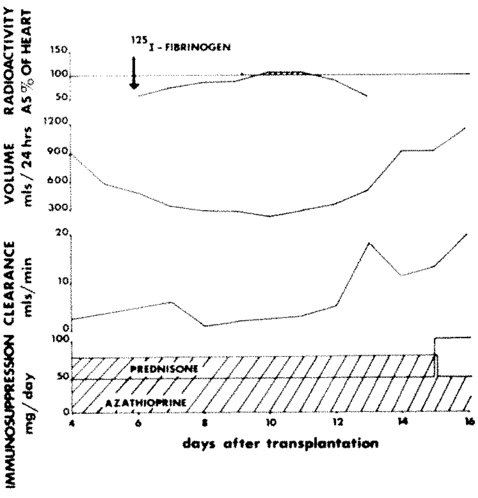

FIG. 3.—*Case* 21. Transplant radioactivity measured at a time of ischaemic tubular necrosis (group 3). Urine volume fell below 500 ml. per 24 hours on the fifth day. ^{125}I-fibrinogen was given on the sixth day, and very little concentration of radioactivity took place in the renal transplant. Renal function started to recover on the thirteenth day and no antirejection treatment was given.

Group 3: Oliguric Transplants with No Rejection.—Ten patients were examined in this group. All were oliguric as a result of ischaemic tubular necrosis, and ^{125}I-fibrinogen was given in most instances when oliguria had persisted for more than 1 week. Rejection could be discounted in 4 cases from evidence obtained by renal biopsy, and was considered to have been unlikely in the remainder when renal function returned without recourse to antirejection therapy.

Table II.—RENAL TRANSPLANT RADIOACTIVITY IN RECIPIENTS WITH REJECTION WHO HAD HAD GOOD RENAL FUNCTION PREVIOUSLY (GROUP 2)

CASE NO.	TYPE OF REJECTION	DAY AFTER TRANSPLANTATION ON WHICH TEST BEGAN	MAXIMUM PERCENTAGE RADIOACTIVITY OF TRANSPLANT	DAY AFTER INJECTION THAT TRANSPLANT RADIOACTIVITY EXCEEDED 120 PER CENT	OUTCOME AFTER ANTI-REJECTION TREATMENT

32	6	150	5	Rejection (13)	Rejected; kidney removed

* Day after transplantation on which histology was obtained is indicated in parentheses.

The results obtained in this group are given in *Table III*. The levels of radioactivity recorded from the transplants were a little higher than those in group 1, but only 1 recipient had a level that exceeded 120 per cent. The results obtained for *Case* 21 are shown in *Fig*. 3 and are typical for the group.

Group 4: Oliguric Transplants with Rejection.—The eight recipients in this group were tested when they were oliguric as a result of ischaemic tubular necrosis. In addition, rejection was suspected and was confirmed by histological examination of renal biopsies in 3 cases and by examination of the excised renal transplant in 3 others. In the remaining 2 recipients histological evidence was lacking and rejection was inferred from the fact that renal function improved within 24 hours of administering a booster dose of corticosteroids. After injection of ^{125}I-fibrinogen all 8 patients exhibited a progressive rise in the percentage radioactivity of their transplants to reach maximum levels of 135–270 per cent (*Table IV*). Detailed results obtained for *Case* 30 are shown in *Fig*. 4. This patient received a cadaveric renal transplant with a warm ischaemic time of 75 minutes. The kidney failed to excrete any urine initially and on the fifth day ^{125}I-fibrinogen was given. A slow but progressive rise was observed in the percentage transplant radioactivity, which reached a value of 165 per cent after 5 days. A biopsy was performed 2 days later which showed the features of advanced rejection (*Fig*. 5). Because of severe herpes simplex infection of the patient's face it was considered unwise to give large doses of immunosuppressive drugs, and instead the transplant was allowed to be rejected completely.

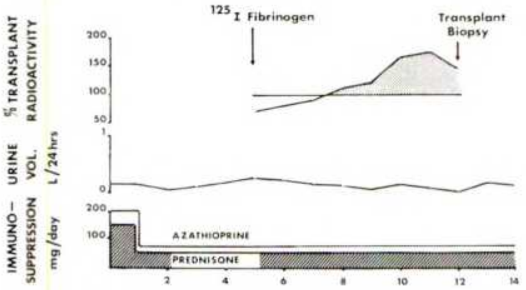

FIG. 4.—*Case* 30. Transplant radioactivity in a case of ischaemic tubular necrosis combined with rejection (group 4). A progressive rise was observed in the percentage radioactivity of the transplant.

In 1 patient (*Case* 28) a rise in transplant radioactivity occurred comparatively late after injection of the isotope, and the significance of this rise was not appreciated until rejection had become irreversible. ^{125}I-fibrinogen had been administered on the seventh day when the transplant was still oliguric as a result of ischaemic tubular necrosis. Although renal function soon showed signs of recovery the percentage transplant radioactivity began to increase steadily (*Fig*. 6). This was not recognized as an early indication of rejection until 1 week later when renal function fell once more. Antirejection treatment was instituted but this was not successful in restoring function, and soon afterwards the rejected kidney was removed.

All the patients in this group were treated for rejection once the diagnosis had been made, and the eventual outcome is recorded in *Table IV*.

DISCUSSION

The results obtained for the recipients in group 1 have shown that well-functioning kidney transplants do not take up radioactive fibrinogen from the circulation to any great extent. The 2 patients who had raised levels of transplant radioactivity were thought to have perinephric haematomata, for both had developed tender swellings beneath their operative incisions without any accompanying fall in renal function. Such a haematoma would 'trap' labelled fibrin in the vicinity of the kidney and would maintain the radioactivity at a high level whilst that in the blood would continue to fall. The resulting effect would be an apparent increase in the percentage radioactivity of the transplant.

During episodes of acute rejection the uptake of labelled fibrinogen by the renal transplant was increased, and this accords with the findings of others who noted fibrin deposits in histological preparations of rejected renal transplants (Lindquist and others, 1968). There was 1 patient (*Case* 16), however, who underwent an acute rejection episode without displaying any increase in the level of transplant radioactivity. This patient had been receiving an anticoagulant drug (warfarin, 4 mg. per day), which might have been a factor in producing this false-negative result, since warfarin is known to have an inhibitory effect on fibrin deposition in renal allografts which are undergoing rejection (Kincaid-Smith, 1970). Low levels of radioactivity were also found over the transplants of 3 recipients with chronic rejection or recurrent nephritis. It is known that in these conditions fibrin deposition does not occur to

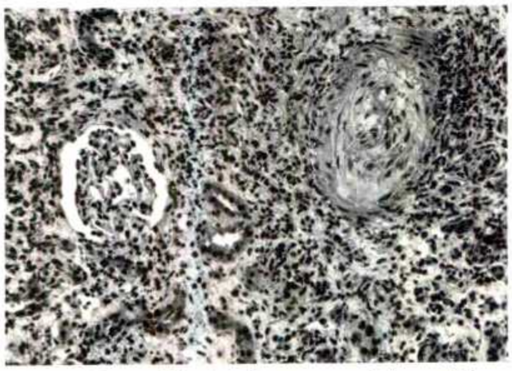

FIG. 5.—*Case* 30. Histological appearance of the renal biopsy. There is a heavy infiltration of mononuclear cells and destruction of tubules. An interlobular arteriole shows marked intimal thickening with virtual obliteration of its lumen.

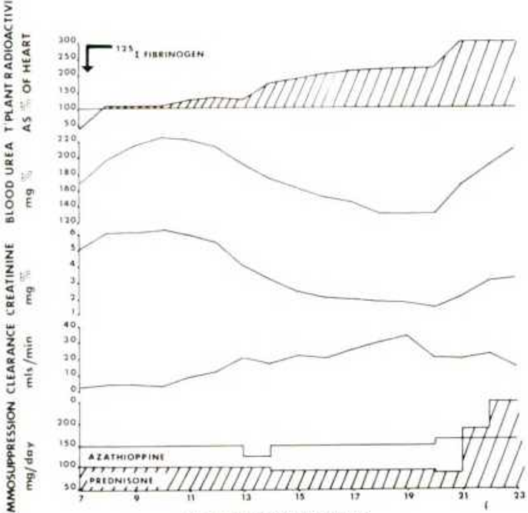

FIG. 6.—*Case* 28. Transplant radioactivity measured in a recipient who underwent rejection following an episode of ischaemic tubular necrosis (group 4). A rise in transplant radioactivity was apparent a week before rejection brought about a fall in renal function.

any great extent (McKenzie and Whittington, 1968; Kincaid-Smith, 1970), and it is quite possible that such small deposits of fibrin may not be detected by this technique.

The period of oliguria which frequently follows cadaveric renal transplantation is a difficult time for the clinician, as rejection is not easy to detect and kidneys may be lost as a consequence. The test described above has been of value in this situation (groups 3 and 4), and the false-positive rate has been acceptably low (1 case). There were no false-negative results, and the raised levels of transplant radioactivity that were observed were related to rejection episodes and were frequently the first indication that such episodes were taking place.

Not infrequently we have observed oliguria in the second week of transplantation after an initial period of renal function. An example is shown in *Fig.* 3. Our previous practice has been to treat all such cases as rejection, but by using ^{125}I-fibrinogen we have now found it possible to differentiate rejection from 'delayed' tubular necrosis and in this way avoid prescribing large, potentially harmful doses of drugs to patients who do not require them.

The ^{125}I-labelled fibrinogen test would appear to be devoid of complications and the results of this trial suggest that it could become a useful tool in the management of renal transplant recipients.

Acknowledgements.—I would like to thank Professor J. P. Blandy and Mr. D. L. Crosby for permission to report patients under their care.

ABDOMINAL WOUND INFECTIONS AND PLASTIC WOUND GUARDS

BY J. ALEXANDER WILLIAMS, G. D. OATES, P. P. BROWN, D. W. BURDEN, JANE McCALL,
A. G. HUTCHISON, AND LORNA J. LEES

THE GENERAL HOSPITAL, BIRMINGHAM

SUMMARY

A study is reported of the influence of plastic wound protectors on the incidence of wound infection in patients having abdominal operations involving the opening of the alimentary tract or biliary system.

Of 167 patients, 84 were randomly allocated to a group in which Vi-Drape wound protectors were used during the operation. In the whole series there was a low incidence of wound infection (12 per cent), but no difference was found between those who had plastic wound protectors and those who did not.

INFECTION in surgical wounds often results from organisms contaminating the wound at the time of operation. These organisms can come from the members of the surgical team, from the operating-room atmosphere, from the patient's skin, or from the organisms in the patient's alimentary tract. The high incidence of wound infection after abdominal surgery, and in particular after operations on the large bowel, suggests that contamination with organisms from the alimentary tract plays an important part. For this reason it would seem wise to protect the wound edges in order to minimize the risk of contamination. Protection with permeable wound guards is likely to be ineffective as these merely act as wicks, dipping into the wound and ensuring prolonged contact between the wound and the organisms. An impervious type of wound guard theoretically offers the greatest chance of protecting the wound edges, and it also has the theoretical advantage of preventing desiccation of the wound edge during the operation and reducing the physical trauma of damage to the wound edge by instruments and handling. The theoretical disadvantage is that infected intraperitoneal fluid may track up around the outside of the plastic drape by capillary action and so contaminate the wound, and also that organisms from the patient's own skin may similarly track along to the wound edge.

Impervious self-retaining wound liners have been produced in convenient sterile packs for use during laparotomy, and there have been enthusiastic reports about their efficacy in reducing the rate of wound infection (Harrower, 1968; Ellis, Manz, Carlson, Humphrey, and Nicoloff, 1969). Other reports, however, have failed to demonstrate any significant reduction in abdominal wound infection when these impervious drapes have been used. The present report is of a prospective controlled trial designed to investigate the effects of the use of plastic wound drapes on the incidence of abdominal wound infection.

MATERIALS AND METHODS

The impervious wound drapes used were Vi-Drape (Parke-Davis). These are transparent plastic sheets having a central hole of 18, 23, or 28 cm. diameter, around which is fixed a semi-rigid circular collar. This collar can be squeezed flat so that the central hole in the drape is introduced into the abdominal wound. When released the collar springs back to a circle beneath the abdominal wall, holding the plastic sheet in close proximity to the wound edge.

Patients were chosen for the trial who were to have a midline or paramedian laparotomy associated with the opening of some part of the bowel or biliary tract. These patients were considered to have a high risk

Bacteriologist's comments:—

of wound contamination with intestinal organisms. The patients were all operated on by one of two surgical firms. Once the suitability for inclusion in the trial of a particular patient had been established the book of record forms (*Table I*) was consulted in order to place the patient in either the trial group, using Vi-Drape abdominal wound protectors, or the control group, using either no wound protection or standard permeable cloth wound guards. After consulting the record book, one half of a form was completed, giving the date, the patient's name, number, and ward, and the type of operation performed, but not indicating the type of wound protection used. This half of the form was detached and sent to the bacteriology department. On the other half of the form the same particulars were indicated, plus a record of the pre- and postoperative antibiotic régime, the operative diagnosis, and a note if there was any particular wound contamination. Apart from the use or non-use of the Vi-Drape abdominal wound protector, there was no other variation from the usual operative routine. Wound lavage, drainage, or local antibiotic application was used according to the judgement of the particular surgeon. Although the surgeon obviously knew which type of wound protection he had used, there was no conscious differentiation in the technique of wound closure or in the treatment of the wound.

The bacteriologist, who was informed of the entry of the patient into the trial by the receipt of the appropriate half of the form, visited the patient in the ward and inspected the wound on two separate occasions after the operation, classifying the wound as showing either no infection, mild wound infection (erythema), moderate wound infection (exudate), or severe wound infection (pus). If he considered the wound to be infected, swabs were taken for culture. The bacteriologist inspecting the wound did not know in which treatment group the patient had been included. For the first 96 patients in the trial the inspection by the bacteriologist was on the third and the seventh postoperative days. It became clear, however, that there was never any indication of infection on the third day even in those patients who later showed infection. The protocol was then altered to allow inspection on the seventh and tenth days. In those patients discharged before the tenth day it was considered that there was no infection if the wound had been normal on the seventh day and if no subsequent wound infection was reported by the patient when he returned to follow-up.

The allocation to either the trial or the control group was by random selection, and was designed to allow equality in numbers after each group of 10 cases.

Completed records were received from 170 patients, 3 of whom had died within 24 hours of operation and were therefore excluded from the analysis. Eighty-four patients were in the Vi-Drape group and 83 in the control. Seventy-five were male and 92 female, the sexes being divided equally between the two groups. The ages of the patients ranged from 16 to 92 years, the median being in the range 51–60 for both groups. There were, however, slightly more older patients in the Vi-Drape group. Of the 44 patients aged over 60, 27 (61 per cent) were in the Vi-Drape group.

The site of operation is shown in *Table II*. The operations on the stomach and duodenum were usually for peptic ulcer, there being 30 vagotomies and pyloroplasties for duodenal ulcer and 12 Billroth-I gastrectomies for gastric ulcer. Three patients had perforated duodenal ulcer. Operations on the small bowel were all for Crohn's disease, and operations on the large bowel were usually for carcinoma, although 3 were for chronic inflammatory disease of the bowel. The commonest operation on the biliary tree was cholecystectomy, which was always accompanied by an operative cholangiogram. Nine of the operations were for acute cholecystitis. There were 5 operations on the common bile-duct.

Preoperative antibiotics were administered in 41 patients: in 20 as part of preoperative bowel preparation, in 11 because of pre-existing chest infection, in 4 because of acute cholecystitis, and in the remainder for a variety of reasons, such as prophylaxis in patients with rheumatic heart disease. Antibiotics were used postoperatively in 94 patients, and in 9 this was a continuation of the antibiotic course started preoperatively. Both the preoperative and postoperative antibiotic cases were equally divided between the two treatment groups.

Table II.—THE SITE OF OPERATION

SITE OF OPERATION	NO. OF PATIENTS		
	Vi-Drape Group	Control Group	Total
Stomach and duodenum or jejunum	30	34	64
Small bowel only	3	3	6
Large bowel	20	12	32
Gall-bladder and bile-ducts	29	31	60
Other	2	3	5

Seventeen patients were recorded as having gross contamination of the wound by the intestinal contents: 4 from the perforated peptic ulcer, 9 from contamination with bile, and the remainder was due to the opening of an abdominal abscess or to leakage from the bowel. All of these patients received postoperative antibiotic therapy. Ten of the patients were in the Vi-Drape group and 7 were in the control group.

RESULTS

In the analysis of results it was decided to include all the patients with some wound infection, even those with mild infection, in the infected group. There were 20 wound infections, giving an overall infection rate of 12 per cent. Ten of these were in the Vi-Drape group (11·9 per cent) and 10 were in the control group (12 per cent). Five of these had only minor infections with wound redness but no suppuration, and 1 had infection in a gastrostomy drainage wound only and not in the main wound which was protected by the Vi-Drape. If these 6 are excluded, the incidence of infection in the remainder is 7·1 per cent (6 patients) for the Vi-Drape group and 9·7 per cent (8 patients) for the control group. Only 2 of the 20 patients were under 40 years old, while 4 were 80 years or more, showing the expected higher incidence of wound infection in older people. Since there were more older patients in the Vi-Drape group a higher incidence of wound infection in this group might have been expected. The infected wounds in relation to the operation site are shown in *Table III*, which also gives the incidence of infection for each site.

In the total series there were more large-bowel operations in the Vi-Drape group than in the control group, which in part explains the large number of wound infections in the large-bowel operations of the Vi-Drape group. Only 3 of the 17 patients with gross wound contamination at the time of operation developed a wound infection, 2 of whom were in the control group: 1 with a perforated duodenal ulcer and the other with acute cholecystitis. Only 1 out of the 10 patients with Vi-Drapes who had operative contamination developed wound infection, and this patient had carcinoma of the colon with a pericolic abscess.

Table III.—THE SITE OF OPERATION RELATED TO THE NUMBER OF INFECTED WOUNDS

SITE OF OPERATION	NO. OF INFECTED WOUNDS			PERCENTAGE INCIDENCE
	Vi-Drape Group	Control Group	Total	
Stomach and duodenum or jejunum	2	2	4	6·25
Small bowel	0	0	0	0
Large bowel	5	1	6	18·8
Gall-bladder and bile-ducts	3	5	8	13·3
Other	0	2	2	40

Table IV.—NON-INFECTION WOUND COMPLICATIONS

Vi-Drape Group (5)	*Control Group* (5)
Late haematoma; no infection	Bullae possibly due to adhesive plaster
Haematoma	Slight wound erythema (2 patients)
Dehiscence; sterile culture	Oedema of centre of wound (2 patients)
Tissue bruising	
Later development of fistula	

In addition to noting wound infection, the bacteriologist made a special mention about the wound in 10 other patients, 5 in each group. These findings are summarized in *Table IV*. In the opinion of the bacteriologist these wounds were not infected, but even if some or all of them were included with the wound-infection patients the results would not materially be affected.

DISCUSSION

Despite the facts that very stringent criteria were laid down for the diagnosis of wound infection and that the assessment was done by an independent observer, the overall incidence of wound infection in this series was low. Four other recent series are summarized in *Table V*. In by far the largest series, that recorded by Jepsen, Larson, and Thomsen (1969) from Copenhagen, 145 cases of purulent wound infection are reported in 706 operations (an incidence of 20·5 per cent).

A comparison of this series with other reported series shows some conflicting results. In a similar series to ours which was reported by Harrower (1968) a prospective trial was performed by allocating patients alternately to receive either impervious wound guards or permeable cloth wound guards after operation. In the control series of 97 patients there were 9 patients with major sepsis and 5 with minor sepsis, an overall infection rate of 15 per cent, whereas in the 127 patients who were treated with impermeable wound guards only 3 patients had wound sepsis, which was of a minor nature, an incidence of 2·4 per cent. In this report, however, no mention is made of the criteria of designation of wound infection, nor what steps were taken to ensure the objectivity of those recording the wound infection. Similar beneficial results following the use of Vi-Drape wound guards were reported by Ellis and others (1969), who allocated their patients to either control or Vi-Drape groups according to the last digit of their hospital number. In their control group they reported 30 patients with wound infection out of a total of 129 (an incidence of 23 per cent), whereas when Vi-Drape wound protectors were used there were only 4 patients with infection out of a total of 135 (an incidence of 3 per cent). Once again this report does not define wound infection or how objectivity of recording of wound infection was ensured. In another recent series by Maxwell, Ford, Peterson, and Richards (1969) a control trial was begun by treating alternate patients by either a plastic adherent skin drape alone or a plastic adherent skin drape plus a Vi-Drape wound protector. Later a third group was added in which only permeable towels were used. In a total of 202 patients having abdominal operations there were 35 wound infections (an incidence of 17·3 per cent). There were no significant differences in the wound infection rates between the three groups. With the plastic skin drape alone the incidence of wound infection was 14·6 per cent, when the plastic skin drape was used with a Vi-Drape protector the incidence was 18·2 per cent, and when skin towels alone were used the incidence was 21·8 per cent.

Table V.—SUMMARY OF RECENT SERIES INVESTIGATING WOUND INFECTION

AUTHOR	INCIDENCE OF WOUND INFECTION (per cent)				
	Site of Operation				
	Gastro-duodenal	Biliary	Bowel Small	Bowel Large	Miscellaneous abdominal
Harrower (1968)*	15	10	—	7·7	22
Ellis and others (1969)*	27	18·5	60	27	—
Maxwell and others (1969)	11	16	83	26	—
Jepsen and others (1969)	37	35	59		—
Present series	6·2	13·3	0	18·8	40†

* Only the patients in the control series are included. In both these reports the wound infection was almost absent in the plastic wound drape series.

† Only 5 patients.

The results of our study provide support for the view that plastic impermeable wound protectors do not significantly reduce the rate of wound infection in patients having abdominal operations involving an opening in the alimentary tract. However, the fact that the Vi-Drape wound protectors were used in a large number of elderly high-risk patients with an overall low incidence of wound infection suggests that there is no contra-indication to their use. Their use could be advocated in an attempt to prevent malignant cells seeding into the abdominal incision during operation for abdominal cancer (Smith and Hilberg, 1955).

During the course of this experimental trial the surgeons involved liked to use the Vi-Drape wound protectors as they kept the abdominal wound tidy and did not interfere with access or dissection.

Acknowledgements.—The Vi-Drape abdominal wound protectors were supplied by Parke, Davis and Company, who also assisted with the design of the trial and the preparation of the random selection schedule.

TREATMENT OF ARTERIOVENOUS MALFORMATION BY ENDARTERIAL ELECTROCOAGULATION

By A. M. N. GARDNER
CONSULTANT SURGEON, TORBAY HOSPITAL, TORQUAY, DEVON

AND I. A. STEWART
DEPARTMENT OF OTOLARYNGOLOGY, DUNDEE ROYAL INFIRMARY

Whether some day it may be possible by electrochemical methods safely to dehydrate one of these angiomas cannot be foretold. Harvey Cushing (1928).

Summary

The successful treatment of an arteriovenous malformation in the parotid region is described. Endarterial electrocoagulation was used and damage to the facial nerve was avoided. The possible use of this method in other situations is discussed.

Most of the congenital arteriovenous fistulae affecting the head and neck lie within the cranial cavity, but a small proportion (1 : 20) are associated purely with branches of the external carotid artery and the corresponding veins. Amongst the latter group, arteriovenous malformations in relation to the masseter muscle are well recognized (Callander, 1920). The pathogenesis of these lesions has been discussed by Holman (1968).

Many therapeutic measures have been tried and these date back at least to 1757 when William Hunter (Holman, 1968) first recognized the true nature of an 'aneurysm by anastomosis'. They include simple ligation of the main feeding vessel, occlusion of all (or as many as possible) vessels feeding or draining the malformation, injection of sclerosants, radiotherapy, and the induction of artificial emboli to occlude feeding vessels (Cushing and Bailey, 1928; Luessenhop and Spence, 1960; Pool and Potts, 1965). The more ingenious latter methods are related in general to the inaccessibility of the lesions under consideration. The general consensus of opinion would appear to be that simple ligation of the major feeding vessel is, by and large, inadequate (Cushing and Bailey, 1928; Olivecrona and Ladenheim, 1957), and that surgical extirpation is the goal to be achieved if possible. It is of interest to note that one of Cushing's cases improved following spontaneous thrombosis (Cushing and Bailey, 1928).

Uncomplicated surgical excision of lesions lying deep to the parotid is not readily achieved. Olivecrona and Ladenheim (1957) claim that their case was the first reported where excision of an arteriovenous malformation of the parotid region was accompanied by the preservation of the 7th cranial nerve. This procedure resulted in temporary facial paralysis following a 5-hour operation (Dolietis, 1949). The subject of the present report is a case of arteriovenous malformation in the same situation which has been successfully treated without injury to the 7th nerve by a simple method that has not, as far as we can ascertain, been previously described.

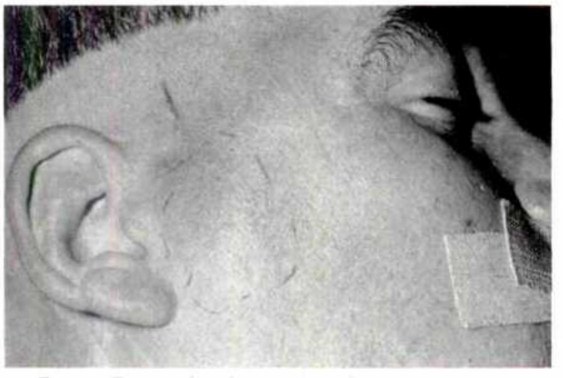

Fig. 1.—Preoperative photograph of the patient. The dotted line marks the limits of the pulsatile swelling. The vertical line above marks the position of the superficial temporal artery.

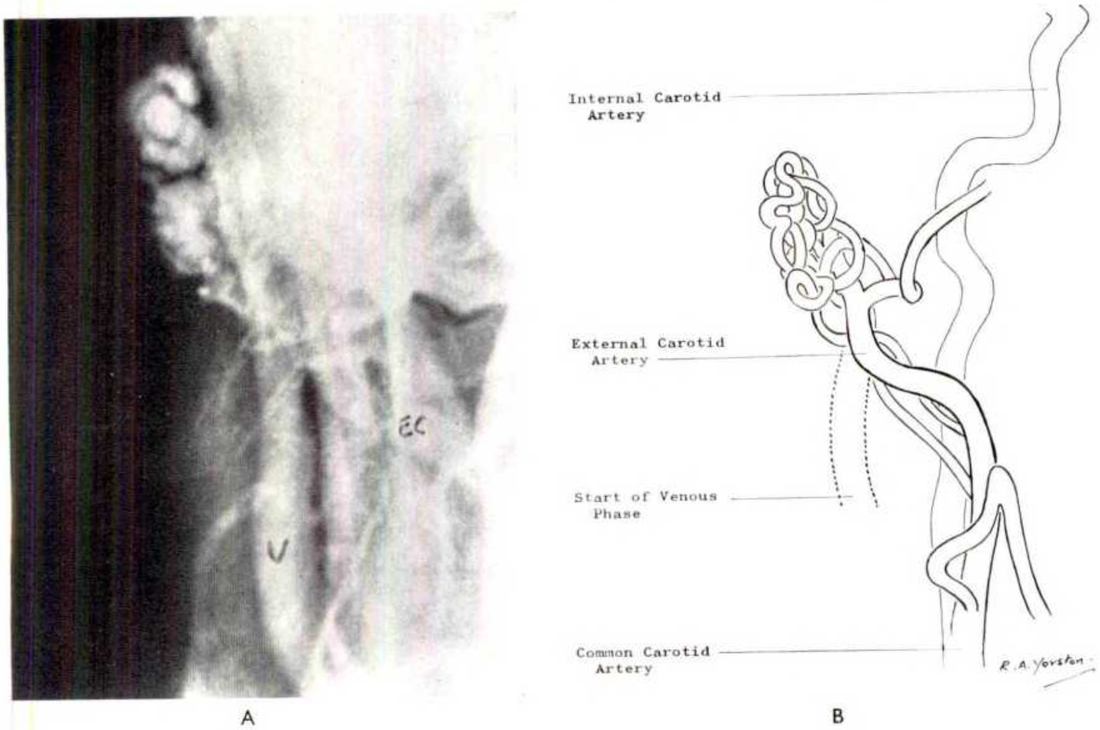
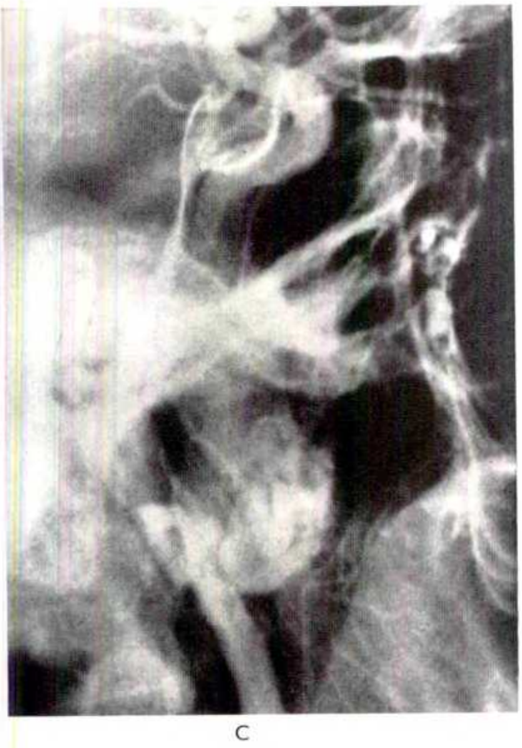
CASE REPORT

A fit 31-year-old male gave a 1-year history of distressing tinnitus, which was synchronous with his pulse, and a pulsatile swelling in front of his right ear. There was no history of trauma. Examination revealed a pulsatile swelling, 3 cm. in diameter, of the right parotid region (*Fig.* 1). Otological examination together with examination of the lower cranial nerves revealed no abnormality.

A right carotid angiogram revealed a well-demarcated arteriovenous malformation of the right parotid region. It was supplied by a greatly enlarged branch of the external carotid artery. There was early venous filling of two large





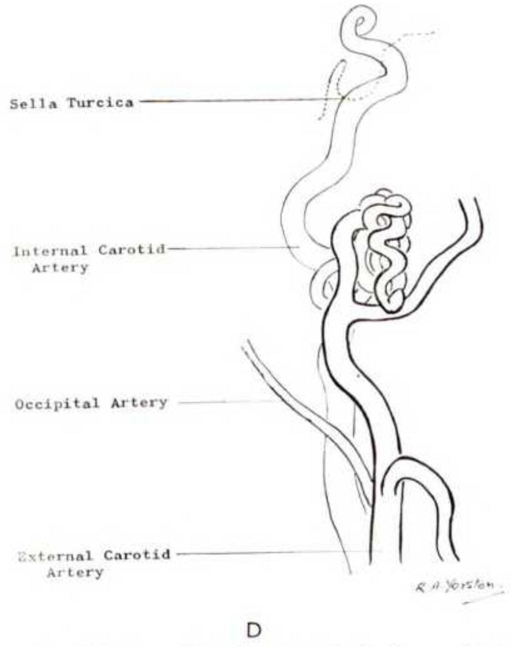


FIG. 2.—Right carotid angiograms and drawings made from tracings. The arteriovenous aneurysm in the parotid region is fed from the enlarged external carotid artery (EC) and is drained by a large vein (V). A, Anterioposterior angiogram. B, Diagram of the anterior aspect. C, Lateral angiogram. D, Diagram of the lateral aspect.

veins lateral to the mandible. No intracranial communication was demonstrated (*Fig.* 2).

In view of the relative inaccessibility of the lesion, the following surgical approach was devised. Through a crease incision the major vessels of the right side of the neck were exposed. Within the common facial vein, streams of arterial and venous blood were visible. There was a high division of the common carotid artery. After it has been established that occlusion of the termination of the external carotid artery resulted in control of the pulsation in the aneurysm, all branches of the external carotid artery peripheral to the superior thyroid were isolated and divided. A small cystodiathermy electrode was inserted into the uppermost part of the external carotid artery and was manipulated into several major feeding arteries in the malformation. The current was applied intermittently to prevent too great a local heat generation, which might have damaged local structures, particularly the facial nerve. This procedure was to some extent controlled by palpation. When endo-electrocoagulation was completed the external carotid was ligated.

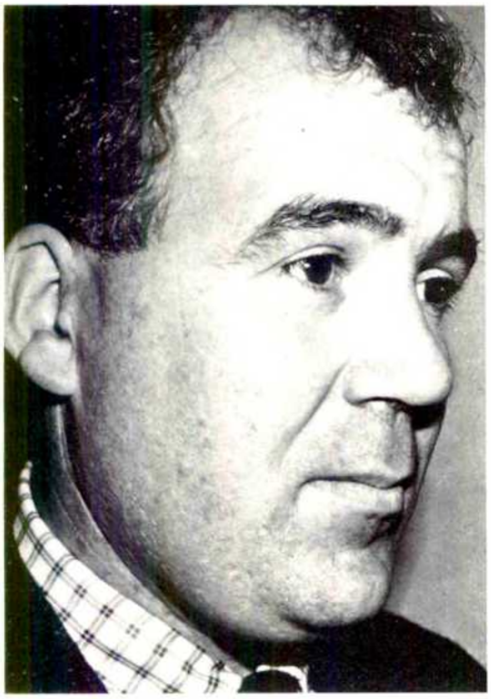

FIG. 3.—Postoperative photograph of patient. The swelling has disappeared.

Postoperatively, the tinnitus and swelling disappeared. The patient experienced trismus, suggesting that the malformation involved the masseter. Initial limitation of jaw opening soon resolved, although slight discomfort on chewing persisted for 4 months after operation. Two and a half years following the operation the patient remains well with no evidence of recurrence (*Fig.* 3).

DISCUSSION

Operation on extracerebral arteriovenous malformations is indicated for cosmetic, symptomatic, and haemodynamic reasons. The simple procedure described above would appear attractive, in that it is of a relatively minor nature and does not endanger adjacent important structures. Endo-electrocoagulation of extracerebral arteriovenous malformations is almost certainly without serious risk. This method of treatment may prove useful in some intracerebral malformations—in this situation radiological control may be desirable. The technique could also be used to coagulate the maxillary artery in conjunction with ligation of the external carotid artery for severe epistaxis.

Arteries, unlike veins, once completely blocked, seldom if ever recanalize. This different behaviour after thrombosis is attributable to the different anatomical arrangements of the blood-supply to their walls. In thrombosed arteries the vasa vasorum are necessarily occluded, whereas in thrombosed veins, blood (with fibrinolysin) can still enter the walls through the vasa venarum.

Acknowledgements.—We are indebted to Dr. H. T. Apsimon and Dr. R. A. Yorston for the angiograms and the diagrams.

SHORT NOTES OF RARE OR OBSCURE CASES

PROLAPSE OF THE ILEUM THROUGH THE RECTUM AND ANAL CANAL

BY J. H. HALL AND W. J. D. BRADFIELD
ST. THOMAS'S HOSPITAL, LONDON

SUMMARY

A case of prolapse of the ileum through a tear in the rectal wall and the anus is presented and 11 previous cases found in the literature are reviewed. The aetiology and the management of the condition are discussed.

INTRAPERITONEAL tears of the rectum are not uncommon in general surgical practice. They are frequently caused by the introduction of foreign bodies into the rectum, either by the patient himself or in the course of medical investigation. In the latter category are included perforation by a sigmoidoscope, by a barium enema (Hartman and Hills, 1957), or by a thermometer (Miller, 1962; Wilkinson, 1965).

Less frequently, intraperitoneal tears are caused by a sudden increase in intra-abdominal pressure. This can result from crush injuries, coughing, or even straining during defaecation. The usual course of events is for the bowel contents to contaminate the peritoneal cavity. It is unusual for a viscus in the peritoneal cavity to pass into the lumen of the bowel.

CASE REPORT

On 30 Nov., 1968, Miss C. D., a 90-year-old spinster, was referred to the Casualty Department of Kingston Hospital. She was confused and unable to give a detailed history, but it appeared that she had fallen the previous day striking her chest and upper abdomen. Since that time she had had vague central abdominal pain and had vomited on two occasions. The last occasion on which she had opened her bowels was on the day preceding the accident, when she passed a normal motion. She said that in the 10 months before the accident she had noticed a mass protruding from her anus after defaecation on several occasions. She had been able to replace this manually.

On examination, she was 4 ft. 10 in. in height (155 cm.), thin, and not in any obvious distress. Her pulse-rate was 80 per minute and her blood-pressure 150/80. No abnormality could be found in the cardiovascular or respiratory systems. Her tongue was furred but she did not appear dehydrated. Her abdomen was not distended, but there was marked tenderness over the lower abdomen, though no guarding or rigidity. There were no palpable masses. Bowel sounds were present in all areas and were normal. However, examination of her perineum showed loops of small intestine prolapsing through the anus (*Fig.* 1). The small intestine appeared viable, with visible peristalsis. Arterial pulsation could be seen in the mesentery.

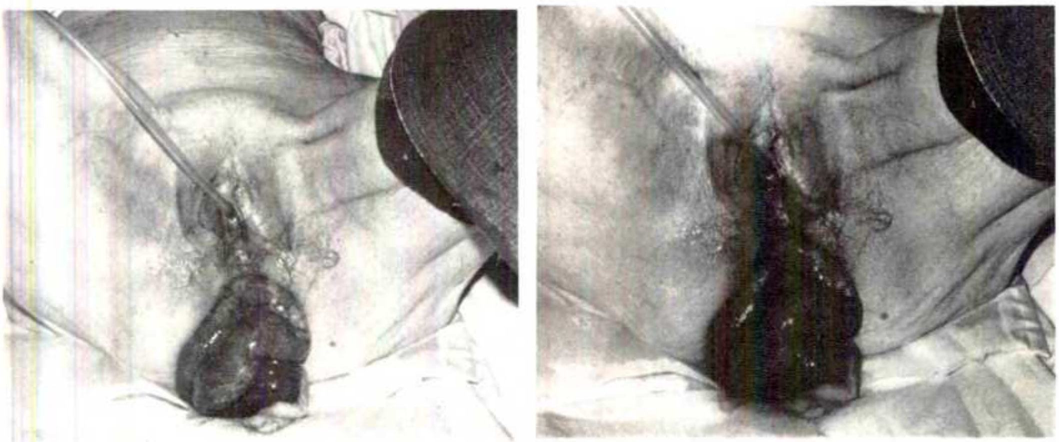

FIG. 1.—Coils of ileum protruding through the anal canal.

A diagnosis of prolapsed ileum through a tear in the colonic wall was made, and the patient was transferred to the operating theatre.

The patient was anaesthetized and examined in the lithotomy position. The loops of small bowel appeared fully viable and the pulsation in the mesentery was confirmed. A finger was inserted into the anus which was found to be patulous. A tear could be felt high up on the anterior wall of the rectum, through which the small bowel had prolapsed. The abdomen was opened through a right lower paramedian incision, and the ileum, after cleansing with Cetavlon, was withdrawn into the peritoneal cavity. The tear was found to be 3·8 cm. in length, lying longitudinally on the anterior rectal wall, 2·5 cm. above the peritoneal reflection (*Fig.* 2). The edges appeared to be viable, with no evidence of ischaemia or infection. There was no soiling of the peritoneal cavity and the other abdominal viscera all appeared normal. As the ileum, 45·7 cm. of which had passed through the rectal wall, appeared normal, no resection was necessary. A biopsy was taken from the edge of the tear, which was then closed in a transverse direction with two layers of 00 chromic catgut. Finally, a sigmoid colostomy was fashioned through an oblique incision in the left iliac fossa and the abdomen was closed in layers, leaving a Ragnall drain to the site of the suture line on the anterior rectal wall. Postoperatively the patient received intravenous fluids and she was given tetracycline 250 mg. q.d.s.

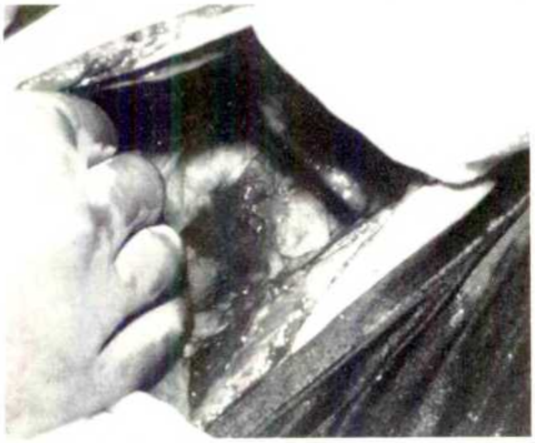

FIG. 2.—Anterior surface of the rectum showing the 3·8-cm. longitudinal tear.

Forty hours later the patient strained in an attempt to open her bowels and prolapsed a loop of ileum alongside her sigmoid colostomy. She was operated upon and the prolapsed loop of ileum was reduced into the abdominal cavity and the colostomy opening was narrowed with sutures to the peritoneum and the skin. Thereafter the colostomy functioned well and the patient was maintained on a normal diet. Subsequently the patient suffered several episodes of rectal prolapse—easily replaceable without anaesthesia.

A barium enema via the distal limb of the colostomy demonstrated no leakage at the site of the original tear. Accordingly, the sigmoid colostomy was closed 14 days later and normal defaecation was established. The patient continued to prolapse her rectum and 2 months following the first operation a Thiersch wire was inserted subcutaneously around the lower end of the anal canal. The patient was discharged 4 days later, and has had no further episodes of rectal prolapse.

REVIEW OF THE LITERATURE

We have only been able to find 11 similar cases reported in the world literature since 1900, and no similar case in the British literature. The main points are summarized in *Table I*.

Table I.—SUMMARY OF THE FEATURES OF 12 CASES OF PROLAPSE OF THE ILEUM REPORTED IN THE WORLD LITERATURE SINCE 1900

CASE NO.	AUTHOR	AGE AND SEX	RECTAL PROLAPSE	SITE OF TEAR	PRECIPITATING FACTOR	PROCEDURE	FATE OF PATIENT
1	Moulton (1901)	M.	Present	Rectum	Not stated	Nil	Died after 36 hours
2	Zena (1914)	14 F.	Absent	Rectum	Injury (by rock fall)	Resection rectum	Recovered
3	Guibe (1931)	78 F.	Present	Sigmoid	—	Resection; gangrenous ileum	Died after 2½ months
4	Guibe (1931)	77 F.	Present	Rectum	Fall	Suture of tear	Died after 5 days
5	Moskalenko (1934)	52 F.	Present	Rectosigmoid	Coughing on defaecation	Resection of ileum and suture of tear	Died after 24 hours
6	Erlikhmana (1937)	45 F.	Present	Sigmoid	Heavy lifting	Suture of tear	Died after 64 hours
7	McLanahan and Johnson (1945)	76 F.	Present	Sigmoid	Fall	Exteriorization of sigmoid	Died after 62 hours
8	Minkari and Turan (1961)	28 M.	Absent	Sigmoid	Defaecation	Resection of ileum and suture of tear	Recovered
9	Alvich and Lepow (1959)	58 F.	Present	Sigmoid	? Spontaneous	Resection of ileum and suture of tear; colostomy	Recovered
10	Henessey (1966)	63 F.	Present	Rectum	? Spontaneous	Suture of tear	Recovered
11	Rowse (1966)	38 M.	Absent	Rectosigmoid	Blow in a fight	Suture of tear	Recovered
12	Hall and Bradfield (1971)	90 F.	Present	Rectum	Fall	Suture of tear and sigmoid colostomy	Recovered

The condition is frequently associated with prolapse of the rectum, for in only 3 cases out of a total of 12 was this absent. The sex incidence was 9 female to 3 male, reflecting the increased incidence of prolapse of the rectum in the female. The age range varies from 14 to 90, our own case being by far the oldest. It is interesting to note that the patients in whom there was no rectal prolapse were the youngest of the series (*Cases* 2, 8, 11).

The precipitating factors resulting in prolapse of the ileum through the anus are varied. These were not recorded in 2 cases (*Cases* 1, 3) and a history of a fall was obtained in 3 (*Cases* 4, 7, 12). One case had a history of constipation, and the prolapse occurred on defaecation (*Case* 8). *Case* 5 prolapsed her ileum whilst coughing when defaecating in the squatting position. *Case* 2 was trapped by a rock fall. The prolapse followed heavy lifting in *Case* 6 and a blow on the abdomen in *Case* 11. No precipitating cause is mentioned in *Cases* 9 and 10, but both these patients were inmates of mental hospitals and were unable to give a clear history.

The site of the tear has always been in the distal large bowel, the sites being the sigmoid colon in 5 cases, the recto-sigmoid junction in 2, and the rectum in 5.

The operative procedures adopted have been basically similar in all cases, except for *Case* 1 in which no treatment was attempted. At operation the ileum has been replaced in the peritoneal cavity or resected if non-viable. The tear in the wall of the large bowel has been either sutured or a portion of the bowel resected. In some cases a proximal colostomy was formed (*Cases* 9, 12) and in 1 patient (*Case* 7) the sigmoid colon containing the tear was exteriorized.

In the pre-antibiotic era the condition was almost uniformly fatal, although it is notable that the case of Zena in 1914 made a remarkable recovery (Zena, 1937) and 1 patient of Guibe (1931) died 2½ months after her operation, having become cachectic, following a faecal fistula. However, the last 5 reported cases have all recovered, doubtless owing partly to the introduction of antibiotic therapy, blood transfusion, and general advances in postoperative care.

DISCUSSION

The factor initiating the passage of the small bowel through the wall of the sigmoid colon or the rectum seems to be an increase in intra-abdominal pressure. It is suggested that in the presence of prolapse of the rectum there is an area on the wall of the abdominal cavity that is unsupported by muscle, namely, the rectovesical or recto-uterine pouch, where the pelvic floor is weak and the anus is patulous. Accordingly, the wall of the sigmoid colon or rectum tears, the site depending on the degree of the rectal prolapse, and the ileum passes into the lumen of the rectum through the anus.

The judicious use of antibiotics, blood transfusion, and other supportive measures all contribute to the survival of the patient with prolapse of ileum through the anus. Early laparotomy is essential. Alvich and Lepow (1964) recommend that the loops of ileum which have prolapsed are divided inside the peritoneal cavity, and that they are then drawn through the rectum and out through the anal canal to avoid further contamination of the peritoneal cavity by non-viable bowel. However, recent cases (Henessey, 1966; Rowse, 1966) and the present case have shown that when the ileum is viable it can be safely preserved by reintroducing it into the peritoneal cavity after cleansing. If the edges of the tear are viable it can be closed in two layers, preferably in a transverse direction. If there is doubt concerning the integrity of the suture line or if the patient is old and enfeebled, a sigmoid colostomy is probably advisable. When prolapse of the rectum is present a further operation at a later date may be necessary to avoid recurrence.

Acknowledgements.—We would like to record our grateful thanks to Mrs. B. Meade for help with the translation of the Russian articles.

BOWEL HERNIATION THROUGH A DEFECT OF THE BROAD LIGAMENT

BY I. G. M. CLEATOR AND W. M. BOWDEN
LEITH HOSPITAL, EDINBURGH

SUMMARY

This is the fifty-fourth reported case of a defect in the broad ligament and the forty-ninth associated with intestinal obstruction.

HISTORICAL REVIEW

Quain is accredited with the first description of a defect in the broad ligament which he noted at an autopsy in 1861 (Baron, 1948). The literature was comprehensively reviewed by Baron in 1948, who collected 45 previous cases and added 1 of his own, and since then only 7 further case reports have been published; 3 collected by Wills (1957), 1 by Bordenca (1959), 1 by Papas (1960), 1 by Rose (1963), and 1 by Johnson (1965), making a total of 53 cases. In 19 of these cases reported, the defect in the broad ligament was a sequel of a uterine suspension operation and may have been due to technical error (Baron, 1948; Wills, 1957). In the remainder there was no direct injury to the broad ligament. In 48 of the patients attention was drawn to the defect by the occurrence of intestinal obstruction or strangulation.

CASE REPORT

HISTORY.—Mrs. F. F., aged 41, a multipara with a previous history of three normal labours, suffering from abdominal pain of 36 hours' duration and vomiting of 24 hours' duration, was admitted to Leith Hospital on 1 April, 1970. The pain had awakened her from sleep on the morning of the day prior to admission. It was initially epigastric in position and 'sharp' in nature but by the following day had shifted to the suprapubic area and was 'like labour pains'. Eighteen hours after the onset of the pain a normal stool was passed. There were no urinary symptoms. Her menstrual periods had been regular over the past 5 years while she was on 'the pill', her last period having ceased 10 days previously and having been quite normal. There was no vaginal discharge, nor were there any other gynaecological symptoms or history of any previous gynaecological or other procedure.

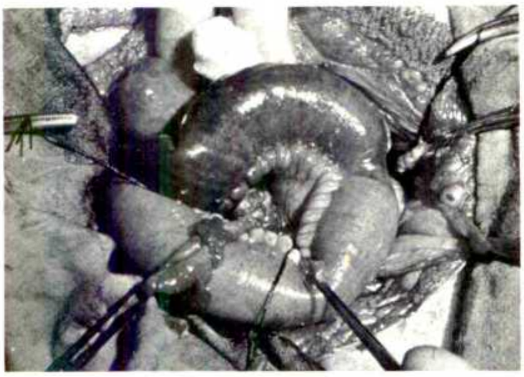

FIG. 1.—The defect in the broad ligament has been divided and the left ovary and Fallopian tube are held in Allis's forceps. The constriction ring in the bowel can be seen.

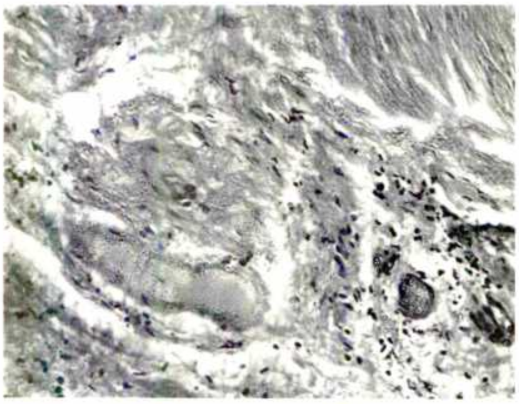

FIG. 3.—Section of the margin of the hole showing fibrous connective tissue. (× 150.)

EXAMINATION.—On examination the patient was a slightly plump woman, pale, anxious, a little dehydrated, and obviously in pain. Her temperature was 36·4° C., pulse, 136 per minute, and respiration rate, 20 per minute. Her face was drawn, her lips were dry, and her tongue was furred. The breath was not foetid. The systolic blood-pressure was 110 and the diastolic 50 mm.

The abdomen moved well in the upper half on respiration but to a lesser extent in the lower half, where there was also some distension but no visible peristalsis. There was true muscle guarding in the lower half of the abdomen. There were tenderness and rebound tenderness in both iliac fossae suprapubically—the maximum point of tenderness being in the left iliac fossa towards its most medial part. There was no tenderness or guarding in the upper abdomen. On auscultation the bowel-sounds were only slightly increased in frequency and volume. Rectal examination revealed diffuse tenderness but no masses were felt. Vaginal examination was not carried out.

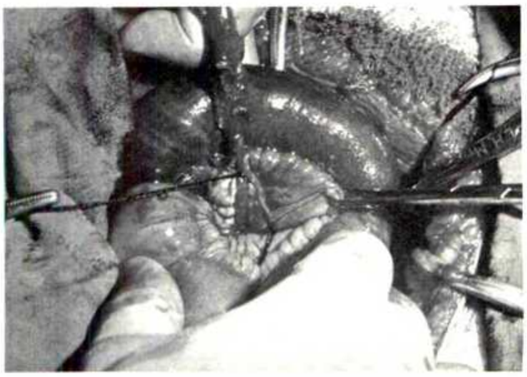

FIG. 2.—The hole in the broad ligament in process of repair with black silk sutures.

INVESTIGATIONS.—Haemoglobin was 136 per cent, P.C.V., 60 per cent, and W.B.C., 19,000 per c.mm. with 77 per cent neutrophils. Erect and supine abdominal radiographs showed that there were one or two small dilated loops of small bowel present and that there was a solitary fluid level in one of them. The appearances were those of a mechanical obstruction in the distal small bowel.

With the foregoing history, examination, and investigations, it was evident that the patient required a laparotomy.

OPERATION.—Preoperatively i.v. fluids were commenced and a nasogastric tube was passed.

On palpation of the abdomen under anaesthesia prior to incision of the skin, a mass, which was relatively mobile and lying to the left of the midline suprapubically, was revealed.

A right, lower, paramedian, rectus-displacing incision was therefore made. On opening the peritoneal cavity the following was found:—

1. There were 300 ml. of serosanguineous fluid in the peritoneal cavity.
2. There was a 2·5-cm. hole in the left broad ligament of the uterus with 7·6 cm. of terminal ileum approximately 2·5 cm. from the ileocaecal valve herniated through this hiatus from anterior to posterior. The herniated bowel was strangulated (*Fig.* 1).
3. The defect was through the broad ligament, with the round ligament, Fallopian tube, and mesovarium passing superiorly, the uterine wall medially, the levator ani muscle laterally, and the uterine artery, ureter, and vault of vagina inferiorly.

The following procedure was therefore carried out. The upper part of the left broad ligament of the uterus was ligated and divided to release the strangulated loop of bowel (*Fig.* 2). The bowel was covered with a warm pack, but on inspection some minutes later, pulsation had not returned to the mesentery and the bowel appeared non-viable. Resection of the bowel with end-to-end anastomosis using two layers of catgut was carried out. The hole in the mesentery was closed with catgut sutures. Attention was then turned to the defect in the broad ligament. The edges of the defect were rigid and sharp and were thought to be the constricting band which had caused the strangulation. A biopsy of the rim of the defect was taken for microscopy and the defect was repaired with interrupted black-silk sutures. A suction drain was brought out through a stab wound from the pouch of Douglas. The main wound was closed with tension sutures, continuous catgut for peritoneum and rectus sheath and interrupted black silk for skin.

PROGRESS.—The wound healed by first intention and the patient made a good recovery. She was discharged from hospital on the thirteenth day after operation and has remained free of symptoms.

PATHOLOGY.—Microscopy showed fibrous tissue and vascular connective tissue only (*Fig.* 3).

DISCUSSION

Internal hernias account for between 0·5 and 1 per cent of all intestinal obstructions (McIver, 1933; Wangensteen, 1955). The classic definition of an internal hernia is given by Treitz in 1857 (Bertelsen and Christiansen, 1967): 'an internal hernia is a hernia situated retroperitoneally'. In common usage, however, there are two types: first, that of retroperitoneal herniation of an abdominal organ through a hernial opening formed by a peritoneal fold, and second, that of herniation of a viscus through a defect in the mesentery or omentum (Bertelsen and Christiansen, 1967). Most of the hernias through the broad ligament fall into the second category, only 5 of the reported cases having a peritoneal sac.

Aetiology.—In patients who have had previous uterine suspension operations (19 out of 53 reported cases) the cause of the defect is probably failure to close the hole made in the broad ligament securely enough around the sling of the round ligament (Wills, 1957). In patients who have not undergone previous surgery the aetiology is more obscure. Our patient falls into this category and she had many of the features reported by authors mentioned in the historical review. The average age at operation was 42 years with a range of 16–79 years (Baron, 1948; Rose, 1963). Our patient was 41 years old.

In 11 out of 25 cases in which the relation to the layers of the broad ligament has been mentioned, the defect involved both layers, as in our patient. In the others one leaf only was involved. The defect was on the left side (as in our patient) in 11 out of 28 patients in whom this finding was recorded, with 14 on the right side and 3 bilaterally.

The relationship to the uterine adnexa is variable and the same relationship as in our patient was encountered in 3 out of 18 patients in whom the exact site was recorded.

Three explanations have been offered for spontaneous defects in the broad ligament. The first is that they occur secondarily to previous infection in the region of the broad ligament. This was probably valid only in the 2 described cases in whom there was evidence of previous pelvic inflammation, as most of the other patients, like ours, were singularly free from adhesions and other evidence of prior inflammation. The second explanation is that the defects are congenital anomalies and this must be invoked in the few patients who were nulliparous. The third explanation, that trauma to the broad ligament during pregnancy results in tears which heal leaving defects, would appear to apply to the majority of the patients including ours. This would explain the fact that 80 per cent of broad ligament defects have occurred in multiparous women and that the site of the defect is variable. There has been 1 report of the condition actually occurring in the eighth month of pregnancy. Bordenca (1959) reported a hernia of the sigmoid colon through the broad ligament in the eighth month of pregnancy.

Biopsy of the margin of the defect would seem to help in deciding which is the most valid of these three explanations. This has only been done in 1 previous case, the findings being quoted by Baron in 1948 as 'typical scar tissue'. In our patient the margin was made up of fibrous and vascular connective tissue. This is consistent with a traumatic tear which had healed satisfactorily in the past leaving the defect.

Acknowledgement.—We wish to thank Mr. I. E. W. Gilmour, under whose care this patient was admitted, for permission to publish this report.

IDIOPATHIC PSEUDOMEMBRANOUS COLITIS SUCCESSFULLY TREATED BY SURGICAL EXCISION

By B. T. JACKSON

SENIOR SURGICAL REGISTRAR, ST. THOMAS'S HOSPITAL, LONDON

AND C. J. ANDERS

CONSULTANT SURGEON, ST. PETER'S HOSPITAL, CHERTSEY, SURREY

SUMMARY

A case is presented of acute idiopathic pseudomembranous colitis successfully treated by panproctocolectomy. The barium enema showed 'thumb printing', an appearance normally associated with ischaemic colitis. The histology of the specimen, however, did not confirm an ischaemic aetiology.

PSEUDOMEMBRANOUS enterocolitis was first described by Billroth in 1867 (Bloomfield and Walters, 1960). Since then there have been many accounts of cases affecting the small intestine (van Prohaska, Mock, Baker, and Collins, 1961) but only sporadic reports of inflammation confined to the colon (Hartmann and Angevine, 1956; Bloomfield and Walters, 1960; Goulston and McGovern, 1965). The aetiology is uncertain, but many authors draw a distinction between the staphylococcal variety which often follows antibiotic therapy and the non-infective forms for which an ischaemic aetiology has been postulated (Hardaway and McKay, 1959; Marston, 1962). Conservative treatment is usually recommended but the disease is often fatal and in many cases the diagnosis is made only at necropsy.

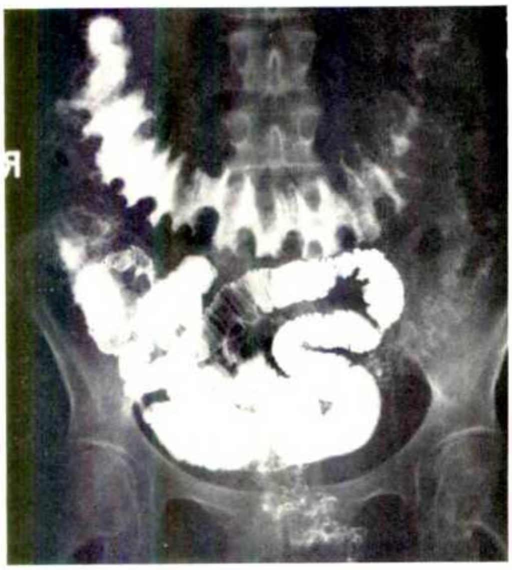

FIG. 1.—Barium enema showing 'thumb-printing' in the transverse colon and widespread 'polyposis'. Reflux into the ileum is also seen.

This report is of a patient with severe pseudomembranous inflammation confined to the colon which was successfully treated by surgical excision. There was no predisposing cause or evidence of infection but the barium-enema appearances were compatible with an ischaemic aetiology.

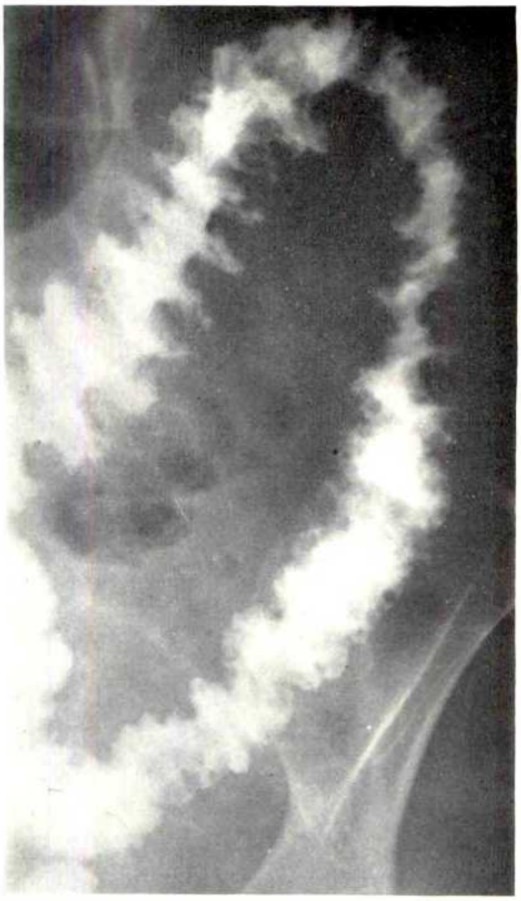

FIG. 2.—Barium enema showing the appearance of the left colon.

CASE REPORT

Mrs. E. B., a housewife aged 66 years, was admitted to St. Peter's Hospital, Chertsey, with a short history of diarrhoea of sudden onset. The bowels were opened up to twenty times daily, the motions being watery and offensive but without blood or mucus. There was a constant pain in the lower abdomen and anorexia but no nausea or vomiting. Previous to this admission the patient had been well apart from a herniorrhaphy and appendicectomy performed many years previously.

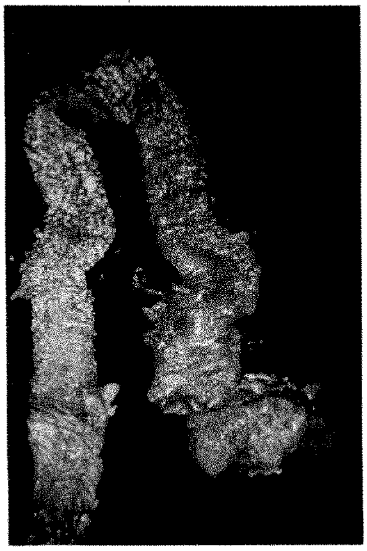

FIG. 3.—The opened specimen showing the colitis extending from the rectum to the caecum. The terminal ileum is spared.

On examination the temperature was raised (37·3° C.) and the pulse-rate was 100 per minute. There was tenderness in the right iliac fossa but no guarding, abdominal distension, or masses. Digital examination of the rectum was normal. Sigmoidoscopy was difficult because of the presence of liquid faeces, but large numbers of small, yellowish-white, raised nodules of an obscure nature were seen lining the rectal mucosa which appeared inflamed. A biopsy was taken which showed severe chronic inflammation but no other abnormality.

Investigations included the following: haemoglobin 15·2 g. per cent, W.B.C. 10,000 per c.mm., E.S.R. 10 mm. per hour, urea 24 mg. per cent, normal electrolytes and bicarbonate, and normal chest and plain abdominal radiographs. A provisional diagnosis of infective enteritis was made and the patient was treated by fluid and electrolyte replacement. No antibiotics were given pending the result of a stool culture. This showed no evidence of pathogens and therefore antibiotics were withheld.

During the next week the patient's symptoms and signs subsided, and 10 days after admission the patient was completely well. Repeat sigmoidoscopy was normal to 13 cm. but a repeat rectal biopsy still showed chronic inflammation with a thickened muscularis mucosa. The patient was discharged and remained well for 1 month when she was readmitted with a 3-day history of abdominal pain and severe diarrhoea. Again there was no blood in the motions and no nausea or vomiting. The diarrhoea was watery and offensive, containing some mucus, and occurred up to twenty times daily. The patient was febrile, her temperature being 37·3° C. Sigmoidoscopy again showed the presence of yellowish-white raised nodules, approximately 3 mm. in diameter, throughout the entire rectum. The mucous membrane was oedematous but there was no contact bleeding. Biopsy again showed non-specific chronic inflammation. Stool culture showed no evidence of pathogens, cysts, ova, or fungi. A barium enema was grossly abnormal showing 'thumb-printing' in the transverse colon, widespread appearances of polyposis coli, and reflux into the ileum (*Figs.* 1, 2).

Her diarrhoea and abdominal pain continued and she became exceedingly ill despite adequate fluid replacement and correction of electrolyte imbalance. A week after admission her condition was critical and a panproctocolectomy and ileostomy were performed. Following this operation a dramatic improvement took place and her postoperative recovery was uneventful. She has remained well for the past 2 years.

PATHOLOGY.—The specimen showed numerous soft yellowish nodules of mucopus throughout its length from the anal canal to the caecum (*Figs.* 3, 4). These nodules were from 2 to 7 mm. in diameter, in places forming confluent masses, and could be removed to reveal underlying superficial ulcerations. The mucosa between the lesions also showed a few minute ulcers. The bowel wall was generally thickened but there were no enlarged lymph-nodes. Histology showed generalized chronic inflammation throughout all coats, with foci of superficial necrosis of the mucosa covered by fibrin and mucopus, in which no protozoa, fungi, or bacteria could be demonstrated. There was no intramural haemorrhage and the lymph-nodes were unremarkable. The blood-vessels were normal and no malignancy was present. A diagnosis of pseudomembranous colitis was made.

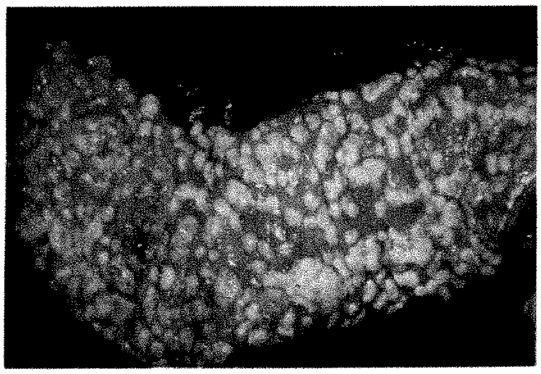

FIG. 4.—Close-up of the transverse colon showing the nodules of mucopus.

DISCUSSION

The pathological findings are those of the focal type of pseudomembranous colitis described by Kay, Richards, and Watson (1958). Goulston and McGovern (1965) claim that pseudomembranous colitis occurs in two groups of patients: those having primary disease of the colon, and those with generalized disease such as uraemia or septicaemia. They suggest that it is a separate entity from staphylococcal enterocolitis, which often follows antibiotic therapy or operation, but refute an ischaemic aetiology on histological grounds. Other authors agree that pseudomembranous colitis develops in association with pre-existing disease (Kleckner, Bargen, and Baggenstoss, 1952; Pettet, Baggenstoss, Judd, and Dearing, 1954; Birnbaum, Lauffer, and Freund, 1961). The above patient was unusual in that no other disease was present, no staphylococci were demonstrated, and no antibiotics had been given.

Penner and Bernheim (1939) were the first to suggest the possibility of local ischaemia causing the inflammation. Hardaway and McKay (1959) reproduced the clinical features and the histological appearances in dogs by causing intravascular clotting in the capillaries of the bowel mucosa. Marston

(1962) also reproduced similar histological appearances in dogs by occluding the superior mesenteric artery. Although the histological features in our patient did not suggest an ischaemic origin the barium enema showed multiple, rounded, filling defects in the transverse colon, a sign known as 'thumb-printing' (Lea Thomas, 1966). This has been described in human ischaemic colitis and is thought to be caused by mucosal oedema and submucosal haemorrhage consequent upon the ischaemia (Boley, Schwartz, Lash, and Sternhill, 1963; Marston, Pheils, Thomas, and Morson, 1966; Marcuson, Arthur, Chapman, and Marston, 1969). It does not appear to have been described in a non-ischaemic condition. The misleading appearance of 'polyposis' seen on the radiographs was caused by the nodules of mucopus.

The prognosis for patients developing pseudomembranous inflammation of the bowel is poor and the majority of reported series are of necropsy cases. Our patient was deteriorating rapidly despite vigorous fluid and electrolyte replacement and seemed certain to die had a conservative regimen been continued. Tanner and Hardy (1968) advocate surgical excision of the affected segment, but their 2 cases were of small-bowel inflammation. This report appears to be the first describing colectomy in the management of pseudomembranous colitis.

Acknowledgements.—We wish to thank Dr. C. F. Ross, Consultant Pathologist, St. Peter's Hospital, Chertsey, for his help in diagnosis, and Mr. T. W. Brandon of the Department of Photography, St. Thomas's Hospital, for reproducing the illustrations.

A CASE OF DIAPHRAGMATIC HERNIA, ABSENT PERICARDIUM, AND HAMARTOMA OF LIVER

BY A. A. DEUTSCH, K. N. BROWN, N. V. FREEMAN, AND D. A. STANLEY
DEPARTMENTS OF SURGERY AND PATHOLOGY, THE ROYAL LIVERPOOL CHILDREN'S HOSPITAL

SUMMARY

A case is described of a diaphragmatic hernia associated with a left pericardial defect and hamartoma of the liver. The possible embryological origin of the first two defects from premature closure of the duct of Cuvier is discussed. The radiographic changes of the absent pericardium are mentioned and the histology of the liver hamartoma is described.

DIAPHRAGMATIC hernia has been known since 1575 when it was described by Ambroise Paré (Rickham and Johnston, 1969). Baillie in 1788 (Moore, 1925) first accurately described a case of absent pericardium, although the earliest report was by Realdus Columbus in 1559 (Moore, 1925). Benign hamartoma of the liver which presented as a large tumour in an 18-month-old child was described by Rewell (1957).

Only 1 case of all three abnormalities found together has been recorded (Ladd, 1936). The histological description of the diaphragmatic sac was similar to our findings, but no explanation was given or name suggested. We feel that the case of Ladd, as in the present case, was a hamartoma of the liver.

CASE REPORT

A 10-day-old baby girl presented as a feeding problem from birth. Chest radiographs (*Fig.* 1 A) suggested left diaphragmatic paralysis; the mediastinum was a little displaced to the right. A urinary infection was found and, after a normal intravenous pyelogram and cystogram, was treated. She improved and was allowed home.

She was readmitted as an emergency at 6 months with a 3-day history of increasing cough and dyspnoea. On examination the baby was cyanosed. The temperature was 40° C. Respirations were grunting and the rate was 60 per minute. The pulse was 172 per minute. The left side of the chest was flattened and expanded minimally. Bowel-sounds were heard in the left lower chest. Radiographs (*Fig.* 1 B) showed the stomach to be in the left chest and the mediastinum displaced to the right.

A diagnosis of left diaphragmatic hernia was made and, after resuscitation, laparotomy was carried out through a left transverse incision.

A large left anterolateral diaphragmatic defect was found, which contained volvulated stomach, spleen, and some left lobe of the liver. The sac was thick and fleshy and bled briskly when cut. Three thickened lobules were found on the pleural surface looking like sequestrated lung. No left pericardium was seen. The heart appeared to lie in the pleural cavity. The left lung appeared small and filled half of the pleural cavity. Postoperatively the left lung did not fully expand and chest radiographs (*Fig.* 1 C) showed the mediastinum displaced well to the left. She was discharged 17 days after admission, clinically well but with radiographic changes (*Fig.* 1 D) as described.

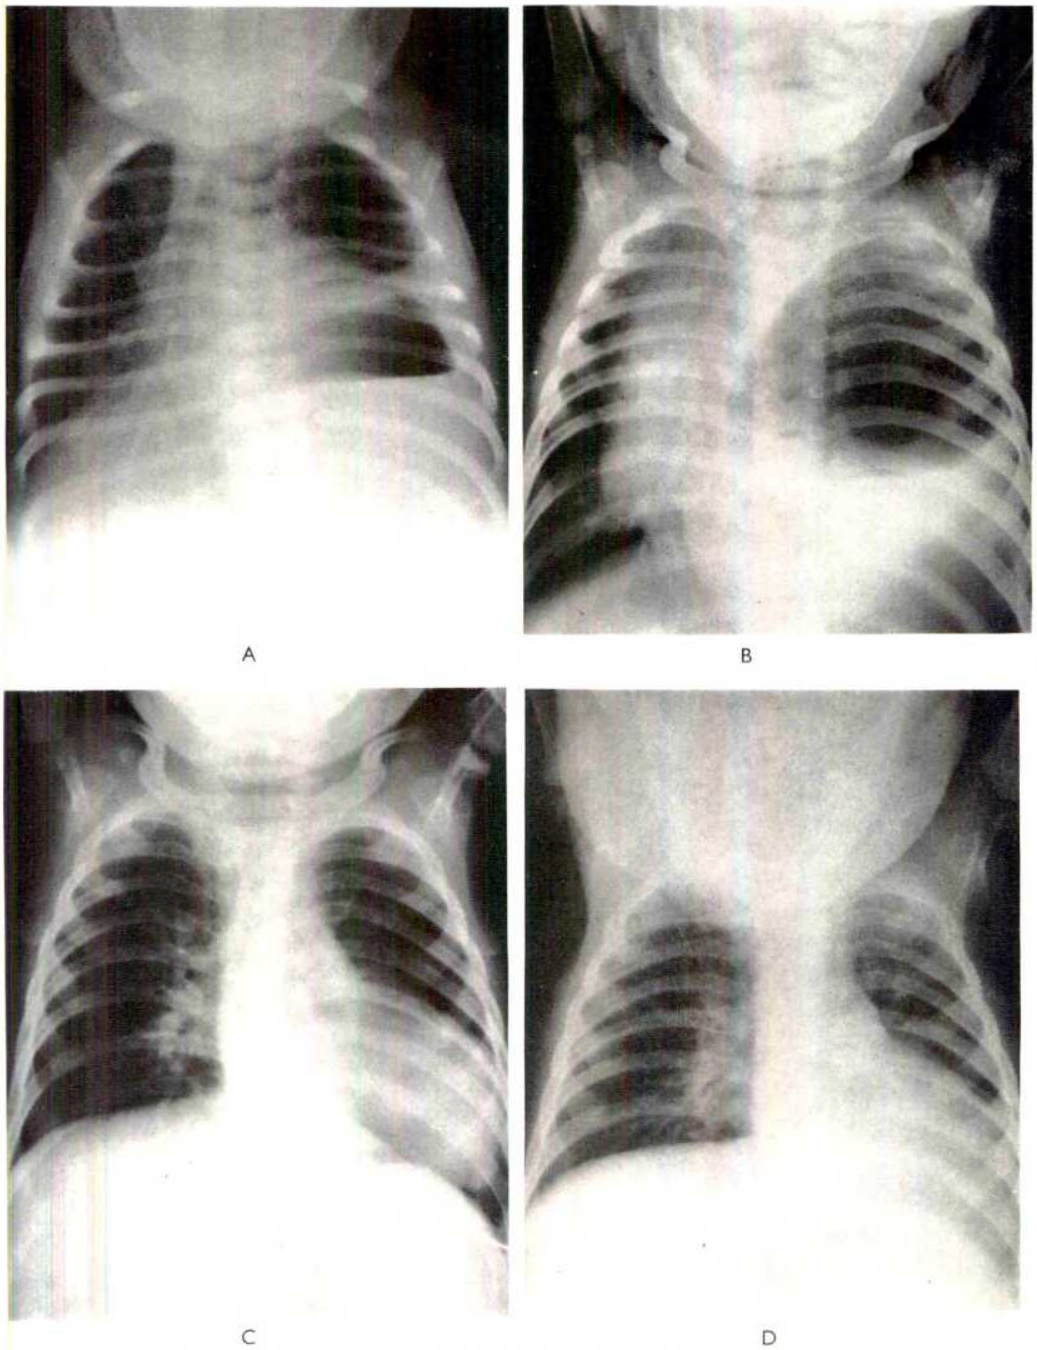

FIG. 1.—Serial radiographs before and after diaphragmatic hernial repair. A, 10 days old. B, 6 months old before operation. C and D, After operation.

PATHOLOGY.—The specimen taken at operation was a flattened hernial sac, 8 by 5 cm. Most of the tissue was fibromuscular in nature and 2 mm. thick, but there were three firm elevations on the pleural surface of the specimen, projecting 5 mm. above the surface. The cut surface was red and homogeneous.

HISTOLOGY.—A number of blocks was taken from the elevated areas and also from the intervening tissue, several of which represented a full thickness. The intervening tissue consisted of fibrous tissue interspersed amongst which were a small number of muscle-fibres. The appearance of the elevated parts was similar and differed only in the relative amounts of the constituents from place to place. Much of the tissue consisted of what appeared to be islands of well-differentiated liver cells in a fibrous stroma. There were also numerous ramifying bile-ducts which varied greatly in diameter. In places (*Fig.* 2) liver cells, bile-ducts, and fibrous stroma could all be seen together and it was possible to find areas in which the liver cells could be seen in continuity with the bile-duct epithelium.

FIG. 2.—Photomicrograph of diaphragmatic sac. (× 170.)

DISCUSSION

Congenital absence of the pericardium is usually left-sided; only rarely does it involve the right side. Deutsch, Yahini, Shem-Tov, and Neufeld (1970) described 116 cases including their own case. The present case and 4 of Tubbs and Yacoub (1968) bring the total number described to 121. Ladd's case (1936) was the first to be discovered during life.

Absent pericardium has been classified by Moore (1925). Complete absence of the left pericardium is harmless. Radiologically it should be considered, as it may be confused with other pathological conditions in the left-lung field.

Numerous associated defects have been described (Tabakin, Hanson, Tampas, and Caldwell, 1965). Diaphragmatic hernia is one of these. Risel (Moore, 1925) described 3 such cases found at post-mortem examination, but they were associated with multiple congenital defects. Keith (1910) described 3 cases of diaphragmatic hernia through the central tendon into the pericardial cavity. In the event of absence of the left pericardium, this type would not easily be distinguished from our own case. His type of hernia was probably due to persistence of the infracardiac bursa.

To explain the defect of absent pericardium embryologically Moore (1925) suggests that it may arise as the result of early closure of the left duct of Cuvier, which conforms with the propensity of this defect to be left-sided. However, the pulmonary ridge lying just medial to the Cuvierian duct gives rise to both the pleuropericardial and the pleuroperitoneal membranes, so the association of both absent pericardium and diaphragmatic hernia is explicable on this basis.

It is generally considered that the endodermal cells of the hepatic diverticulum give rise to the parenchyma of the liver, whilst the capsule and fibrous stroma are derived from the mesoderm of the septum transversum. Elias (1955) considers that there is a contribution to the hepatic parenchyma from the septum transversum. Meyenberg (1918) has suggested that even some of the small bile-ducts arise from the mesoderm derived from the septum transversum. Rewell (1957) described a benign hamartoma of the liver in an 18-month-old girl, and regarded the hamartoma as taking its origin from well-differentiated mesenchymal cells. The histological appearance encountered here would appear to be in accord with his view.

In Ladd's case (1936) with deficiency of the pericardium associated with diaphragmatic hernia, he described numerous duct-like structures in the histological examination of the hernial sac although he does not mention the presence of differentiated liver cells. It is felt that this appearance, like our case, may be a liver hamartoma.

Acknowledgements.—We would like to thank Dr. R. E. Rewell for his advice and Professor R. G. Harrison for his help in the preparation of this paper.

PERFORATION OF A PEPTIC ULCER IN DUPLICATED ILEUM

By C. D. COLLINS

SENIOR SURGICAL REGISTRAR, BRISTOL ROYAL INFIRMARY

SUMMARY

A case of perforation of a peptic ulcer in a tubular duplication of the ileum is presented with a brief review of the relevant literature.

THE term 'duplication' appears to have been first used by Fitz in 1884 and has now widely replaced such terms as 'enterocystoma', 'enterogenous cyst', 'ileum duplex', or 'giant diverticulum' which have more limited connotations (Gross, Holcomb, and Farber, 1952) and for which a classification has been proposed by Smith (1960).

Duplications have certain characteristics in common. They occur anywhere along the course of the gastro-intestinal tract, are spherical or tubular in shape, and have a wall which reproduces the normal bowel structure. The mucosal lining may possess microscopic features of one or more than one specific region of the bowel. The outer muscular and serosal layers of the duplication may be shared by the normal bowel along part or all of its length. They may communicate with the normal lumen, in which case the lesion is usually tubular, or they may not communicate, in which case the lesion is cystic. The majority of duplications tend to lie within the leaves of the mesentery and to share the blood-supply of the adjacent normal bowel.

Duplications are named according to the segment of normal bowel with which they are in contact or communication, not according to the type of bowel which they resemble either macroscopically or histologically.

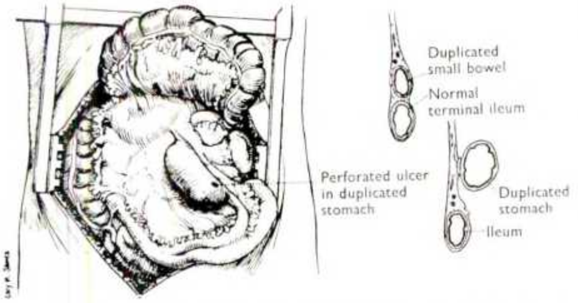

FIG. 1.—Appearance of the duplicated bowel at operation, showing a sac-like 'stomach' with a perforated ulcer, and cross-sectional drawing to show the relation of the 'stomach' and distal duplicated bowel to the mesentery of the normal ileum.

The present case is classified as a 'communicating tubular duplication of ileum'. Duplications are uncommon but not rare, and from a review of several hospital series totalling 168 cases (Donovan and Santulli, 1947; Gross and others, 1952; Moore and Battersby, 1952; Sieber, 1956; Mellish and Koop, 1961) those in relation to the ileum are found to occur most frequently. Of these, almost half contain some areas of heterotopic gastric mucosa. Anaemia from occult blood-loss is the usual presenting feature of peptic ulceration in these duplications, but frank perforation is very rare. This case is presented as a rare complication of an uncommon condition, treated surgically with success.

CASE REPORT

G. S., aged 7 years, presented with the clinical features of generalized peritonitis. He was born on 19 July, 1962, with a benign cystic lymphangioma on his back which was removed 10 days later and from which he has had no subsequent disability. At each of two subsequent annual follow-up visits he was found to be underweight for his age and to be slightly anaemic. He remained underweight for his age, lethargic, and pale for the next 5 years. One month prior to admission he complained of stabbing abdominal pains and vomiting. The vomiting continued intermittently despite symptomatic treatment and the abdominal pains became more severe. He was referred for a paediatric opinion, at which time nothing specific was found other than an iron-deficiency anaemia (Hb., 7·6 g. per cent). Thirty-six hours later he collapsed with sudden generalized abdominal pain.

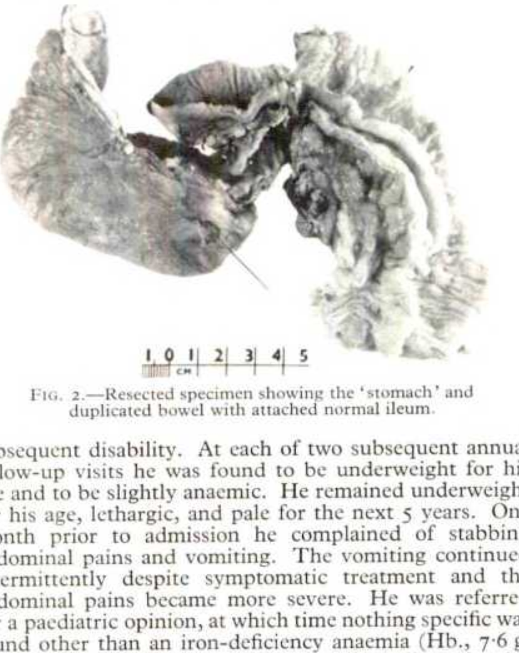

FIG. 2.—Resected specimen showing the 'stomach' and duplicated bowel with attached normal ileum.

EXAMINATION.—He was a pale underweight boy with obvious signs of peritonitis. Haemoglobin on admission was 7·4 g. per cent. After urgent fluid replacement he was submitted to laparotomy.

OPERATION.—The abdomen was explored through a right paramedian incision. One hundred ml. of blood-stained peritoneal fluid were sucked out from the peritoneal cavity. The bowel was mobilized to reveal the lesion shown in *Fig.* 1. The appearance was of a miniature 'stomach' and small bowel attached to the mesentery of the terminal ileum. The 'stomach' contained a perforated ulcer proximal to a constriction which felt like a stenosed 'pylorus'. The duplicated small bowel approached the normal terminal ileum and passed between the two leaves of its mesentery for a distance of 8 cm. before the two parallel lumina communicated (*Fig.* 2). The duplicated 'stomach' was filled with altered blood which looked like 'coffee grounds' and whose *p*H was 3.

The duplicated bowel was resected along with 15 cm. of normal terminal ileum and the two ends were anastomosed. The patient made an uninterrupted recovery, and oral iron therapy has since corrected his anaemia. Thorough examination failed to reveal any other congenital malformations although slight abnormalities were found on analysis of the palmar dermatoglyphics. This showed three whorls and seven ulnar loops in the fingerprints. On the palms, all triradii were normally situated except for a distal displacement of the right t triradius to a t' position. Palmar flexion creases were normal. Thenar patterns were absent, and there was a right hypothenar arch and a left hypothenar mutant loop. This last feature is rare and present in only 1 of 500 normal controls.

PATHOLOGY.—The duplication consisted of a cystic structure, 12 cm. long and 4 cm. in diameter, in communication with a tube, 12 cm. long and 1·5 cm. in diameter (*Fig.* 2). The 'cyst' was lined by rugose gastric-like mucosa. Most of the wall was 0·5 cm. thick but this increased up to 1·2 cm. at one end where a narrow lumen communicated with the duplicated small bowel. A perforation, 0·3 cm. in diameter, was present just proximal to the narrowed segment. Like the 'cyst' the duplicated small bowel had a complete muscular wall up to 0·5 cm. proximal to its communication with the normal ileum where the two parallel lumina were separated only by a thin mucosal web.

Histological examination showed the large cystic structure to be lined by mucosa indistinguishable from normal gastric mucosa. The perforation was through an active peptic ulcer with marked adjacent fibrosis and infiltration with polymorphs, macrophages, plasma-cells, and fibroblasts. The attached duplicated 'small bowel' had the appearance of normal ileum.

DISCUSSION

Little is known of the pathogenesis of enteric duplications although several mechanisms for their formation have been proposed. Lewis and Thyng (1907) considered that they might arise from the buds of intestinal epithelium which they sometimes found in the submucosal connective tissue of human embryos and foetal rabbits and pigs. Bremer (1944) suggested that tubular duplications might develop from the abnormal persistence of fluid-filled vacuoles, first described by Johnson in 1913, which form among epithelial cells during the 'solid stage' in the development of the intestine. However, neither hypothesis explains the almost invariable position of the duplications on the mesenteric side of the intestine. McLetchie, Purves, and Saunders (1954) reported the association of vertebral anomalies and alimentary diverticula, and concluded that there was abnormal adherence of the endoderm to the neuro-ectoderm in the early embryo with subsequent mesenchymal development around these buds of epithelium which later canalized to form duplications. Of the cases reviewed, Donovan and Santulli (1947) reported one similar to the present case in that there was a long tubular duplication with well-defined subdivisions into 'stomach' and 'bowel', but with the additional intriguing feature of a cord-like projection extending cephalad from the 'stomach' to the base of the small-bowel mesentery, with a wall histologically indistinguishable from that of common bile-duct. Moore and Battersby (1952) noted an old perforated ulcer in a 'diverticulum' which was plugged by omentum, and a similar finding was described by Donovan and Santulli (1947). Black and Benjamin (1936) report a necropsy finding of peritonitis from a perforated peptic ulcer in a tubular jejunal duplication in a patient who also had an intrathoracic 'enterogenous cyst'.

Cystic duplications usually present as an abnormal mass but there are no characteristic clinical features of communicating tubular duplications, although the diagnosis might be considered as an alternative to 'Meckel's diverticulum' in a patient presenting with abdominal pains, failure to thrive, and anaemia from occult blood-loss. Meckel's diverticulitis was in fact the diagnosis proposed by the general practitioner on referral of this child to hospital.

Acknowledgements.—I would like to thank Mr. H. J. Espiner, F.R.C.S., for permission to publish this case and Dr. R. Blight for his assistance with the pathology. I also thank Dr. T. David for his assessment and interpretation of the dermatoglyphics.

REVIEWS AND NOTICES OF BOOKS

Malignant Tumors in Organ Transplant Recipients. By I. PENN, M.B., B.Ch., F.R.C.S., Colorado. Pp. 51, with 12 illustrations. 1970. Berlin: Springer-Verlag. DM.24.

THIS small monograph is concerned with malignant tumours in organ-transplant recipients.

Transplantation of organs has much to contend with, and a vast literature has accumulated in world medical literature concerning the relationship between immunity and cancer. Now another hazard has reared its ugly head—namely, the occurrence of malignant disease in patients who have received organ transplants.

The author has been at some pains to produce evidence to show that cancer does occur more frequently in experimental animals and in humans who have been subjected to organ transplantation.

Manuel d'Osteosynthèse. Technique A.O. By M. E. MÜLLER, Berne, M. ALLGÖWER, Basle, and H. WILLENEGGER, Liestal. 10½ × 7½ in. Pp. 296 + viii, with 306 illustrations. 1970. Paris: Masson et Cie. 150F.

PENDING the publication of a new edition of their well-known book on operative treatment of fractures, the authors wrote this preamble on the techniques of internal fixation according to the principles of A.O. The result is a very welcome atlas. Biological and mechanical principles of internal fixation are clearly illustrated by diagrams. The text is brief, concise, and of necessity a little dogmatic. An excellent case is made for the use of drill, tap, and screws, instead of self-tapping screws. Good illustrations of internal fixation of fractures are given. Treatment of non-union is outlined and internal fixation of osteotomies and of arthrodesis is illustrated.

Cardiovascular Surgery, 1970. By EARLE B. MAHONEY, M.D., New York. 10⅝ × 7⅜ in. Pp. 158. Illustrated. 1971. New York: The American Heart Association, Inc. $5.

THIS monograph is Number 34 to be published by the American Heart Association. It contains a series of articles covering almost every aspect of cardiac surgery as practised today in the various clinics of America.

A large number of the articles deal with congenital heart conditions in infants. Various operations using prostheses make interesting reading. Balloon closure of ventricular septal defects and other interesting operative procedures are well described.

Many research projects dealing with animal hearts are included in this book. Some very useful information is given on the rehabilitation following cardiac surgery.

This monograph will interest all clinicians, but especially cardiologists and cardiac surgeons.

Surgeons' Decisions. By H. L. DUTHIE, Professor of Surgery, University of Sheffield. 7 × 4¼ in. Pp. 112 + vii, with 28 illustrations. 1971. Edinburgh: Oliver & Boyd. 37½p.

THIS small paperback is a mine of information which cannot be found in the standard textbooks of surgery.

Professor Duthie has written chapters on all the major fields of surgery, and his lucid style of writing is one which will appeal to many classes of readers who want to know more about surgeons and their craft.

The illustrations, all line drawings, are quite a feature of this book.

The price of this small book is remarkably cheap and we look forward to seeing more of this type of surgical literature.

Psychiatric Aspects of Organ Transplantation. Edited by PIETRO CASTELNUOVO-TEDESCO, M.D., Torrance, California. 10 × 7 in. Pp. 172. 1971. New York: Grune & Stratton Inc. $7.75.

THIS book is in reality a reprint from the February, 1971, issue of *Seminars in Psychiatry* published by Henry M. Stratton of New York. It contains some fifteen chapters, all of which deal with the different aspects of psychiatric complications occurring in patients who have undergone cardiac, renal, or lung transplantation.

As one would expect, the majority of the papers in this book come from America, yet there is one from Belgium and one from England. Professor Alec Paton, of Birmingham, contributes the last chapter in this volume in which he considers the moral and ethical questions which surround the surgical extension of life and the donation and reception of organs in transplantation.

The problems of the relatives and the general practitioner with regard to donors are fully discussed.

This book brings a new angle on the subject of organ transplantation in man.

Gathorne Robert Girdlestone. By J. TRUETA. 8½ × 5½ in. Pp. 101 + viii, with 8 illustrations. 1971. Oxford: Published for the Girdlestone Orthopaedic Society by the Oxford University Press. £1·50.

PROFESSOR TRUETA has put the medical profession in his debt by writing such an interesting account of the life of G. R. Girdlestone. It is true that he knew his subject well as he worked with Girdlestone at Oxford and eventually held the same post as Girdlestone, namely, Nuffield Professor of Orthopaedic Surgery, at Oxford.

One of the interesting features of this book is the inclusion of letters written by Sir Robert Jones to Girdlestone and the replies. These letters give the reader a first-class insight of both these men and their burning interest in the care of crippled children.

Girdlestone will always be remembered as an outstanding orthopaedic surgeon and the founder of the Wingfield Morris Orthopaedic Hospital, which today is known as the Nuffield Orthopaedic Centre. Lord Franks, a patient of Girdlestone, writes a foreword to this book and whole-heartedly recommends it, and so does the reviewer.

Progress in Pediatric Surgery. Vol. 2. Edited by P. P. RICKHAM, W. Ch. HECKER, and J. PRÉVOT. 8¾ × 5½ in. Pp. 178 + vii. Illustrated. 1971. Berlin: Urban & Schwarzenberg. DM.45.

THE editorship of this interesting paperback comes from England, Germany, and France, an excellent combination as far as paediatric surgery is concerned.

The papers which comprise this book were delivered in July, 1970, at the Alder Hey Children's Hospital, Liverpool, where a postgraduate course on recent advances in neonatal surgery took place.

Such subjects as recent advances in the surgery of the diaphragm in the newborn, surgery of oesophageal atresia, intestinal obstruction, anorectal abnormalities, renal cystic disease in children, and exstrophy of the bladder are included.

This book demonstrates in no uncertain way the importance of paediatric surgery and that special centres are required to deal with neonatal surgery.

The illustrations are excellent.

Engineering and Living Systems. Interfaces and Opportunities. By D. R. RUTSTEIN, M.D., Harvard, and M. EDEN, Massachusetts. 9 × 5¾ in. Pp. 320. 1971. London: The M.I.T. Press. £5·85.

THIS book rightly calls for closer co-operation between medicine and engineering, which includes mathematics and the use of computers. Such items as artificial internal organs, bio-engineering curricula, diagnostic instrumentation, image processing and visualization techniques, neurophysiology, sensory aids, skeletal prostheses, and subcellular engineering are discussed at length in this book.

If all branches of medicine and surgery are to progress in the future a much closer appreciation is necessary of all the newly invented engineering products.

The book also highlights the importance of mathematics in the medical curriculum.

Basic Practical Surgery. By C. BARRIE WILLIAMS, M.D., F.R.C.S., Bristol. 7¼ × 4¾ in. Pp. 180, with 107 illustrations. 1971. Bristol: John Wright & Sons Ltd. £1·75.

THIS cheap paperback is the ideal book for the student of today, for it gives the reader all the basic facts concerning modern-day surgery. It is written in a clear, concise way and the illustrations, all line drawings, are excellent. This is a book for the student to carry in his pocket for ready reference. There are some blank pages at the end of the book for notes, a real asset for the student. This is by far the best book on basic practical surgery that has so far been published.

Fractures of the Mandible. By H. C. KILLEY, F.D.S. R.C.S. (Eng.), F.D.S., H.D.D. R.C.S. (Edin.), L.R.C.P. (Lond.), M.R.C.S. (Eng.), F.I.C.S., London. Second edition. 8¾ × 5½ in. Pp. 74, with 42 illustrations. 1971. Bristol: John Wright & Sons Ltd. 75p.

THIS excellent paperback now appears in a second edition. The author's clear decisive style and the excellent illustrations make this an ideal book for students, and the price is well within the pocket of all students. Both dental and medical students will find this book of real use in this traumatic age. The book is well printed and there is a full bibliography at the end.

Full Dentures. The Treatment of the Edentulous Patient. By ALAN MACK, M.D.S. (U. Durh.), F.D.S. R.C.S. (Eng.), London. 8¾ × 5½ in. Pp. 105, with 130 illustrations. 1971. Bristol: John Wright & Sons Ltd. £1·70.

THIS excellent paperback is No. 13 of the well-known Dental Practitioner Handbooks published by John Wright & Sons Ltd. of Bristol. It is one of the best in the series, for it gives the reader an admirable account of the 'why' and the 'wherefore' of full dentures. The book is comprehensive and complete. From the examination of the patient, conditions before extraction, impressions, centric occlusion, to the finished denture—all are described in a vivid and clear style. The illustrations throughout the book are excellent. A useful bibliography is to be found at the end of the book.

Fractures of the Middle Third of the Facial Skeleton. By H. C. KILLEY, F.D.S. R.C.S. (Eng.), F.D.S., H.D.D. R.C.S. (Edin.), L.R.C.P. (Lond.), M.R.C.S. (Eng.), F.I.C.S., London. Second edition. 8¾ × 5½ in. Pp. 78, with 39 illustrations. 1971. Bristol: John Wright & Sons Ltd. 90p.

THE second edition of this excellent paperback is very welcome, for it contains a wealth of useful information concerning the treatment of the all-too-common injuries of the middle third of the facial skeleton.

In this age of trauma, road-traffic accidents are on the increase and motor-cyclists and motorists are constantly involved, and facial injuries are common.

This book, which is well illustrated with clear drawings, reveals the importance of the co-operation of the dental surgeon with the plastic surgeon to achieve good results.

The cost of this useful book is most moderate.

Anatomy of the Brain and Spinal Medulla. By NEVILLE G. SUTTON, M.B., Ch.M., D.S., F.R.C.S., F.R.A.C.S., Brisbane. 8½ × 5½ in. Pp. 162 + viii. Illustrated. 1971. London: The Butterworth Group. £2·80.

THERE can be no doubt whatever that medical students find that anatomically the brain and spinal cord are the most difficult parts of the body to understand. This being so, this small manual will be welcome as it sets out in a clear and practical way the essential points in the anatomy of the brain and spinal medulla. The illustrations, for the most part line drawings, are good and not too detailed. The X-ray pictures, including ventriculograms and angiograms, are excellent. This is a book that every medical student will find essential for his preclinical studies of anatomy. Final-year students will find this book of value in their surgical anatomy programme.

Plastic and Reconstructive Surgery. Edited by J. T. HUESTON, M.B., M.S. (Melb.), F.R.C.S., F.R.A.C.S., Melbourne. 9½ × 7 in. Pp. 1300. Illustrated. 1971. London: The Butterworth Group. £18·60.

THE numerous papers in this large work were presented in Melbourne in February, 1971. The editor must be congratulated in getting this volume published some six months after the papers were delivered.

There is a pleasing photograph of Mr. B. K. Rank, who was the President at this important international gathering.

This volume deals with various conditions which are discussed in ten sessions.

Session I deals with malignant melanoma, and some seven papers are included which detail the many and varied factors concerned in this disease. Facial paralysis is also considered under this section and the various plastic treatments are dealt with in detail.

Session II gives a very good survey of facial injuries and their treatment.

Session III is concerned with the treatment of cleft lip and palate. This is a large section and the modern methods of dealing with this condition are described and beautifully illustrated. Hypospadias is also considered at length.

Session IV discusses nasal deformities, correction of protruding ears, and the reconstruction of the ear.

Session V surveys tendon surgery and soft-tissue and skeletal repair of the hand.

Session VI deals with Dupuytren's contracture, rheumatoid hand surgery, and congenital abnormalities of the hand.

Session VII is concerned with basic science studies, and deals with skin-grafting from every aspect.

Session VIII is a most comprehensive survey of burns and their treatment.

Session IX is devoted to the reconstruction of facial defects and is interesting and practical.

Session X, a very large section of the book, is concerned with aesthetic surgery and general techniques.

One of the features of this large volume is the excellence of the illustrations, especially the clinical pictures depicting conditions before and after operative intervention.

This is an excellent reference volume dealing with plastic and reconstructive surgery.

Oral Diagnosis. Oral Medicine. By DAVID F. MITCHELL, B.S., D.D.S., Ph.D.; S. MILES STANDISH, D.D.S., M.S.; and THOMAS B. FAST, D.D.S., M.S.D., Indianapolis. Second edition. 10 × 7 in. Pp. 458 + xi. Illustrated. 1971. London: Henry Kimpton. £8·30.

THE authors of this large work rightly insist that oral diagnosis/oral medicine is the foundation upon which the dental curriculum as well as dental practice rests. There are four large sections to this volume: Section 1 is a very complete introduction to oral diagnosis, while Section 2 is concerned with comprehensive clinic oral diagnosis, which includes radiographic examination. Section 3 gives a very interesting account of the recognition and management of oral *pathosis*. This is a curious word and one with which we are not familiar. Section 4 is taken up with treatment planning and patient management.

The illustrations are uniformly good throughout the book. It is interesting to note that the stethoscope can be used in the diagnosis of a fracture of the lower jaw.

This book will be useful not only for students but also to resident medical officers and casualty officers.

Diseases of the Breast. By C. D. HAAGENSEN, M.D., Columbia. Second edition. 10⅕ × 7⅕ in. Pp. 829 + xvi. Illustrated. 1971. London: W. B. Saunders Company Ltd. £14·90.

THE second edition of this large work appears some fifteen years after the original one, and considerable progress has been made in this interval with regard to cancer of the breast in particular. This new volume is comprehensive and is beautifully illustrated with clinical pictures, pathological specimens of breast conditions, and photomicrographical material. It is stimulating to find such a wealth of original drawings. The operative techniques are clear and enhance the written word.

The mature clinical acumen of the author is seen in the whole presentation of this work.

There is a complete author index at the end of the book, but it is a pity that there are some mistakes in the names of the British authors. There is also an extensive index.

Many surgeons will find this work an excellent reference volume on diseases of the breast.

Transperikardiale Operationen an den Hauptbronchien und Lungengefassen. By L. K. BOGUSCH, A. A. TRAVIN, and J. L. SEMENENKOW, Moscow. 10⅔ × 7 in. Pp. 232. Illustrated. 1971. Stuttgart: Hippokrates Verlag. DM.148.

THIS book on transpericardial surgical procedures on the main bronchus and the pulmonary vessels originated in Moscow and has been translated into German. There is a detailed anatomical description of the mediastinum in relation to the surgical project. Preoperative investigations and anaesthetic problems are discussed in detail. The second part of the book analyses the author's experience with 42 patients who underwent such surgical procedures, usually for advanced tuberculosis, where other standard operations had resulted in fistulae and persistent infection. There were 6 deaths.

The book is well illustrated and the colour reproductions are excellent. The translation is rather stiff and at times difficult to follow. The book is beautifully produced, but at over £15 it is expensive. It will be of interest to a rather small number of surgeons involved in this highly specialized field.

The Immunobiology of Transplantation. By RUPERT BILLINGHAM and WILLYS SILVERS, University of Pennsylvania. 9 × 5¾ in. Pp. 209 + xiii. Illustrated. 1971. London: Prentice-Hall International Inc. £2.

THIS paperback is one of the 'Foundations of Immunology' series edited by Abraham G. Osler and Leon Weiss. This series provides an authoritative treatment of important problems in major research areas where rapid development of new information requires an integrated and reliable evaluation.

This book provides an excellent account of the immunological problem in the operation of transplantation.

Consideration is given to the genetic determination of the fate of grafts, the genetics of histocompatibility in man, and weak histocompatibility factors. The problems of thymus and transplantation immunity and immunological tolerance are discussed at some length. There is an excellent chapter on immunosuppression at the end of the book.

This is a useful book and one that will be read by pathologists, physiologists, and research workers who are dealing with transplantation of organs.

Atlas of Ear Surgery. By WILLIAM H. SAUNDERS, M.D., Columbus, Ohio, and MICHAEL M. PAPARELLA, M.D., Minneapolis. Second edition. 10¾ × 8½ in. Pp. 390 + ix. Illustrated. 1971. London: Henry Kimpton. £14·40.

THE second edition of this comprehensive atlas of ear surgery will be welcomed by students and postgraduates alike. The drawings, mostly line, are clear and concise; every detail in the various and many operative techniques on the external, middle, and internal ear are excellent. The second chapter in the book is concerned with dissections of the temporal bone, and the way in which this bone can be removed from the skull of the cadaver. It is only by making himself familiar with the minute anatomy of the temporal bone that the would-be aural surgeon can hope to be able to operate on pathological conditions.

Aural surgery has made vast strides since the Second World War and the various operations involving stapedectomy are now perfected.

Decompression of the seventh cranial nerve by an antral or a transcranial approach is described in detail.

This volume should be in every medical school library, for it is the best atlas of ear surgery that has so far been produced.

Modern Trends in Surgery—3. Edited by W. T. IRVINE, B.Sc., M.D., Ch.M., F.R.C.S., London. 8½ × 5½ in. Pp. 325 + x. Illustrated. 1971. London: The Butterworth Group. £3.

THIS third volume in the series of 'Modern Trends in Surgery' contains some very interesting articles from surgeons in this country and in America.

The articles range over a wide field, from the treatment of shock to the treatment of malignant tumours of the paranasal sinuses. The value of radiotherapy in the treatment of oesophageal cancer is discussed at some length and some favourable results are reported. Articles on rectal prolapse, cancer of the breast, surgical treatment of coronary artery disease, and the topical use of 5-fluorouracil cream for skin cancer are outstanding.

Senior students and postgraduates preparing for higher degrees or diplomas will find this paperback of real value.

The printing and illustrations of this book are excellent and the price is quite moderate.

Amputees and their Prostheses. By MOHINDER A. MITAL, M.D., M.Sc.Bio., and DONALD S. PIERCE, M.D., F.A.C.S., Boston. 9¾ × 7¼ in. Pp. 214 + x, with 58 illustrations. 1971. Edinburgh: Churchill Livingstone. £6·50.

Two World Wars and the increase in road-traffic accidents all over the world have extended the number of amputations performed. In this book a brief outline of the amputee services at Massachusetts General Hospital is presented and then the whole wide subject of the causes and treatment of amputation cases comes under review. The various levels of amputation are considered in detail and the impact of amputation on the patient and society is discussed at some length.

The prosthesis is considered: concepts, components, fabrication, and limitations are all included.

The pre- and postoperative treatment is considered in a practical way.

The book is illustrated with clear and concise line drawings.

A useful reference volume.

Glossaire d'histopathologie des tumeurs humaines. By RENE GÉRARD-MARCHANT, Anatomopathologiste de l'Institut Gustave-Roussy. 8¼ × 5¾ in. Pp. 144 + vi. 1971. Paris: Masson et Cie. 42F.

THIS glossary offers a short and clear histological description of the benign and malignant tumours of the body tissues, though colonic and rectal tumours are omitted.

The author has been successful in creating uniformity in the nomenclature.

The book is very useful for specialists and general practitioners who are not too familiar with tumour pathology and are in need of a quick orientation after the reports of the pathologist are received.

The Structure and Support of Contemporary Residency Programs in Surgery. Edited by HAROLD G. BARKER, M.D., New York. 9 × 6 in. Pp. 290 + xxi. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $12.50.

THIS volume contains the papers which were presented at the Thirteenth Annual Meeting of the Allen O. Whipple Surgical Society which was held in the University of Pennsylvania. The large number of contributors cover the whole field of surgical training programmes in a very critical and comprehensive style.

The volume is divided into four parts: Part 1 is devoted to the development of surgical training programmes; Part 2 deals with the important problem of financial support for surgical training programmes; Part 3 is concerned with the federally insured patient in surgical education; while Part 4 deals with the problems and solutions for graduate surgical education.

As one would expect with the affluent society in America, they seem to be entering an era when many members of their society are asking for a modification of the traditional health care. More and more people want personal physician's and surgeon's services and are willing to pay for them.

This book, which is full of useful information, presents the problems which are causing some concern in the training and payment of the interns in American hospitals.

Nephron Failure: Conservation, Substitution, Replacement. By JOHN B. DOSSETOR, B.M., Ph.D., F.A.C.P., F.R.C.P., Edmonton, and M. HENRY GAULT, M.D., C.M.M.Sc., F.A.C.P., Montreal. 9¾ × 6¾ in. Pp. 303 + xi. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $19.75.

THIS is a useful monograph which fills in many facts which are often hard to find in one single book. 'Nephron failure' is a name that will soon be universally used instead of 'renal failure'.

Many physicians and surgeons have patients suffering from renal failure under their care and this book will be of great value to them and to all clinicians. It covers the whole wide field of renal failure. The drugs used in the treatment of renal failure are discussed in detail, including the corticosteroids and immunosuppressive drugs.

Neurorenal syndromes come under review. Haemodialysis and peritoneal dialysis are discussed in full.

The final chapter is an attempt to put the logistics of the whole renal failure problem into current perspective.

The illustrations throughout the book are good and have been well chosen. This book will appeal to all clinicians, to research workers, and especially to urologists.

Surface and Radiological Anatomy. Fifth edition. Edited by W. J. HAMILTON, M.D., D.Sc., F.R.C.S., F.R.C.O.G., F.R.S.E., Emeritus Professor of Anatomy in the University of London; G. SIMON, M.D., F.R.C.P., D.M.R.E. (Cantab.), F.F.R., Radiologist to the Diagnostic X-ray Department, St. Bartholomew's Hospital, and to the Brompton Hospital; and S. G. IAN HAMILTON, M.A., M.Chir. (Cantab.), F.R.C.S., Consultant Surgeon, Royal Cornwall Hospital, Truro, Cornwall. Pp. 397 + x. Illustrated. 1971. Cambridge: W. Heffer & Sons Ltd. £6.

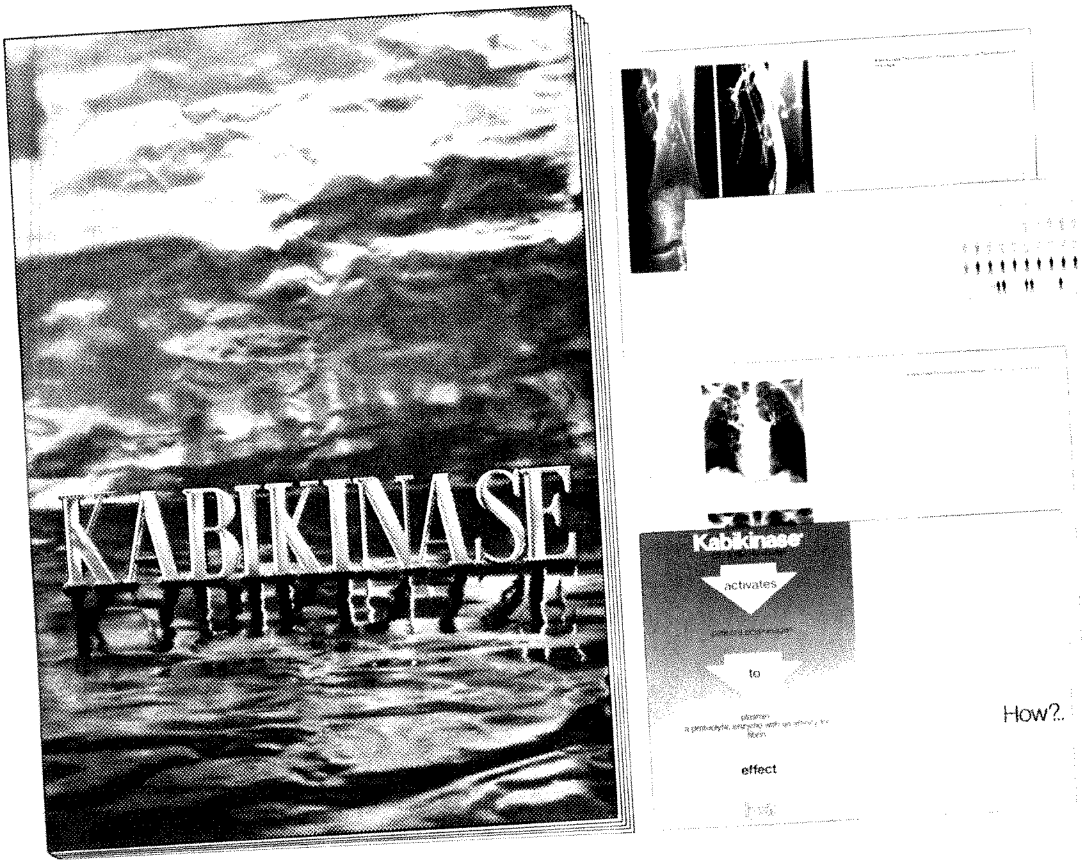
THIS is one of the really useful books for the student today, and its value will be appreciated throughout his medical career. It can be used by the student in his undergraduate days; it can be used by the postgraduate who wishes to polish up his surface and radiological anatomy before he sits for higher diplomas or degrees; it will also be useful for ready reference in the library of any doctor.

There are many unique features in this volume and the most important is the excellence and the beautiful reproductions of the numerous illustrations, which number nearly five hundred. The drawings of A. K. Maxwell are outstanding and could not be bettered. It is stimulating to see so many new and original illustrations.

The editorial trinity have established a wonderful text; the association of an anatomist, a radiologist, and a surgeon seems to be ideal.

The book is divided into sections which enable it to serve as a complement to the study of anatomy in the cadaver both for preclinical and postgraduate students. Much of the book could be studied with profit by students of physiotherapy, radiotherapy, and physical education, and all who use radiology to investigate man in health or disease will find it an invaluable guide.

The first edition of this book appeared in 1938, and since then it has gone from strength to strength. The book is a great credit to British medical literature.



Immediately available on request
the up-to-date manual on **Thrombolytic Therapy**

This manual describes how highly purified streptokinase (Kabikinase), potentiates the body's natural ability to dissolve thrombi.

It discusses the respective roles of thrombolysis and anticoagulation, and defines the place for Kabikinase Thrombolytic Therapy in:

venous thrombosis "... 30 per cent of ill medical and surgical patients develop thrombi...." There are comments on clinical detection, diagnostic procedures and sequelae;

pulmonary embolism "... the cause of death of 1 in 200 hospital admissions." The "at risk" patient is identified;

acute arterial thromboembolism – the results of thrombolysis are discussed;

chronic arterial occlusive disease – recent work is described.

Reference is made also to:

Thrombolysis for coronary thrombosis, clotted haemodialysis shunts, occlusion of retinal vessels, meningitis and ventriculitis.

Early treatment of deep vein thrombosis preserves valvular function and should avert the post-phlebitic leg.

Medical embolectomy for pulmonary embolism is now the first line of attack.

Thrombolytic therapy is facilitated by the Kabikinase Standard Dosage Scheme.

With the **HANAULUX GLASS FIBRE OPTIC LAMP**

The Glass Fibre Optic Satellite Lamp gives concentrated illumination for cavities and other areas requiring additional light, and because the light emitted is absolutely cold (being free from infra-red) the sterilizable flexible light-head can be adjusted by the surgeon and the possible drying of a wound is obviated.

Of particular value in neurosurgery, ENT and gynaecology, this lamp has maximum manoeuvrability and remains firmly in any adjusted position. The light-head can, in fact, be moved down to table top level.

This Hanaulux Glass Fibre Optic Lamp can be satellite-mounted on the main operating lamp, or installed as a separate wall or ceiling unit.

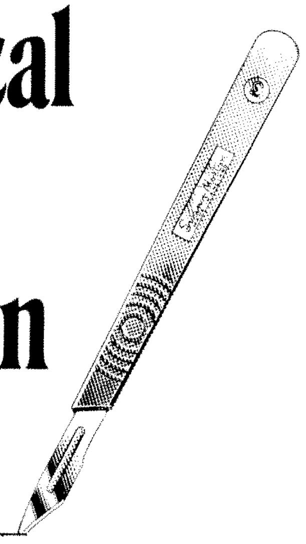
Swann-Morton surgical blades have an edge over the others



Swann-Morton of Sheffield are one of the largest manufacturers of surgical blades in the world. The Company achieved this leading position through the unvarying high quality of its products.

Swann-Morton blades are manufactured of the finest tempered surgical steel, precision-ground to give edges of the high degree of sharpness essential for the most delicate surgery. Swann-Morton blades are safe, stable and economical. They are sterilized by gamma radiation, packed in quick-peel foil envelopes and colour-coded for easy recognition. They can also be kept indefinitely under any conditions of storage and climate.

Here are details of the Swann-Morton range of products:

Sterilized stainless steel blades
Sterilized carbon steel blades
Standard carbon steel blades
Sterile disposable scalpels
Sterile disposable stitch cutters
Surgical handles
Autoclavable plastic surgical handles

WRIGHTS of BRISTOL

For rapid, safer post operative wound healing
Redivac closed suction apparatus
TO PREPARE
KEEP UPRIGHT
IMPORTANT
Zimmer

First intention wound healing after operation is prolonged by the accumulation of tissue fluids and blood at the site. This accumulation often encourages infection.

The problems associated with these traditional procedures are solved by Redivac Closed Suction Apparatus, which removes blood and tissue fluids and avoids the formation of haematoma.

The Redivac evacuator bottle supplies a negative pressure of 600 mm Hg. The drainage tube is laid in the wound and is passed through intact skin, some distance from the incision. It is then connected to the evacuator bottle and suction commenced.

The Redivac Closed Suction System is simple, inexpensive and comfortable for the patient. It is applicable in all deep surgical procedures. The Redivac Closed Suction System facilitates nursing and results in shorter hospitalisation of patients.

Congenital Deformities of the Testis and Epididymis

C. Gordon Scorer, MBE, MD, FRCS, FRCS(Ed) and Graham H. Farrington, MCh, FRCS

This is a clear and very thorough appraisal of a subject which is of great importance to general practitioners and school medical officers as well as paediatricians and surgeons, prepared by authors who have devoted many years to the study and surgical correction of testicular anomalies in children.

Surgical Departments in Hospitals—The Surgeon's View

Professor Donald Macleod Douglas, MBE, MBChM, MS(Minn), FRCS(Ed)

The economic effects of two world wars within twenty-five years resulted in a virtual standstill in hospital planning between 1914 and 1950. As a result little thought was devoted to hospital organization until the pioneering studies of the Nuffield Provincial Hospitals Trust shortly after the end of the second world war. Since then there has been great activity in the field and the capital building programme for new hospitals in the National Health Service has gradually increased to the current figure of 120 million pounds per annum. However, although much has been written by architects and administrators on hospital planning and design there has been a dearth of publications by practising surgeons involved in the day-to-day clinical care of patients and all the administrative problems associated with it.

With the agreement of the President and Council of the Royal College of Surgeons of Edinburgh, a study group was set up, with individual surgeons being responsible for the examination of a particular issue, which was researched by a group of people concerned. Finally a conference was held in the Royal College of Surgeons in Edinburgh on October 13th, 1969, at which the various reports were presented. This volume constitutes an edited version of the conference. Although its reports were confined to an examination of the situation in Scotland, it will be a most welcome approach to the problem for administrators and others concerned throughout the world. No comparable consideration of the question from this viewpoint exists elsewhere.

Now ICI bring to surgical scrubs the proven advantages of Hibitane in

TRADE MARK
# hibiscrub

Antibacterial Activity

From the bacteriological point of view the demand is for a surgical scrub which combines maximum antibacterial activity with pronounced residual effect.

'Hibiscrub' fulfills these requirements. It is not only rapidly effective against both gram positive and gram negative organisms but also exhibits good residual activity – a major advance in the development of surgical scrubs.

Hand Care

The effect of prolonged usage on the hands of surgical staff is a critical factor in the acceptability of any surgical scrub. Sensitivity reactions, excessive detergency etc., can lead to the abandonment of certain scrub regimes.

'Hibiscrub' is positively pleasant to use – nurses using it regularly have reported on the excellent condition of their hands.

Why go on using substitutes

when you can have the real thing?

Why use second best when you can use DEXON - the only material specifically *designed to be a suture*

DEXON is the most documented suture in the history of surgery. It is far stronger than gut, handles like silk, absorbs uniformly and predictably yet retains its strength throughout the critical healing period. Above all, DEXON is inert therefore tissue reaction is minimal

So why not change to DEXON

the Ideal Suture

- you owe it to your patients and to yourself -

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·10	£2·80	£3·20	£3·80	£4·30	£4·80	£5·90	£6·90
4	2·70	3·90	4·60	5·40	6·16	6·90	8·40	9·90
6/8	4·50	5·80	7·10	8·30	9·60	10·80	13·40	15·90
10/12	7·20	9·80	11·70	13·70	15·70	17·70	21·80	25·40
14/16	8·70	11·10	13·50	15·90	18·30	20·70	25·50	30·30
18/20	11·40	15·10	18·20	21·30	24·50	27·70	33·90	39·00
COVERS	1·50	2·10	2·70	3·30	3·90	4·50	5·70	6·90

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 58. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St. Martin's House,* 159 *Clapham High Street, London, S.W.*4.

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

Post-prostatectomy EPSIKAPRON® is better than post-prostatectomy bleeding*

**This observation has a high degree of clinical significance.*

Post-prostatectomy blood loss may be a litre or more[1,2]. Use of EPSIKAPRON can reduce this loss by 80-90%[3,4]. "The control of blood loss has proved to be not only statistically but also clinically significant"[2]. Blood transfusion, which is costly and not without risk, ". . . can be avoided and draining catheters kept patent without difficulty and removed earlier, which makes the post-operative course smoother and shorter"[3].

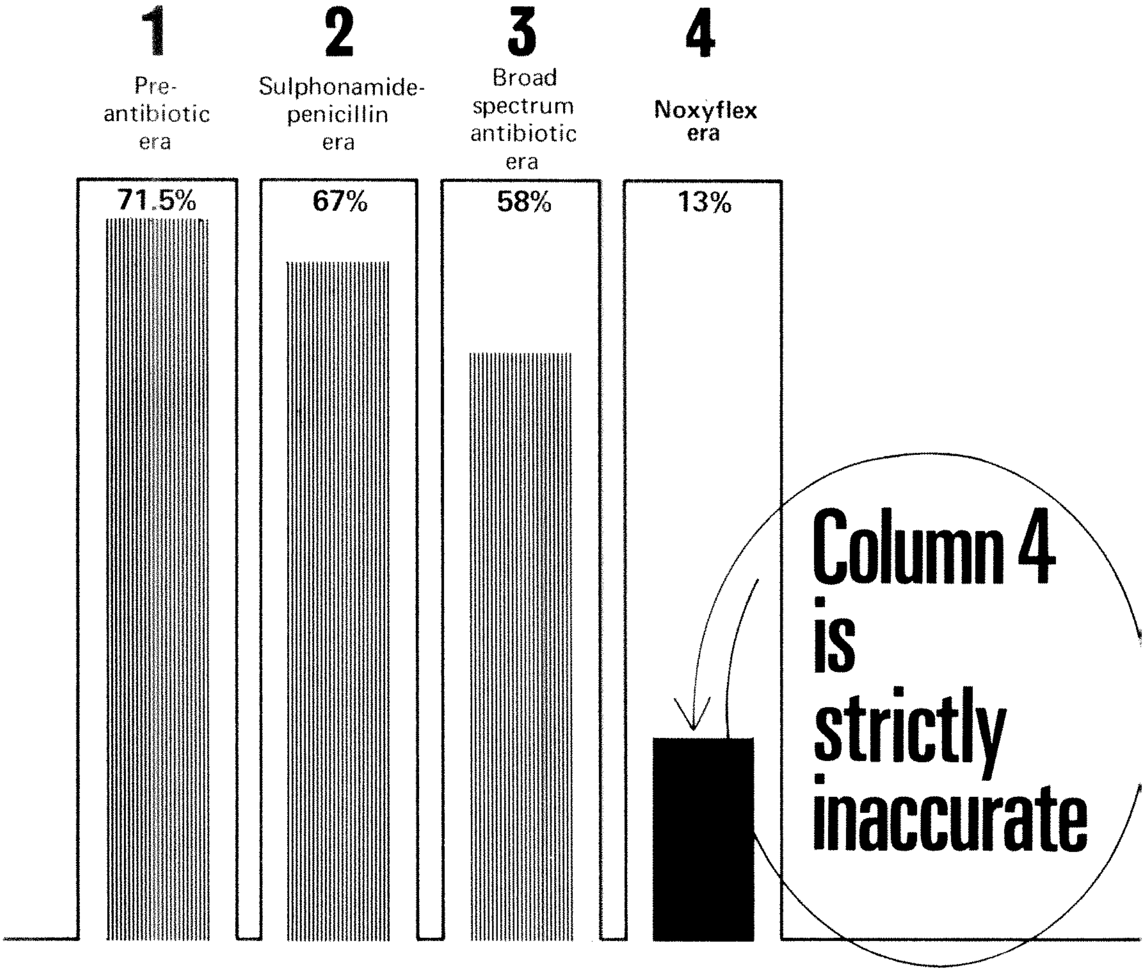
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

When bacterial contamination of the peritoneum is diagnosed or suspected: Noxyflex

Geistlich Chester

Now, to simplify treatment of pseudomonas chest infections:

Pyopen infusion

In the published papers, Pyopen's success rate in chest infections is 65% even though the majority of the patients described had severe underlying pathology.

The best results have been achieved with a dosage of 20-30G. I.V. daily. Pyopen infusion makes this dosage simpler to administer by providing Pyopen in ready-to-use infusion bottles with diluent and transfer needles for the easier preparation of infusion solutions.

Pyopen is, of course, a penicillin, and has proved valuable in patients with known renal impairment: in such cases, however, dosage should be reduced.

Adult dosage: 20-30G. I.V. daily.
In patients with renal impairment dosage should be reduced.
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen

DICONAL TABLETS

for relief of severe pain when morphine injection would normally be given

DICONAL* is indicated in conditions where potent analgesics such as morphine would normally be used.

DICONAL Tablets contain dipipanone, which has a morphine-like action. The inclusion of the anti-nauseant and anti-emetic cyclizine enables the drug to be given by mouth.

Each tablet contains Dipipanone Hydrochloride, BP, 10 mg and Cyclizine Hydrochloride, BP, 30 mg.
DICONAL is subject to the DDA.

Full information is available on request.

For rapid, safer post operative wound healing
Redivac closed suction apparatus
TO PREPARE
KEEP UPRIGHT
Zimmer

First intention wound healing after operation is prolonged by the accumulation of tissue fluids and blood at the site. This accumulation often encourages infection.

The problems associated with these traditional procedures are solved by Redivac Closed Suction Apparatus, which removes blood and tissue fluids and avoids the formation of haematoma.

The Redivac evacuator bottle supplies a negative pressure of 600 mm Hg. The drainage tube is laid in the wound and is passed through intact skin, some distance from the incision. It is then connected to the evacuator bottle and suction commenced.

The Redivac Closed Suction System is simple, inexpensive and comfortable for the patient. It is applicable in all deep surgical procedures. The Redivac Closed Suction System facilitates nursing and results in shorter hospitalisation of patients.

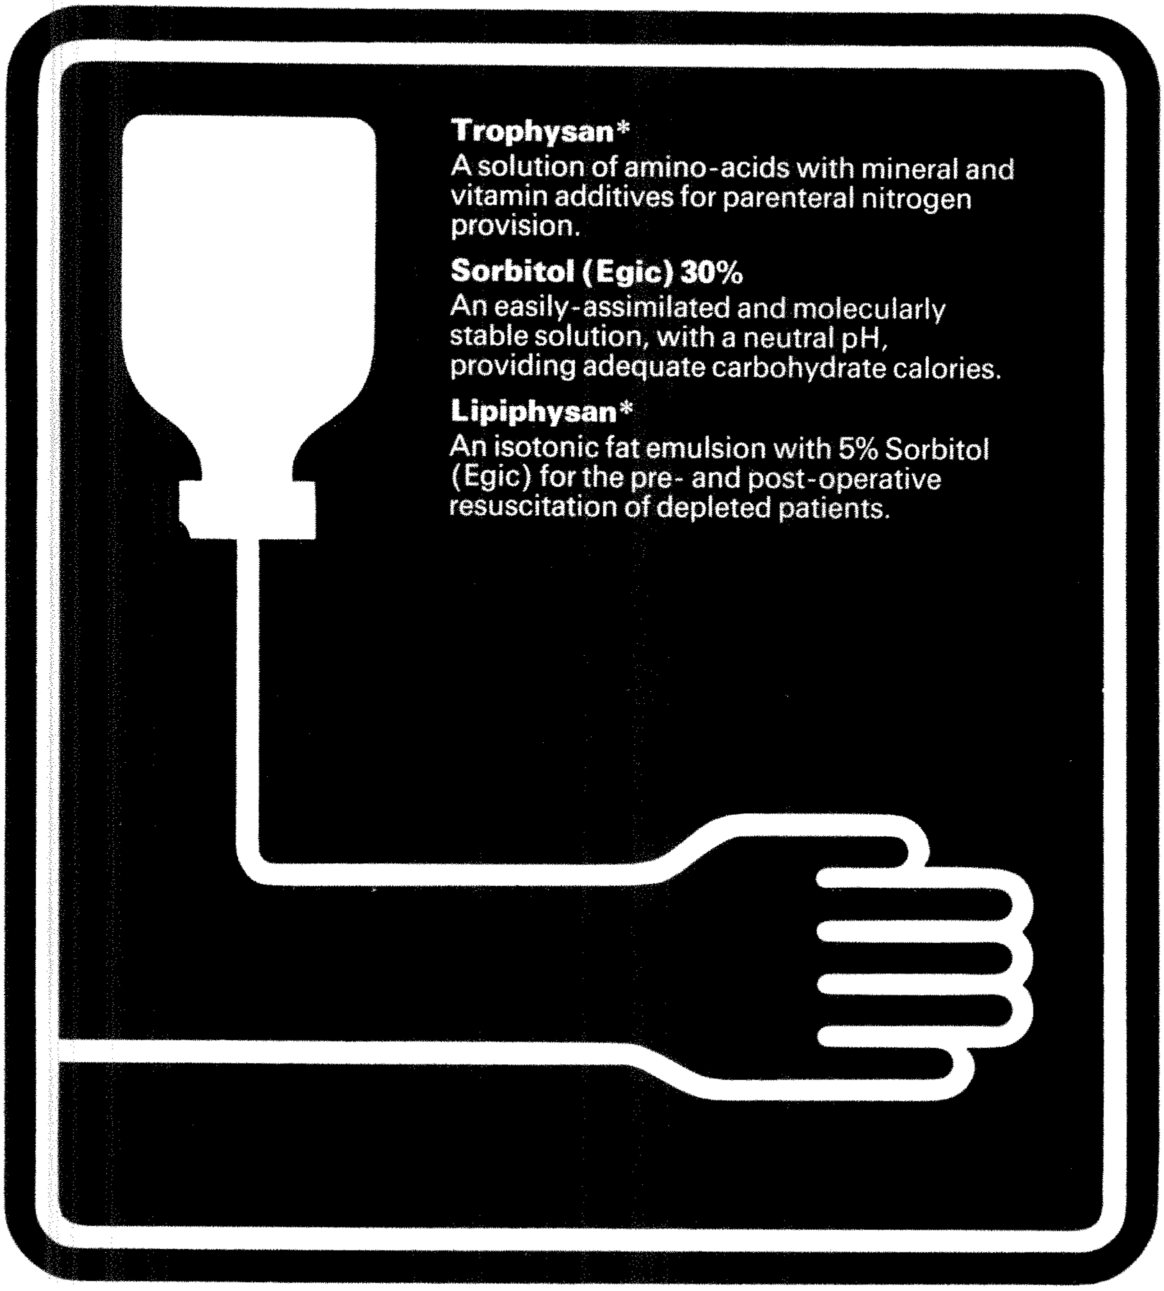
The problem of nutritional deficiency in surgery

In surgery of the GI tract the malnourished patient is a poor surgical risk. Pre-operative parenteral nutrition ensures adequate provision of nitrogen and calories and the correction of any electrolytic imbalance. This is best achieved by the use of SERVIER intravenous nutritional solutions.



Trophysan*
A solution of amino-acids with mineral and vitamin additives for parenteral nitrogen provision.

Sorbitol (Egic) 30%
An easily-assimilated and molecularly stable solution, with a neutral pH, providing adequate carbohydrate calories.

Lipiphysan*
An isotonic fat emulsion with 5% Sorbitol (Egic) for the pre- and post-operative resuscitation of depleted patients.

When nutritional deficiency is a problem, Servier has the solution.

Matburn Built-in Equipment for the Operation Theatre

There is a growing tendency in theatre design towards the use of built-in equipment systems in order to clear the theatre floor of trailing wires and tubes, suction and electrosurgery units and similar equipment.

To meet the needs of fixed services systems, a superb range of Matburn equipment has been evolved, representing many years of experience in this specialised field.

Matburn Fixed Services Systems are designed for installation in both new and existing hospitals; the technical advice of a team of skilled engineers is available at all stages of projects.

The illustration, reproduced by kind permission of the South East Metropolitan Regional Board, shows a fixed services table with mobile base installed in the Abnormal Delivery Theatre of the Greenwich District Hospital, London.

TRIALS CONFIRM FLOXAPEN'S EXCELLENT PERFORMANCE

Treatment succeeded clinically in 26 patients with staphylococcal infections and failed in four. It was unsuccessful either clinically or bacteriologically in two of three patients with pneumococcal infections.

There were no serious side-effects; three patients showed gastro-intestinal upset and two pyrexia due to penicillin hypersensitivity. No undue pain was experienced at the site of the injection.

It is concluded that flucloxacillin is a useful addition to the therapeutic armamentarium against benzylpenicillin-resistant staphylococci.

and cloxacillin has made any dramatic cures of staphylococcal infection with new agents less impressive and remarkable than would have been the case 10 years ago. Nevertheless, highly satisfactory responses were obtained with flucloxacillin at a dosage of 1·0 g daily, and cures obtained late in the trial in very ill patients using higher dose régimes can only be assessed as excellent by comparison with any other currently-available compounds and indicate the efficacy of flucloxacillin. It became apparent as the trial continued severe staphylococcal infection contained by the tions

Above: Clinical Trials J. (1970) 7, 375.
Right: Clinical Trials J. (1970) 7, 372.

Floxapen, like Orbenin (cloxacillin B.P.), is active against virtually all staphylococci and all streptococci and pneumococci irrespective of their sensitivity to traditional penicillins, tetracyclines, fusidic acid, erythromycin and lincomycin.

The standard dose of Floxapen is only 250 mg. and will attain similar serum levels by oral or injectable routes. Therapy is therefore simpler and more effective than with Orbenin.

Floxapen offers the penicillin advantages of low toxicity and bactericidal action. It is also ideal for continuing outpatient treatment because of its convenient oral dosage.

Further information is available on request.

Indications: Infections due to sensitive Gram-positive organisms, including resistant staphylococci: skin and soft tissue infections, otitis media, sinusitis, infected wounds and burns, osteomyelitis and septic arthritis, pneumonia empyema, septicaemia, endocarditis and meningitis.

Dosage Oral and intramuscular:
Adults: 250 mg. q.i.d.
Children: 2-10 years—½ adult dose.
Under 2 years—¼ adult dose.
Oral doses should be taken one hour before meals.
In severe infections dosages may be increased if required.

Availability Syrup 125 mg./5 ml.
Capsules (black/caramel) and
Vials, each containing 250 mg. flucloxacillin.

Contra-indications Penicillin hypersensitivity.
Subconjunctival injection.

Side-effects As with other penicillins.

Floxapen *simplifies antibiotic treatment in hospital and after*
flucloxacillin

Floxapen* (flucloxacillin) is a British product originated by

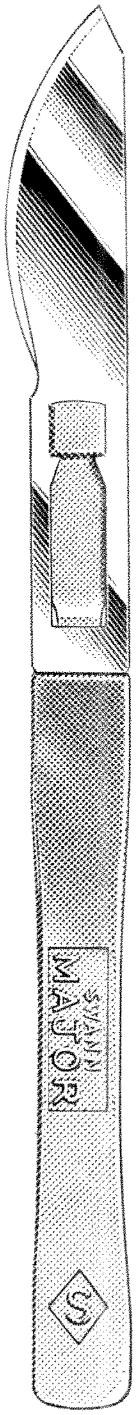
SWANN **MAJOR** SCALPELS

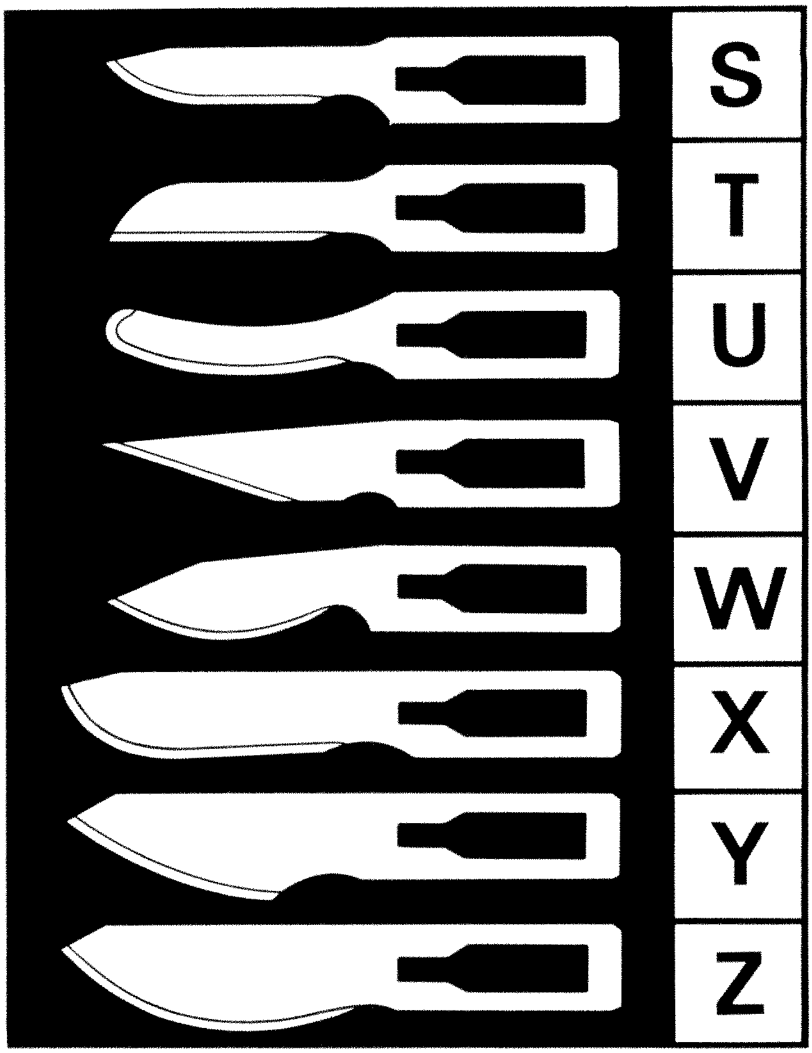
Heavy Duty-Detachable Blades for Orthopaedic and General Surgery



Combines the stability and safety of the solid scalpel with the sharpness and economy of detachable types. Single blades are enclosed in V.P.I. wrappers and sealed in an airtight metal foil packet for complete and lasting protection.

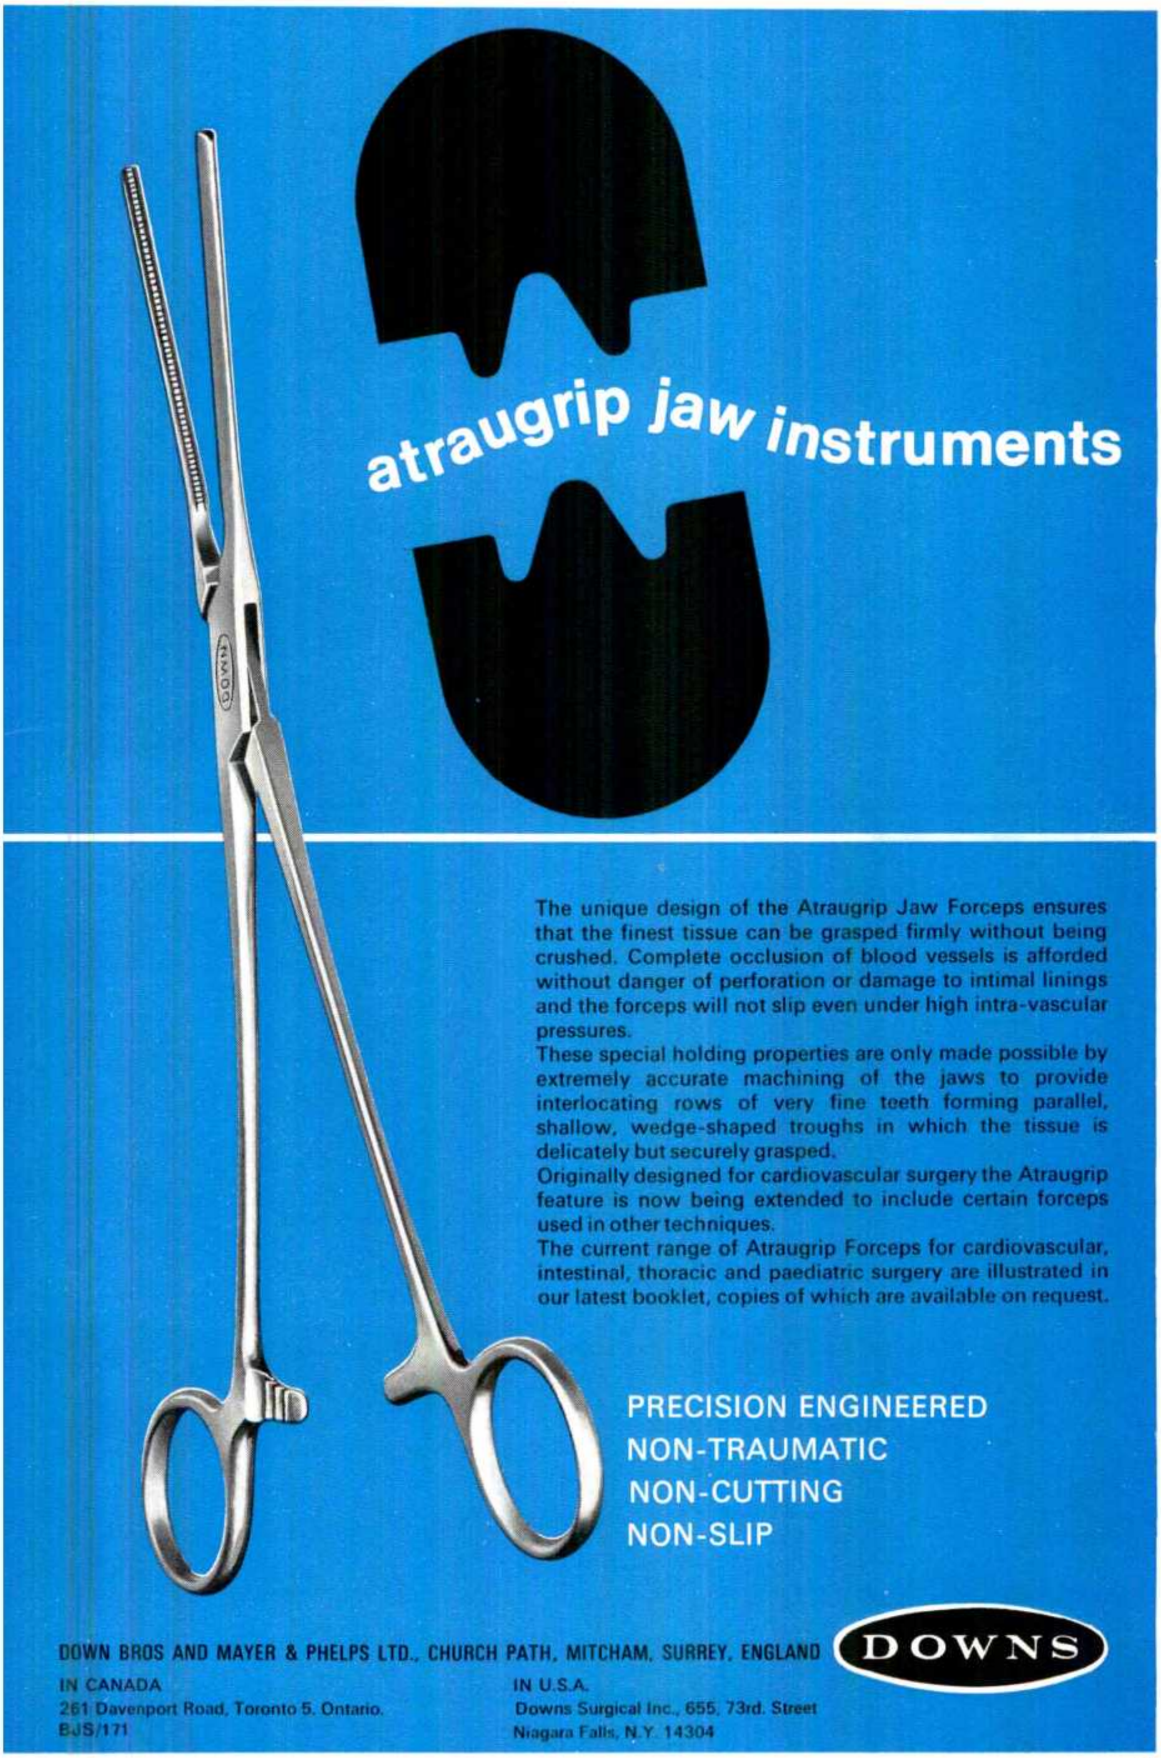
Sterilized by Gamma Radiation 2.5 M.Rads.

Handles packed singly in Autoclaving Nylon.



Swann-Morton obtainable through all Surgical Distributors.

Swann-Morton Swann-Morton (Sales) Ltd. Sheffield 6 England



atraugrip jaw instruments

The unique design of the Atraugrip Jaw Forceps ensures that the finest tissue can be grasped firmly without being crushed. Complete occlusion of blood vessels is afforded without danger of perforation or damage to intimal linings and the forceps will not slip even under high intra-vascular pressures.

These special holding properties are only made possible by extremely accurate machining of the jaws to provide interlocating rows of very fine teeth forming parallel, shallow, wedge-shaped troughs in which the tissue is delicately but securely grasped.

Originally designed for cardiovascular surgery the Atraugrip feature is now being extended to include certain forceps used in other techniques.

The current range of Atraugrip Forceps for cardiovascular, intestinal, thoracic and paediatric surgery are illustrated in our latest booklet, copies of which are available on request.

THE BATTERED BUTTOCK SYNDROME—FAT FRACTURES

A REPORT ON A GROUP OF TRAUMATIC LIPOMATA

By B. F. MEGGITT and J. N. WILSON
THE ROYAL NATIONAL ORTHOPAEDIC HOSPITAL, LONDON AND STANMORE

SUMMARY

1. A group of 12 women with traumatic fat swellings around the buttock region is presented.

2. The structure of the subcutaneous tissue and the mechanism in formation of the lipomata are described.

3. Treatment of the essentially cosmetic deformity is discussed and excision of the lipomatous mass is advised when symptoms indicate this.

THE fat covering in man gives roundness to the body and serves to transform unsightly straight lines and irregularities of the deeper structures into more graceful contours. Its greater importance, however, is that by virtue of its resilient, sponge, rubber-like composition this panniculus adiposus provides a protective lining and anchorage to the skin. It acts as a buffer between external pressures on the surface and the deeper tissues beneath. Alterations in this tissue layer through abnormal fat deposition may occur generally as nutritional or endocrine forms of obesity, or locally as fat neoplasms—the lipomata. There is, however, another group of local fat tumours which has a traumatic aetiology and is the subject of this paper.

The 12 cases reported in this series occurred in women, and the lesions were situated in the gluteal, trochanteric, or lower lumbar fat pads. They were mostly the result of blunt trauma and have been variously labelled 'battered buttock syndrome', 'fat fracture', or 'traumatic lipoma'.

As far as we can tell, this condition has not been reported previously in the literature. This is possibly because, not being very common, it has been misdiagnosed as a resolving haematoma. However, with the increase in road-traffic accidents, the condition is likely to become more frequent and, as the residual deformity may often be large, corrective surgical treatment may be required.

CASE REPORTS

Case 1.—A 21-year-old woman was referred from the neurology department complaining of a large tender swelling over the right buttock which was painful on walking. Six months previously she had been knocked down by a car in a road accident and had sustained severe concussion with transient paraparesis. There had also been extensive bruising of the right thigh with a laceration anteriorly that had been sutured. When the bruising had absorbed, the large swelling had remained. Examination confirmed a large, flabby, tender mass just below the greater trochanter, and a hollow deficiency just anteriorly with a 7·5-cm. scar in the lower part (*Fig.* 1). There was no weakness of the abductors.

At operation under general anaesthesia, using a long, anterior, curved incision, the subcutaneous fat was found to have been split obliquely across the trochanter region and it formed a large mass inferiorly. An adventitious bursa was found extending down on the deep fascia from the greater trochanter to the underpart of the fatty tumour. Repair of the defect was undertaken with difficulty by advancing the lower fat mass anteriorly after scarifying the bursa. The fat itself could not be flattened, but a cosmetic improvement which was very acceptable to the patient was obtained, although a bulge remained (*Fig.* 2). The tenderness and pain were completely relieved.

Case 2.—A 25-year-old woman was referred complaining of a lump on the right thigh which produced a dragging pain on walking and was tender to lie on. Two years previously she had been thrown out of a car in a traffic accident and had fallen heavily on to the right thigh and buttock. She had developed extensive bruising with haematoma formation, requiring aspiration of 100 ml. blood from the buttock. When the bruising had eventually settled, the residual lump had become apparent and had remained unaltered over the following 2 years. Local examination showed a large, soft, tender mass

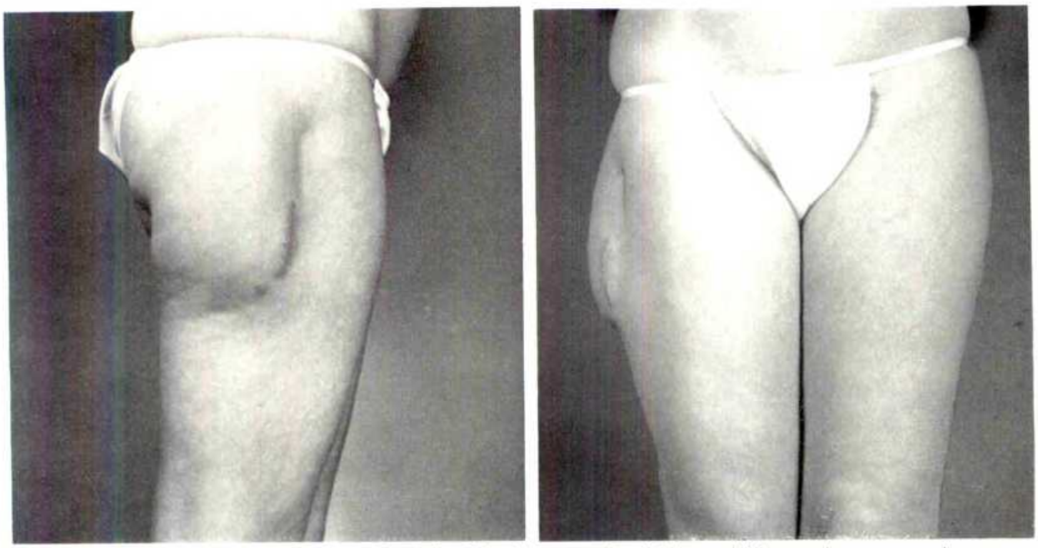

FIG. 1.—*Case* 1. Preoperative fat mass in the right thigh with an anterior deficiency visible over the greater trochanter.

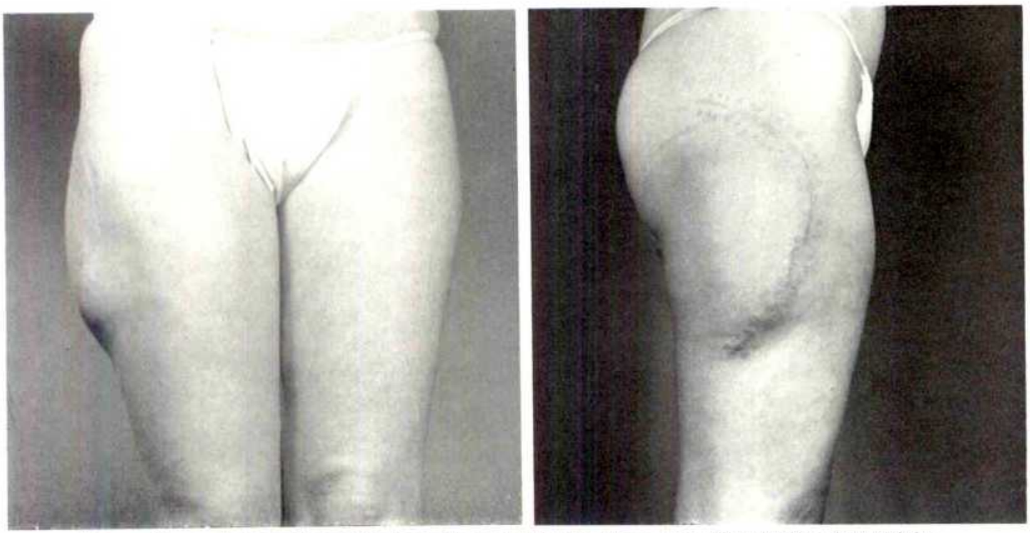

FIG. 2.—*Case* 1. Postoperative result of repair by advancing the fat mass over the greater trochanter defect.

(22·5 × 17·5 × 3·7 cm.) protruding from the lateral aspect of the right thigh (*Fig.* 3). There was a large deficiency which was palpable above the mass.

At operation under general anaesthesia a large fibro-fatty mass was excised through a curved horizontal incision (*Fig.* 4), as an advancement repair was not possible. An adventitious bursa beneath the tumour was also removed and found to contain fifteen large, free fat lobules (*Fig.* 4, inset).

The deformity was considerably improved, with restoration of the smooth thigh contour (*Fig.* 5). The aching pain produced by walking and rolling on the area was completely relieved.

Case 3.—A 35-year-old woman was referred with a large swelling (20 × 15 × 3·7 cm.) just below the right trochanter following a glancing impact by a car in a road accident 6 months previously. There had been considerable bruising around the buttock initially, with a painful limp for 4 months. This had settled, leaving the swelling in which a dragging aching pain had developed with walking, which was severe enough to require surgical relief if possible.

At exploration under general anaesthesia a large fibro-fatty mass was excised through a curved anterolateral incision. The subcutaneous fat was seen to have been split transversely just below the trochanter and it had retracted inferiorly. It had formed a conglomerate mass, free from its deep fascia attachment, with a pseudobursa underlying it. After removing all the excess fat the skin was sutured, leaving a vacuum drain. An almost normal thigh contour was obtained with complete relief of the aching pain.

Case 4.—A 6-year-old girl was admitted to hospital having been knocked down by a lorry. She was found to have sustained severe concussion, fractures of the pubic rami and right tibia, and extensive bruising of the righ

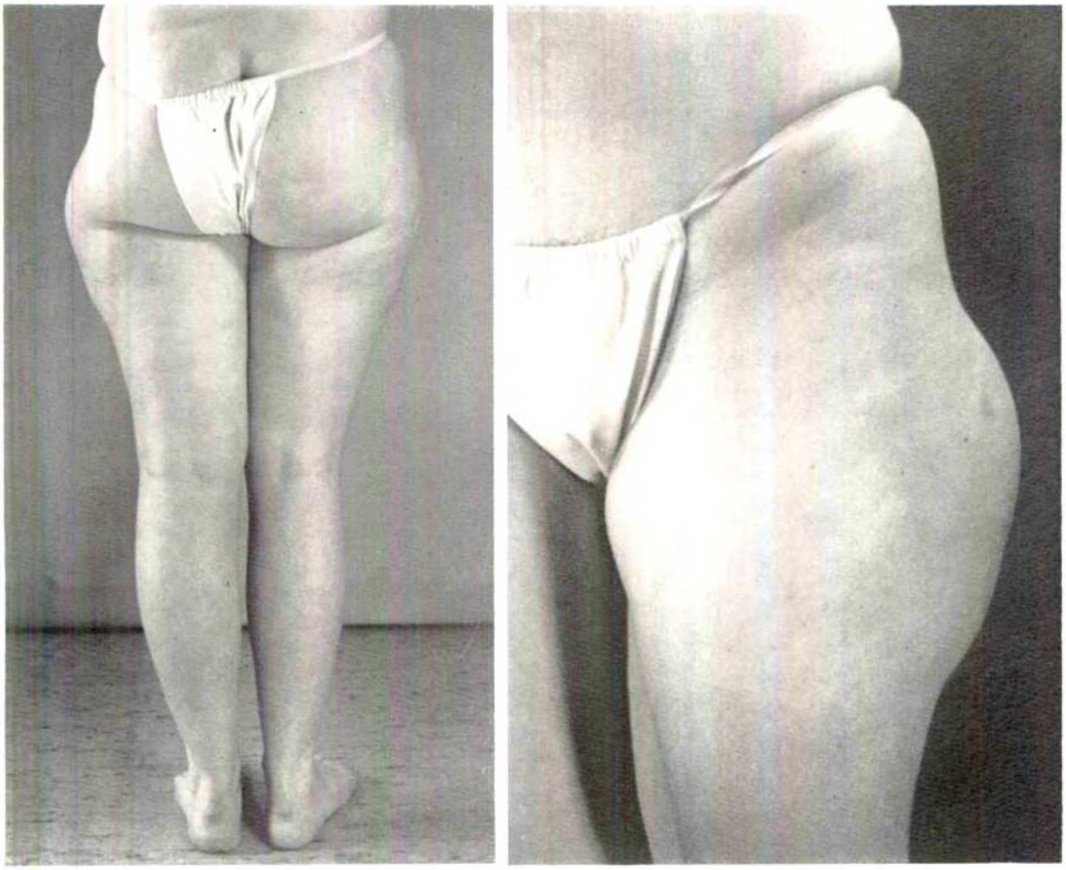

FIG. 3.—*Case* 2. Preoperative mass in the left buttock with the fat fracture defect shown above.

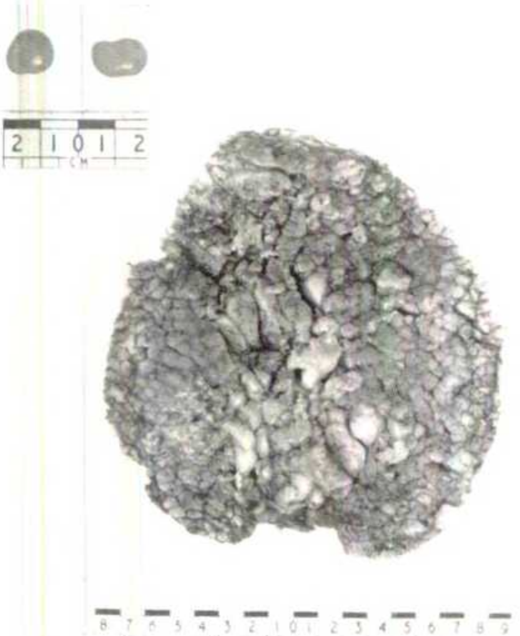

FIG. 4.—*Case* 2. Lipoma mass excised at operation. *Inset*, Two of the free fat lobules from the underlying bursa.

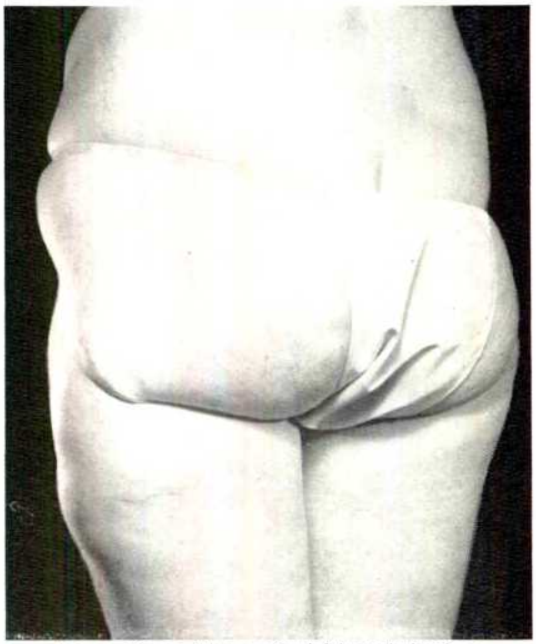

FIG. 5.—*Case* 2. Postoperative left buttock showing a good cosmetic result.

buttock. Three months later she had made a good recovery from the head injury and fractures, but was left with a large prominent swelling over the right lateral buttock (*Fig*. 6). There was a palpable transverse deficiency in the right upper buttock where a wide section of the gluteal fat had retracted laterally, producing the large deformity. At follow-up examinations over the past 12 months the size of this swelling has not altered very much. It is hoped that the swelling will get relatively smaller as the child grows, and no operation has been advised as yet.

Cases 5, 6, 7, 8, 9, and 10.—These cases are all similar to *Case* 3, being women aged between 25 and 60 years who presented with large fatty lumps in the buttock or lateral thigh of 6 months to 3 years' duration. These lumps were all the result of direct impact either from a car or from falling heavily on to the buttock, as in *Cases* 9 and 10, who were thrown out of a car on crashing. Extensive bruising occurred in all patients similar to that in *Case* 5 (*Fig*. 7), which on absorption revealed the fat fracture and a lipomatous mass below, as in *Case* 2 (*Fig*. 3). The main symptom was cosmetic deformity, but occasionally aching pain or tenderness was present. Once the nature of the swelling was understood, none of these patients was sufficiently worried to make further surgery necessary.

Case 11.—A 42-year-old woman was referred with a large tender swelling in the left lateral thigh. This had appeared immediately after a fall on to the hip region which had occurred 3 weeks earlier. There had been no bruising, but on examination there was a 10-cm. scar down the anterolateral trochanteric region. The patient had undergone two explorations of the greater trochanteric

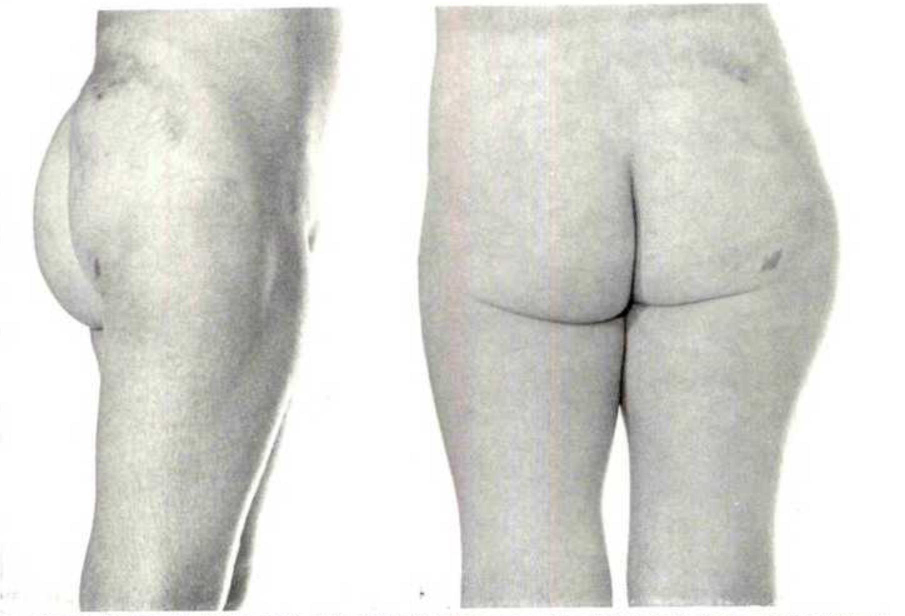

FIG. 6.—*Case* 4. Downward displacement of the right gluteal fat mass with a defect visible in the superior buttock.

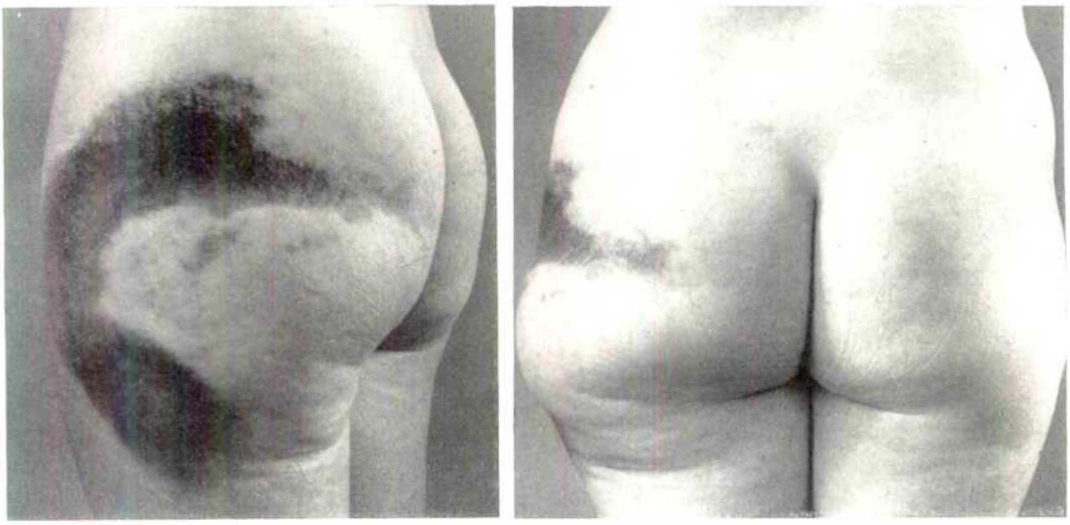

FIG. 7.—*Case* 5. 'Battered buttock' 2 weeks after injury, with the fat swelling being revealed as the bruising absorbs.

region 4 and 17 years previously for persistent pain, when non-specific bursitis was the only finding. It was in this operative area that the fat splitting had occurred (pathological fat fracture). Over the next 4 weeks the tenderness completely settled and no further treatment was required.

Case 12.—This case had a similar pattern to that in *Case* 11, but the lesion was much higher, occurring in the lumbar region posteriorly. The patient, a 56-year-old woman, was admitted to hospital following a road accident when she had been struck in the low back by a car. There was some local swelling and bruising in the lower left lumbar region and radiographic examination showed fractures of the left transverse processes of the fourth and fifth lumbar vertebrae. Over the following 4 months the back pain and tenderness settled, leaving a fatty swelling in the lower left lumbar region with a defect just above. The patient was not unduly concerned by the cosmetic deformity and no further treatment was indicated.

DISCUSSION

The structure of the panniculus adiposus would seem from a biomechanical consideration to be well adapted to maintain a resilient cushion system over the body surface for handling normal body loads. The individual fat lobules form the compressile units and are contained under some pressure by the fibrous capsule and septa which compose the tension elements. The lobules are arranged in layers of two to four deep with separating horizontal fibrous septa supported by vertical septa anchoring the epidermis to the deep fascia (gluteal or lata). This arrangement can be readily appreciated in the buttock during standard approaches to the hip region, and the fat lobules will be seen to pout where the fibrous compartments have been opened by the incisions. The whole region has a rich, fine, vascular network with larger vessels traversing the deep fascia.

Under normal body loads, local pressure produces flattening of the lobules and transference of the weight over a wider area, but the fibrous supporting septa prevent lateral migration of the fat. On release, this compression/tension system enables the tissue to return to its resting shape and position. If sudden excessive force is applied locally, such as impact from a moving vehicle (as in 9 of the cases described) or heavy falling on to the area (as in the 3 other cases reported), the fat compartments are burst open with rupture of the septa and shearing off of the anchorage between the skin and the deep fascia. Also, with local vascular damage, a varying amount of bruising and haematoma formation occurs, as in all of the present cases except for *Case* 11. The end-result is the battered buttock picture with fat fracture and traumatic lipoma formation after retraction of the detached subcutaneous tissue into the buttock or thigh. After the bruising and haematoma have been absorbed, the tissue defect above and the fat swelling below produce the typical deformity. It is a characteristic of fat tissue that it does not undergo local resorption or regeneration (the principle of abdominal apronectomy and some forms of mammoplasty), and hence the deformity is permanent in adults at least.

It is interesting to note that all the patients were female. This might be coincidence—or that women are more cosmetically conscious than men. However, it is a characteristic feature that women are more endowed with subcutaneous fat than men, especially around the buttocks and thighs. This may render the skin fascia anchorage weaker, with more liability to splitting and to the formation of larger lipomata. All the patients described here were well covered, but none was grossly overweight.

The main symptom in all the reported cases was local deformity, with aching and tenderness occurring early, but mostly settling later. Four patients with large swellings, tenderness, and local pain requested surgical treatment, and this was undertaken in 3; the fourth, a 6-year-old-girl, is still being followed up as it is thought that the swelling may well recede with general body growth.

Treatment of these traumatic lipomata may be by surgical repair or excision. The former proved partially successful in *Case* 1 where some cosmetic improvement was obtained by advancing the swelling into the defect. However, this was not possible in *Cases* 2 and 3 where the fat formed a localized fibro-fatty mass by retraction (*Fig.* 4) and could not be stretched or advanced sufficiently. Correction of the deformity by wide excision of the fatty mass gave good results in these 2 cases, with complete relief of the tenderness and pain. In the other 6, however, the deformity gave little trouble and no further treatment was necessary once the nature of the swelling was understood.

LIGATION OF THE LEFT RENAL VEIN IN SPLENORENAL ANASTOMOSIS WITHOUT IMPAIRMENT OF RENAL FUNCTION

By JOHN S. SIMON, ASHLEY A. BROWN, AND HARVEY B. ROSS
DEPARTMENT OF SURGERY, ST. BARTHOLOMEW'S HOSPITAL, LONDON

SUMMARY

This paper draws attention to the fact that the left renal vein or one of its major tributaries may be ligated without apparent impairment of function of the left kidney. This information has been of great value in constructing splenorenal shunts in operations for portal decompression. Other situations in which this information might be of value are suggested.

END-TO-SIDE anastomosis of the splenic vein to the left renal vein is an accepted method of portal decompression. Occasionally, owing to abnormal anatomy of the renal vessels, an end-to-side anastomosis is technically unsatisfactory if not impossible. Previously, when this situation was encountered, a left nephrectomy was performed and the free end of the renal vein was used for an end-to-end anastomosis with the splenic vein. This technique proved technically easier, having two free mobile vessels to be brought together (Hunt, 1958). It did, however, mean sacrifice of the left kidney.

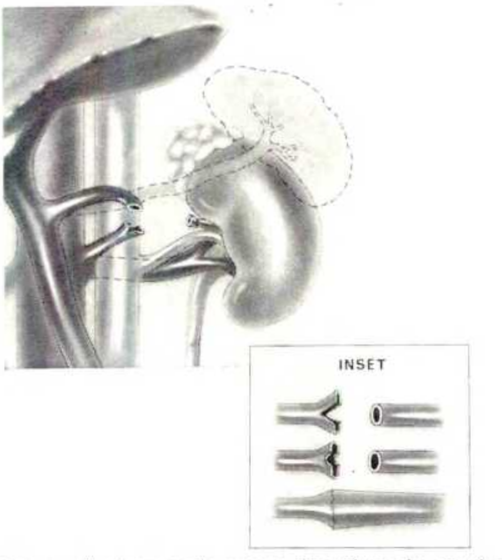

FIG. 1.—A circum-aortic venous ring where the anterior venous limit is used for an end-to-end splenorenal anastomosis. The inset shows how the vein(s) may be tailored if necessary.

In more recent years end-to-end anastomoses have been performed with preservation of the left kidney. Thirteen such cases have been carried out at St. Bartholomew's Hospital, using the entire left renal vein in 5 and a major tributary in 8. This paper emphasizes the already known fact that in certain instances the left renal vein may be ligated and divided without apparent embarrassment to the left kidney. It also points out a clinical situation in which ligation of the left renal vein may be of use.

ANATOMY

The left renal vein is more commonly anomalous than the right, probably in part owing to its greater length, and there is frequent deviation from the textbook picture of the left renal vein crossing the aorta and entering the hilum of the left kidney as a single vessel. The left renal vein may form a circum-aortic venous ring, from which there may be further branching of the anterior or posterior limbs (*Fig.* 1). There may be multiple segmental tributaries entering the left renal vein in any part of its course. It is, however, rare for more than one left renal vein to enter the inferior vena cava. Anson, Cauldwell, Pick, and Beaton (1947) point out: 'Complexity in the venous arrangement is the result of the Y-shaped bifurcation of the renal vein, or of communication with neighbouring veins or of these circumstances combined. Intricacy of this nature is characteristic of the left side.'

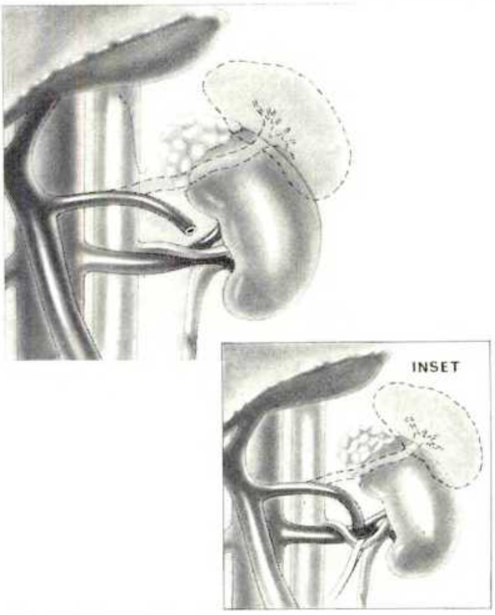

FIG. 2.—The renal artery lying anterior to the renal vein. The inset shows that the artery must be retracted away from the site of the end-to-side anastomosis and when released would interfere with the lie of the anastomosis.

A single left renal artery usually lies behind the left renal vein, allowing the standard end-to-side splenorenal anastomosis to be completed without undue interference. Owing to the segmental origin of the kidney the left renal artery may have important branches in front of the renal vein. Occasionally the entire left renal artery lies anterior to the vein, making coaptation of the renal and splenic veins difficult and interfering with the lie of the anastomosis (*Fig.* 2).

Table I.—DETAILS OF 8 SURVIVING PATIENTS WHO HAD AN END-TO-END SPLENORENAL SHUNT FOR PORTAL DECOMPRESSION

CASE	TYPE OF SHUNT	AGE AT TIME OF SHUNT (years)	DURATION OF SHUNT (years)	BLOOD-PRESSURE	BLOOD-UREA NITROGEN	URINALYSIS	INTRAVENOUS PYELOGRAM	COMMENT
1	End-to-end	39	$3\frac{1}{2}$	110/75	36	N.A.D.	Normal	Easier coaptation; left spermatic vein ligated
2	End-to-end	31	3	120/70	21	N.A.D.	Duplex left collecting system. Otherwise N.A.D.	Easier coaptation
3	End-to-end	18	$2\frac{3}{4}$	115/70	35	N.A.D.	Normal	Easier coaptation; left ovarian vein preserved
4	Partial end-to-end	14	2	118/78	16	N.A.D.	Normal	Two large branches tailored (as shown in *Fig.* 1) for easy coaptation
5	Partial end-to-end	60	$4\frac{3}{4}$	180/110	23	N.A.D.	Normal	Triple renal vein; highest branch used for easy coaptation
6	Partial end-to-end	11	$15\frac{1}{2}$	120/80	21	N.A.D.	Left peripelvic cyst. Otherwise N.A.D.	Circum-aortic ring; anterior branch used
7	Partial end-to-end	19	$6\frac{1}{2}$	110/70	20	N.A.D.	Normal	Early bifurcation to two renal veins; superior branch used
8	Partial end-to-end	56	$5\frac{3}{4}$	N.A.D.*	N.A.D.*	N.A.D.	Would not attend	Renal artery in front of three renal veins; middle vein used

N.A.D. = No appreciable disease.

* Per general practitioner.

It was noticed that when the left renal vein was occluded with a vascular clamp there was little or no venous congestion of the left kidney. Hollingshead and McFarlane (1953), in animal experiments, demonstrated by arteriography that after gradual surgical occlusion of the left renal vein the stellate and capsular veins of the kidney assumed the major role in collateral flow. They also found significant collateral flow via the lumbar, gonadal, and ureteric vessels. Erlik, Barzilai, and Schramek (1965) ligated the left renal vein in cadavers and did arteriograms showing venous drainage via the suprarenal and inferior phrenic veins above, by the gonadal and lumbar veins (second and third) below, and by a retro-aortic plexus of veins ultimately associated with the lumbar vessels behind.

Whether the bulk of the drainage is via capsular vessels or via the fixed collaterals is probably governed by the chronicity of the occlusion, the suprarenal, gonadal, and lumbar plexus of veins probably being more important in acute occlusion. These vessels usually enter the left renal vein at about 6 cm. from its junction with the inferior vena cava. Thus, if a left renal vein is to be ligated the ligature should be placed within 6 cm. of this junction with the inferior vena cava, although this was not always done in the present series (*Case* 1).

Cases have been reported of thrombosis of the inferior vena cava, including the renal veins, with pyelographic evidence of left renal function (Erlik and others, 1965). This is not true of the right kidney which has few anastomotic vessels available for the development of a collateral circulation.

MATERIALS AND METHODS

Thirteen patients have undergone an end-to-end splenorenal shunt for portal decompression at St. Bartholomew's Hospital over the past 16 years. Of these, 5 patients have had complete transection of the left renal vein, and 8 patients have had transection of a major branch of the left renal vein. Five of the patients died of various causes which were primarily related to their underlying liver disease. Where available, the pathology of these cases has been reviewed.

Renal function was evaluated in 7 living patients by estimation of blood-urea nitrogen, urinalysis, and measurement of blood-pressure, and 1-, 3-, and 5-minute hypertensive intravenous pyelograms were carried out. It is appreciated that these tests do not produce a delicate evaluation of the function of a single kidney, but arteriography and differential ureteric catheterization were considered to be unjustified in otherwise well patients. One patient (*Case* 8) could not come to hospital for the necessary examinations and declined to have an intravenous pyelogram.

RESULTS

Table I shows the details of the 8 patients who are alive with end-to-end splenorenal anastomoses. It is noteworthy that all of these patients are alive and well with no problems which are related to the left kidney.

These patients have had shunts for lengths of time varying from 2 to 16 years. All the patients had normal blood-urea and normal urinalysis. One patient was found to be hypertensive and is currently being treated with Aldomet. An accurate preoperative blood-pressure was not available for this patient; she entered the hospital in shock, and she was shunted as an emergency. In all the cases the intravenous pyelogram, where available, showed prompt bilaterally equal excretion of contrast material. There was no variation in the renal size. One patient (*Case* 2) showed a left duplicated collecting system which was unchanged from her preoperative intravenous pyelogram. A second patient (*Case* 6) showed a peripelvic cyst which was not seen on an intravenous pyelogram which was taken 15 years previously. Anatomical variations which prompted an end-to-end anastomosis are listed in *Table I*, but in some of the later cases an end-to-end anastomosis was performed because of the ease of the method rather than because of a distinct abnormality in the renal vasculature.

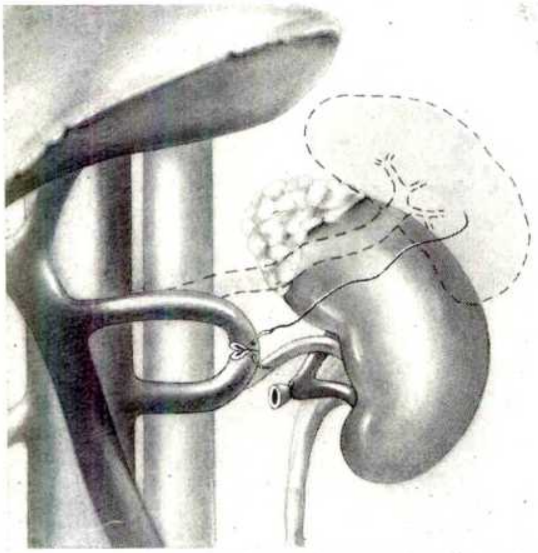

FIG. 3.—An end-to-end splenorenal anastomosis utilizing the entire left renal vein.

Table II lists the patients who had an end-to-end splenorenal anastomosis and who later died. Again, none of the patients had symptoms referable to the left kidney. Blood-pressure, urea nitrogen, and urinalysis were unchanged pre- and postoperatively in all instances. Post-mortem examinations were done on 2 patients: one (*Case* 13) showed normal kidneys bilaterally; the other (*Case* 9) showed left hydronephrosis. This patient, however, showed an abnormal left kidney with somewhat delayed excretion on the preoperative intravenous pyelogram.

DISCUSSION

It has been pointed out by others that the left renal vein may sometimes be divided without detriment to the left kidney. This paper confirms this finding and suggests an instance where the manœuvre may be of some importance. Since anomalies of the left renal vasculature are quite common, the surgeon doing splenorenal anastomoses will find instances when an end-to-side splenorenal shunt may be technically quite difficult. This may be due to the anatomical position of the vein, for example, located behind the artery (*Case* 8, *Fig.* 2), or due to the branching of the vein, making an end-to-side anastomosis difficult and tedious. It may also be found that having two completely divided ends of vessels gives more mobility for making the anastomosis (*Fig.* 3). In such instances an end-to-end anastomosis may be done without undue concern for the left kidney. A non-crushing vascular clamp is applied to the left renal vein and this is left in place for approximately 15 minutes while completing the dissection of the splenic vein. On application of the clamp the kidney may become mildly congested, but this is not common and is not a progressive phenomenon. In no instance in the present series was it necessary to abandon an end-to-end anastomosis because of the appearance of the left kidney. In

cases where a major tributary was utilized the clamp was applied to the tributary in the same fashion.

It is not suggested that end to end is a more effective method of anastomosis in achieving portal decompression than end to side; it is probable that there is no functional difference between the two. We wish to point out that in certain anatomical situations the construction of an end-to-side anastomosis may be very difficult and that in these instances division of the left renal vein or one of its major tributaries does not cause any apparent damage to the left kidney.

Situations may arise in which this knowledge may be of value in other procedures: both in the field of portal hypertension and also in other branches of general surgery. For example, when attempting a portacaval anastomosis, occasionally the portal vein is too short to bring down to the inferior vena cava. In such instances the left renal vein has been used to form the anastomosis with the portal vein (Simeone and Hopkins, 1967). Another example is in vascular surgery when resecting an abdominal aneurysm. If the left renal vein were damaged in obtaining proximal control or might prevent satisfactory proximal anastomosis, then it would be important to know that the left renal vein could be ligated (Szilagyi, Smith, and Elliott, 1969).

RECTAL AND COLONIC ULCERATION IN BEHÇET'S DISEASE

By D. W. EMPEY[*]

WESTMINSTER HOSPITAL, LONDON

SUMMARY

Two patients with Behçet's disease and involvement of the gastro-intestinal tract are described. One patient presented with rectal bleeding and perianal pain, and later developed peritonitis due to perforation of the sigmoid colon. The second patient developed rectal bleeding 4 years after the diagnosis of Behçet's disease, and examination showed this to be due to an ulcer in the anal canal. Behçet's disease should be considered as a possibility, albeit rare, in the differential diagnosis of rectal and colonic ulceration.

In 1937 the Turkish dermatologist, Behçet, first described the clinical syndrome of inflammation in the eye with ulceration in the mouth and genital tract. Characteristically, it is a chronic disease with relapses throughout life. It occurs most frequently in the age-group 15–40 years and is slightly commoner in males. The histopathology is generally non-specific ulceration. The more severe disabilities come from involvement of the eye and central nervous system, and these can lead to blindness or death. The classic triad is not always seen but the diagnosis can still be made even if not all of the features are present at any one time. The missing symptom may develop in later years. In addition to the characteristic triad of symptoms, Behçet's disease may have more widespread manifestations such as arthralgia, erythema nodosum, pyrexial attacks, and thrombophlebitis. Gastro-intestinal involvement has been reported infrequently.

It is the purpose of this paper to present 2 patients in whom intestinal ulceration was a prominent feature, and in the first case it was the presenting system.

CASE REPORTS

Case 1.—Miss M. E., a laboratory technician aged 25 years. This patient presented to the surgical out-patients' department at the Gordon Hospital on 7 Sept., 1969, complaining of 1 month's progressive perianal pain which was aggravated by defaecation. One week prior to attending the hospital she had noticed blood on the outside of her stool. Also she had been feeling tired and anorexic, and had lost 2·25 kg. in weight. Apart from tonsillectomy as a child and pneumonia at the age of 14 years, her general health had been good. One year previously she had been found to be anaemic (haemoglobin 58 per cent) and had been treated with oral iron. Six months previously she had given blood for research purposes and had been told that she had very low iron stores.

On examination the patient was pale, with two aphthous ulcers on the uvula and a painful fissure in ano. These were the only abnormal clinical findings.

The patient was admitted to hospital for investigation. At sigmoidoscopy and proctoscopy under general anaesthesia an acute posterior fissure and an anterior rectal ulcer were found. The ulcer was 3 cm. across with overhanging edges. The remaining mucosa was granular to 15 cm., but no other lesions were found. The ulcer was biopsied, and the histology showed: 'Ulceration with dense collections of plasma cells, lymphocytes, and some polymorphs, and areas of tissue necrosis. There is some vasculitis, but polyarteritis nodosa or allergic vasculitis are not likely because of the lack of eosinophils in the section.'

The next day the patient developed generalized aches and pains with shivering, anorexia, tachycardia, and pyrexia (37·8° C.). Blood cultures were negative. Two days after admission an ulcer developed on the right pinna, and then others rapidly appeared on the back of the neck, the right lateral border of the tongue, and over the right scapula. These ulcers were punched out with necrotic bases, the largest being 2·5 cm. in diameter. She also had some transient dysphagia but a barium swallow was normal. In view of the typical appearances of the lesions a provisional diagnosis of Behçet's disease was made.

---

[*] Present address: The London Hospital, E.1.

INVESTIGATIONS.—The haemoglobin was 9·6 g. per 100 ml., E.S.R. was 84 mm. in the first hour (Wintrobe), and W.B.C. was 5400 per c.mm., with a normal differential. A film showed a hypochromic anaemia with toxic granulation of the polymorphs and a shift to the left. Biochemical tests revealed the following: urea 38 mg. per 100 ml., bilirubin 0·5 mg. per 100 ml., alkaline phosphatase 9 K.A. units, serum glutamic oxalo-acetic transaminase 10 U., and serum glutamic pyruvic transaminase 12 U. Examination of the plasma proteins revealed a total protein content of 6·5 g. per 100 ml. (albumin 2·9 g. per 100 ml., α_1-globulin 0·4 g. per 100 ml., α_2-globulin 0·8 g. per 100 ml., β-globulin 0·8 g. per 100 ml., γ-globulin 1·6 g. per 100 ml., fibrinogen 611 mg. per 100 ml.).

The serum iron was 19·5 μg. per 100 ml. The Wassermann and Kahn reactions were negative. The antinuclear factor was negative to 1 : 20. A xylose absorption test was normal, and a chest radiograph was also normal. Swabs from the cutaneous ulcers grew *Staphylococcus aureus*.

The patient was treated initially with a course of erythromycin and novobiocin for 10 days and this resulted in a slow but definite improvement in the cutaneous ulceration. She was given oral iron, folic acid, and ascorbic acid for her anaemia, and was discharged to continue this medication on 14 Oct., 1969, when her haemoglobin was 10·2 g. per 100 ml. At this time the cutaneous ulcers had healed and she had no perianal symptoms.

The patient remained well for 3 weeks, but on 2 Nov. she was readmitted with a 6-hour history of severe upper abdominal pain which became generalized. She had vomited five times but her bowel action was normal. On examination she was pale, ill, and dehydrated. The cutaneous ulcers were healed. Her pulse was 112 per minute and her blood-pressure was 110/70 mm. Hg. The abdomen was rigid, and rebound tenderness, particularly in the left iliac fossa, was noted. Bowel-sounds were absent, and rectal examination demonstrated marked tenderness anteriorly.

A diagnosis of peritonitis was made, and at laparotomy faecal peritonitis from a perforating ulcer at the apex of the sigmoid colon was found. The rest of the large bowel and the other viscera were normal, apart from an intense peritoneal reaction. The sigmoid colon was mobilized and exteriorized by a Paul-Mikulicz procedure, and after irrigation of the peritoneum the abdomen was closed. The ulcerated area was excised with a wide margin, and histology showed: 'Chronic inflammation and ulceration of all layers of the colon. No recognizable mucosa is seen. There is marked serositis. Appearances are similar to those seen in the rectal biopsy, and are entirely compatible with a diagnosis of Behçet's disease.'

Postoperatively the patient made a slow but satisfactory recovery and her colostomy functioned normally. No gross abnormalities were found by a barium enema which was performed 1 month later, and a barium meal and follow-through were normal. She was discharged on 16 Dec. when she was feeling well.

The patient was subsequently admitted twice with subacute large-bowel obstruction, which on both occasions was due to constipation, and the obstruction responded to conservative therapy.

Five months later the colon was shown to be normal by further barium studies, and the patient was admitted for closure of the colostomy on 3 May, 1970. At sigmoidoscopy and proctoscopy prior to operation the rectum was found to contain a large amount of pus, and the ulcer which had previously been noted was healed. The mucosa was friable and bleeding. An extraperitoneal closure of the colostomy was performed and the patient made a good recovery. Biopsies of the colon taken at operation showed non-specific inflammation only.

Three weeks after operation an abscess developed at the previous colostomy site, and after drainage it was clear that a fistula had developed from the colonic lumen to the skin. On 22 July an examination under anaesthesia, proctoscopy, and sigmoidoscopy to 20 cm. were performed. There was an ulcer, 4 cm. long, in the anal canal. There were no ulcers above this point but the mucosa was granular and friable. A low fistula was laid open and a posterior sphincterotomy was performed.

At the present time there is only a small amount of discharge from the fistula and the patient's bowel action is normal. She is still anaemic (haemoglobin 10·5 g. per 100 ml.) and the E.S.R. is currently 48 mm. in the first hour (Wintrobe).

Case 2.—Mrs. E. S., a telephonist aged 57 years. This patient was diagnosed as having Behçet's disease in March, 1966, when, having previously been well, she gave a 6-month history of recurrent mouth ulcers and sore throats. At that time she had extensive ulceration of the fauces, tongue, and lips, and had developed a deep-vein thrombosis in the right leg with pulmonary emboli.

INVESTIGATIONS.—The haemoglobin was 10·6 g. per 100 ml., W.B.C. was 23,400 c.mm. with a normal differential, and E.S.R. was 50 mm. in the first hour (Wintrobe). Wassermann and Kahn reactions were negative. No lupus erythematosus cells were present.

The patient was treated with 5 mg. prednisone twice daily, but she continued to be troubled by recurrent ulcers, new ones appearing on the right ankle in February, 1967, and in the natal cleft in April, 1968. Biopsy of the ankle ulcer showed non-specific inflammatory changes only.

In spite of treatment with corticosteroids the patient continued to experience relapses and remissions, and in November, 1969, she was readmitted with rectal bleeding which had occurred for the first time. Examination under anaesthesia was performed and an ulcer 4 cm. across was found high on the left side of the anal canal. Sigmoidoscopy to 22 cm. and proctoscopy were otherwise normal, and the bleeding appeared to have arisen from the ulcer. A biopsy showed non-specific ulceration only.

The patient was treated for 4 weeks in hospital, and she received initially 60 mg. prednisone daily which was gradually reduced to 20 mg. daily. She was discharged to continue on this dose and remains well on follow-up with no further rectal bleeding.

DISCUSSION

Diseases involving the gastro-intestinal tract may often be associated with skin lesions. Ulcerative colitis and some malabsorption syndromes are examples of this, and Mountain (1970) has emphasized the occurrence of cutaneous ulceration in Crohn's disease.

The occurrence of gastro-intestinal symptoms in patients with Behçet's disease has been described infrequently. Oshima, Shimizu, Yokohari, Matsumoto, Keno, Kagami, and Nagaya (1963), reporting the clinical features of 85 patients with Behçet's disease, found that 40 per cent had symptoms such as diarrhoea, nausea, or abdominal pain, and 1 case had proved jejunal ulceration. Jensen (1944) was the first to recognize the association of Behçet's disease and disease of the bowel when he described ulcerative colitis occurring in 2 patients who were known to have Behçet's disease. Cottini and Randazzo (1956) made similar observations and even suggested the use of the term 'cutaneous muco-intestinal syndrome'. Other cases of colitis as a manifestation of Behçet's disease have been described by Bechgaard (1940), Boe, Dalgaard, and Scott (1958), and Ramsay (1967).

The occurrence of rectal and colonic ulceration and perforation of the bowel, as happened in the first of our 2 patients, have only rarely been reported (Ono and Yamamoto, 1962; Somemura, Nishio, Nishida, Hashimoto, and Matsuhara, 1963; Tsukada, Yamazaki, Iyo, Nishio, Hashimoto, and Matsuhara, 1964). Curth (1964) described a man with a 5-year history of Behçet's disease who then developed rectal ulcers, sloughing of the rectal mucosa, and multiple colonic perforations necessitating proctocolectomy.

The aetiology of Behçet's disease remains uncertain, but amongst those factors which have been suggested are venereal diseases, tuberculosis or staphylococcal infections, and viral infections. Allergic or auto-immune processes and thromboses of small veins have also been invoked as causes. Because the pathological appearances are entirely non-specific the diagnosis is always based upon the association of the various clinical features.

Although more common in the Orient, the incidence of Behçet's disease in this country is probably greater than is usually quoted. Many cases may be missed because no specific inquiry is made about symptoms such as vulval ulceration in patients with other manifestations such as aphthous ulceration of the mouth. The information is often not volunteered by the patient because of modesty or the feeling that it is irrelevant.

The treatment of Behçet's disease is much disputed and usually not very successful. Heavy doses of corticosteroids are often used (as with our second patient) to suppress severe manifestations, but they have not been shown to be of any value in slowing the course of the disease. Immunosuppressives have been proposed as a rational treatment, and Cunliffe and Menon (1969) have used phenformin and ethyl oestriol with some success.

Now that the other features, such as polyarthralgia, thrombophlebitis, and gastro-intestinal symptoms, are accepted as part of the overall clinical picture in Behçet's disease, more cases will be diagnosed in general medical and surgical clinics. The differential diagnosis of rectal ulcers is large (Madigan and Morson, 1969); our first patient demonstrates that Behçet's disease should be borne in mind as one of the less common causes of this condition.

Acknowledgements.—I am grateful to Mr. M. Naunton Morgan and Dr. Peter Emerson for permission to publish details of patients under their care, to Dr. Martin Lewis for the histology reports, and to Dr. Lavinia Loughridge and Mr. J. E. Hale for their help and encouragement.

THE MAINTENANCE OF MALDESCENDED TESTICLES WITHIN THE SCROTUM USING A DARTOS POUCH

By W. J. PRYN*

MILITARY HOSPITAL, CATTERICK CAMP, YORKSHIRE

SUMMARY

A method of maintaining a testicle within the scrotum in the operation of orchidopexy for maldescent using a dartos pouch is described.

THAT orchidopexy is required for maldescent of the testicles is well documented (Wangensteen, 1935; Pace and Cabot, 1936; Mimpriss, 1938; Gilbert and Hamilton, 1940; Gross and Jewett, 1956; Scott, 1962; Collins and Pugh, 1964; Altman and Malament, 1967; Cohn, 1967; Dow and Mostofi, 1967; Hecker and Heinz, 1967). This paper is concerned only with the maintenance of the mobilized testicle within the scrotum in orchidopexy.

For orchidopexy to have the optimum of success the operation should be carried out at the age of 5 years, as histological development of the testicle is only a little delayed at this age (Scott, 1962; Cohn, 1967; Hecker and Heinz, 1967), the macroscopic structures are sufficiently developed to handle easily, and there is minimal interference with schooling. Certainly the operation should be completed before puberty. In cases with troublesome hernia, surgery may be indicated earlier.

---

* Present address: British Military Hospital, Dhekelia, BFPO 53.

At operation any tension placed on the cord structures to maintain the testicle within the scrotum must be slight, neither interfering with the venous return from nor the arterial supply to the organ. The testicle should be placed in the scrotum on its own side so that it is unable to return to the groin and is not left riding high. The operation should be finalized in one stage, should be simple to carry out, and should cause only the minimum of postoperative discomfort.

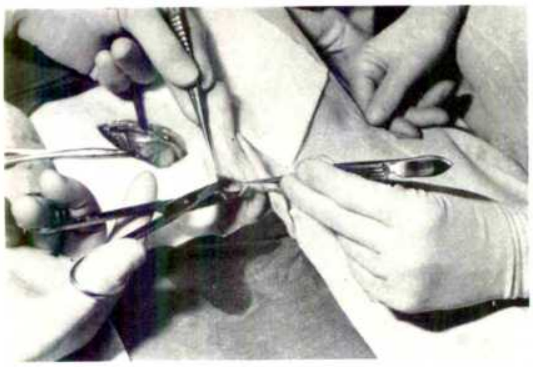

FIG. 1.—Formation of a pouch between scrotal skin and dartos muscle.

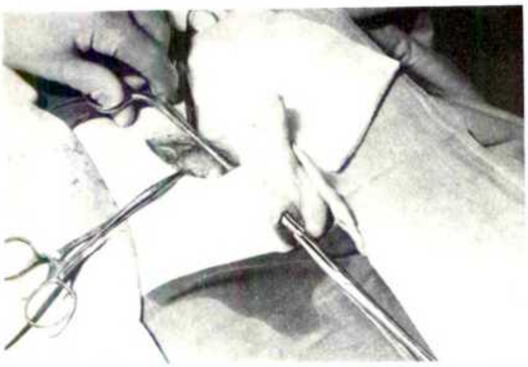

FIG. 3.—Method of introducing haemostats for the withdrawal of the testicle from the groin to the pouch.

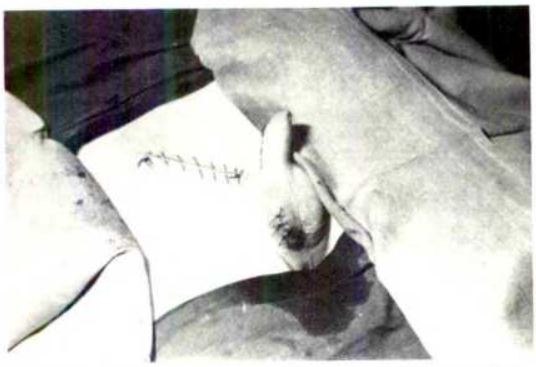

FIG. 5.—The appearance at the termination of the operation.

Using these criteria the following operative procedure using a dartos pouch to maintain a maldescended testicle within the scrotum has been devised.

OPERATIVE TECHNIQUE

Under general anaesthesia the maldescended testicle is mobilized through the usual groin incision (Bevan, 1899; Browne, 1933; Poole Wilson, 1939; Gross and Jewett, 1956; Hand, 1957). A finger is passed from the groin wound into the scrotum and the scrotal wall is stretched. A short vertical incision is made through the skin only near the apex of the scrotal wall on the same side as the maldescended testicle. By blunt dissection using scissors or a haemostat a pouch sufficiently large to accommodate the testicle is formed between the scrotal skin and the dartos muscle (*Figs.* 1, 2).

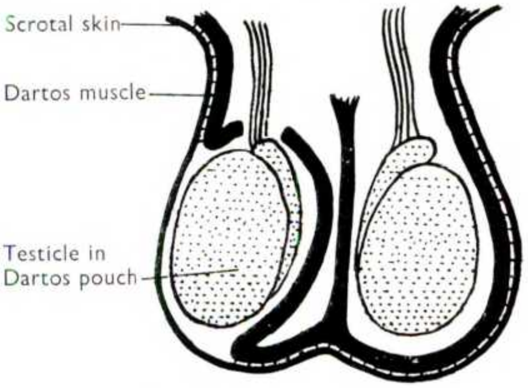

FIG. 2.—The dartos pouch.

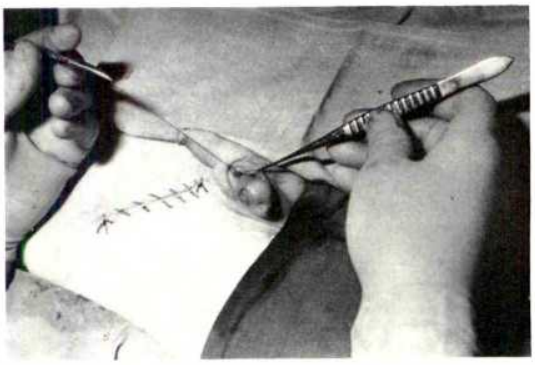

FIG. 4.—Approximation of the edges of the opening in the dartos pouch.

A closed haemostat is passed from the groin wound into the scrotum and through the centre of the dartos of the newly formed pouch. The hole in the dartos is stretched by opening the haemostat. A second haemostat is now grasped by its point by the first haemostat and is withdrawn into the groin wound (*Fig.* 3). This second haemostat is used to grasp the gubernacular tissue attached to the testicle, which is then drawn into the scrotum through the hole in the dartos pouch without twisting or pulling unduly on the cord.

One or two sutures are inserted to approximate the gap in the dartos sufficiently to prevent the testicle from returning to the groin, but equally they should be quite loose enough to prevent circulatory embarrassment of the testicle (*Fig.* 4). It is sometimes

CASE	AGE AT OPERATION (years)	SIDE OF MALDESCENT	ASSOCIATED HERNIA	COMPARATIVE PREOPERATIVE SIZE OF AFFECTED TESTIS	POSITION OF TESTIS OBTAINED AT OPERATION	LENGTH OF FOLLOW-UP	COMPARATIVE SIZE AND POSITION OF TESTIS AT LAST FOLLOW-UP	ADDITIONAL COMMENTS
1	12	Left	No	Both testes small but equal	Well down	3½ yr.	Both testes small, but equal in size and well down	Not yet at puberty. Possible genetic defect. Has an associated deficiency in pseudocholinesterase
2	15	Left	Yes	Smaller	Well down	3 yr.	Testis well down but remains smaller	—
3	6	Right	Yes	Equal	Well down	2½ yr.	Well down and equal in size	—
4	5	Right	No	Equal	At scrotal neck	2 yr.	Well down and equal in size	—
5	26	Left	No	Both testes smaller than normal but equal	At scrotal neck	1¾ yr.	Well down, equal in size, but both testes smaller than normal	Normal sperm count and is a father
6	9	Bilateral	No	Equal	Well down	1¾ yr.	Well down and equal in size	—
7	24	Right	No	Small	At scrotal neck	—	—	Lost from follow-up, having moved from a caravan site without trace after being turned down for military service
8	11	Right	No	Equal	Well down	1½ yr.	Well down and equal in size	Also has a very highly retractile left testis
9	15	Left	No	Smaller	Well down	1 yr.	Well down but remains smaller	—
10	8	Left	Yes	Equal	Well down	11 mth.	Well down and equal in size	Also has a very highly retractile right testis
11	8	Left	Yes	Equal	Well down	11 mth.	Well down and equal in size	A perineal left testicle
12	10	Right	Yes	Equal	Well down	10 mth.	Well down and equal in size	—
13	8	Right	No	Equal	At scrotal neck	10 mth.	Well down and equal in size	—
14	15	Right	Yes	Equal	Well down	9 mth.	Well down but right testis slightly smaller than left	There is a left-sided varicocoele. Normal sperm count
15	10	Left	Yes	Small	Well down	9 mth.	Well down but remains equally small	—
16	14	Right	Yes	Smaller	Well down	8 mth.	Well down but remains smaller	—
17	16	Right	Yes	Smaller	Well down	8 mth.	Well down and near equal in size	—
18	11	Left	No	Equal	Well down	7 mth.	Well down and equal in size	—
19	17	Right	No	Equal	Well down	7 mth.	Well down and equal in size	Previous right orchidopexy elsewhere for undescended testis. Testis lying over pubic tubercle prior to this second operation
20	15	Right	No	Equal	Well down	7 mth.	Well down and equal in size	—
21	15	Left	No	Smaller	Well down	7 mth.	Well down but remains smaller	Previous bilateral orchidopexy at age 13 elsewhere. Right testicle well in scrotum but left smaller and lying over pubic tubercle prior to this second operation
22	15	Right	No	Equal	Well down	6 mth.	Well down and equal in size	—
23	6	Bilateral	No	Equal	Well down	6 mth.	Well down and equal in size	—
24	15	Right	No	Equal	At scrotal neck	6 mth.	Well down and equal in size	—
25	18	Right	Yes	Small	Well down	6 mth.	Well down but remains equally small	—

easier to place these sutures before drawing the testicle into the pouch, and to tie them afterwards.

The scrotal skin and the groin wounds are closed (*Fig.* 5) and the skin sutures are removed in 5–7 days.

DISCUSSION

Over the past 3½ years, 27 orchidopexies for maldescent using the dartos pouch method to maintain the testicle within the scrotum have been carried out in 25 patients (*Table I*).

The operation is simple, and even if the cord is short and the testicle is left riding high in the scrotum at operation the gentle continuous pull of the dartos pouch allows for gradual elongation of the cord structures without disturbance to the vascular requirements of the testicle, which will subsequently be found to lie well within the scrotum. This was seen in *Cases* 4, 5, 13, and 24 (*Table I*); the outcome of *Case* 7 is unknown, having been lost to follow-up. None of these 5 cases had associated inguinal hernial sacs.

In this series no testis has atrophied following operation, though those testes which were small prior to orchidopexy remained so.

Postoperative discomfort was minimal.

The dartos pouch operation compares very favourably with other techniques which have previously been described.

The advantages of the trans-septal operation (Ombrédanne, 1910) are similar. Of necessity, the testicle lies on the opposite side in the same anatomical scrotal department as its neighbour, though the final cosmetic result is usually highly satisfactory. This method, however, is unsuitable for short cord cases and bilateral maldescent.

In cases with a short cord and a high-riding testicle, operations using a simple purse-string suture at the neck of the scrotum (Bevan, 1899), or a fibrous band between the floor of the scrotal tunnel and the pectineus (Browne, 1949), leave the testicle riding high and vulnerable to trauma.

Other methods of maintaining maldescended testicles within the scrotum in which traction is applied for several days via a suture placed in the tunica albuginea through the scrotal skin and attached to the thigh of the same or opposite side by direct stitching, elastic bands, or appliances are also described (Cabot and Nesbitt, 1931; Wangensteen, 1932). These operations are often uncomfortable and are subject to accidental, sudden, or prolonged pulling or tugging on the traction suture which is liable to result in injury to the testicular vessels with subsequent testicular atrophy.

Also, as shown in *Cases* 19 and 21 (*Table I*), when the traction suture is removed, or if it cuts out, it is not infrequently found that the testicle retracts to lie over the pubic tubercle, where it remains, becoming vulnerable to trauma with subsequent reoperation being necessary.

The Keetley-Torek operation (Keetley, 1894; Torek, 1909) should no longer be carried out, for of necessity a second operation is required, it is uncomfortable, the testicular blood-supply is often jeopardized, and small boys not infrequently fail to wash the crutch between the scrotum and the thigh.

Many of the cases in this series were regrettably referred for surgical treatment when they were well past the optimum age for orchidopexy (*Table I*). Those who had past puberty were all potential recruits for the Services and had been found at routine medical examination prior to acceptance or otherwise to have maldescent of the testicle.

A plea is put forward for greater diligence in seeking out and referring cases of maldescent of the testicle for surgery in early childhood, for which the dartos pouch operation is recommended.

PERITONITIS FROM AMOEBIC LIVER ABSCESS

By E. Q. ARCHAMPONG

DEPARTMENT OF SURGERY, GHANA MEDICAL SCHOOL, ACCRA

SUMMARY

Four consecutive cases of peritonitis from rupture of amoebic liver abscess presenting late with the condition have been described. After treatment involving intensive resuscitation with adequate fluid therapy, ampicillin and hydrocortisone, and early laparotomy all 4 cases survived. The likelihood of this result recurring by chance is calculated at 0·3 per cent ($P < 0·05$).

The conclusion is drawn that now that surgery is safer and metronidazole is available as a rapidly acting non-toxic amoebicide, perhaps amoebic abscesses should no longer be regarded differently from other hepatic abscesses, at least when they rupture into the peritoneal cavity.

AMOEBIC liver abscess is a common complication of amoebiasis in areas of high endemicity of the disease. While the incidence of peritonitis from rupture of these abscesses has been diminishing since the advent of the potent systemic amoebicide metronidazole, there has been no appreciable decrease in the mortality. De Bakey and Ochsner (1951) reported an incidence of intraperitoneal rupture of 10 per cent with a 75 per cent mortality. More recent authors (Schiff, 1956; Adi, 1966) report a similar disquieting mortality. The factors which are responsible for this state of affairs are not readily evident. It is for this reason that the survival of 4 consecutive patients presenting late with the condition is reported.

CASE REPORTS

Case 1.—A farm labourer, aged 35 years, presented with a 2-month history of fever and intermittent pain in the right hypochondrium. Three years previously he had suffered a similar attack which had been treated conservatively. He had never had diarrhoea. Two days before admission he had developed a severe attack in which the abdominal pain had become generalized with vomiting and prostration. On admission he appeared mildly shocked, his blood-pressure was 90/60, his pulse-rate was 120 per minute, and he showed evidence of anaemia and weight-loss. There was generalized tenderness of the abdomen with guarding and moderate distension, but no masses were palpable. A plain radiograph showed two small radio-opaque calculi in the gall-bladder area. Peritonitis probably arising from inflammatory biliary disease was suspected.

Laparotomy revealed large quantities of thick amoebic pus which were traced to two abscesses in the right lobe of the liver. There were several adhesions and pockets of abscesses in the peritoneal cavity, indicating previous minor episodes. Two calculi were palpable in the gall-bladder, confirming the radiographic findings. The liver abscess was evacuated and the peritoneum was drained.

The patient responded well to specific anti-amoebic treatment with metronidazole (800 mg. thrice daily for 5 days) and emetine hydrochloride (60 mg. i.m. daily for 7 days). Four months later he had a cholecystectomy, from which he made an uneventful recovery. When last seen 3 months ago the patient was well and was continuing at work.

Case 2.—A heavy-duty lorry driver, aged 47 years, presented with fever, abdominal pain, and vomiting of 3 days' duration. Six weeks previously he had consulted his private doctor complaining of abdominal pain and bouts of diarrhoea, passing mucus, blood, and pus, which had settled on symptomatic treatment. On examination the patient was very pale with a tinge of jaundice (bilirubin 1·6 mg. per cent). He was shocked with a pulse-rate of 126 per minute and a blood-pressure of 70/50; his temperature was 37·7° C. Signs of peritoneal irritation were evident. The liver was grossly enlarged and exquisitely tender and there was a fluctuant swelling in the epigastrium which was continuous with the liver.

A diagnosis of peritonitis from rupture of an amoebic abscess was made and was confirmed by the aspiration of thick amoebic pus by diagnostic paracentesis. Intensive resuscitation was carried out in an attempt to prepare the patient for laparotomy, and after 24 hours of intravenous fluid therapy (1·5 litres isotonic saline, 1 litre dextrose saline, 1 litre dextran 40, and 2 U. blood), tetracycline (2 g. i.v.), hydrocortisone (1·2 g.), chloroquine (300 mg. i.m.), and metronidazole (1·2 g.) anti-amoebic therapy, his blood-pressure was barely 95/70 and his pulse-rate was 100 per minute.

He was not considered fit for general anaesthesia and therefore laparotomy was carried out under a bilateral intercostal regional block. Large quantities of pus were found and were traced to a large amoebic abscess of the left lobe of the liver. The right lobe was free of abscesses and there were no amoebic lesions in the rest of the gastro-intestinal tract. Peritoneal toilet was performed and the abscess cavity was irrigated with emetine hydrochloride solution. The abdomen was closed with drainage.

The patient's immediate postoperative course was stormy, with high pyrexia, rigors, and abdominal distension, and in spite of intensive anti-amoebic and antibiotic therapy this persisted for 10 days. The drainage site also continued to discharge large quantities of thick creamy pus. He gradually recovered from this poor physical state and left hospital after 6 weeks, all his wounds having healed.

The patient was readmitted a month later with recurrence of abdominal pain and fever, and the reappearance of a swelling in the epigastrium. On examination he had a large, tender, hepatic swelling but the rest of the abdomen was normal. The recurrent amoebic abscess was treated with repeated aspirations and the instillation of emetine hydrochloride, with very little improvement. At a second laparotomy a large loculated right lobe abscess was evacuated. There was an associated subphrenic collection which was drained. The patient had an uneventful recovery. When last seen he was back at work and was well.

Case 3.—A labourer, aged 27 years, was admitted with a 2-year history of recurrent upper abdominal pain. Each episode of fever had been accompanied by vomiting and weight-loss, culminating with the discharge of pus through a sinus in the epigastrium. On the present occasion the pain had spread rapidly throughout the abdomen and had been followed in 24 hours by jaundice.

On examination the patient was not shocked but was pale and emaciated. His pulse-rate was 110 per minute and his blood-pressure was 100/70. His abdomen was generally tender with guarding and absent bowel-sounds. There was a partially closed sinus in the epigastrium. Peritonitis from intra-abdominal rupture of an amoebic liver abscess was thought to be likely, and the patient was subjected to immediate laparotomy. This revealed several loculated pockets of amoebic pus with numerous adhesions. The pus was evacuated and the abdomen was drained by means of two corrugated rubber drains in the iliac fossae. The patient responded satisfactorily to anti-amoebic and antibiotic treatment (metronidazole 1·2 g. per day for 7 days and tetracycline 1 g. per day for 5 days). He was discharged on the sixteenth postoperative day.

Case 4.—The patient, a 30-year-old trader, presented in similar fashion to *Case* 1, complaining of intermittent pain in the right hypochondrium and epigastrium of 6 weeks' duration, which was not associated with bowel disturbance. He was admitted during an attack which had started 24 hours previously. He was anaemic and mildly shocked, and signs of peritonitis were evident in his abdomen. In the light of the experience of the previous cases a diagnosis of ruptured amoebic abscess was quickly arrived at and was confirmed at laparotomy. The patient's recovery after peritoneal toilet and drainage and chemotherapy (consisting of metronidazole 1·2 g. per day for 5 days and tetracycline 1 g. per day for 5 days) was rapid. He was discharged after a fortnight in hospital.

DISCUSSION

Intraperitoneal rupture remains the most dreaded complication of amoebic liver abscess. Manson (1917), Castellani and Chalmers (1919), Rogers (1922), and Manson-Bahr (1943) all regarded it as almost inevitably fatal, and Schiff in 1956 still recorded a mortality of 75 per cent. Adi (1966) found in Nigeria a mortality of 67 per cent in cases with free leakage into the peritoneal cavity. An important factor predisposing to rupture in the hepatic lesion and to the poor prognosis is delayed or inadequate treatment (Biggam and Ragab, 1931). Poor nutrition or diminished host resistance associated with other diseases contributes to an unsatisfactory outcome, and the persistence of these conditions in many tropical countries is responsible for the continuing high mortality. The encouraging outcome of the cases described here is probably partly due to the improved nutritional status of the patients and their relative youth. However, early surgical intervention was undoubtedly important in determining the result.

Rupture is more commonly seen in abscesses of the left lobe of the liver, probably because of its smaller size and more complete peritoneal cover. This together with delayed diagnosis of abscesses of the left lobe on account of their more hidden localization (Alkan, Kalmi, and Kalderon, 1961) considerably increases the mortality from these abscesses. Alkan and others (1961) reported intraperitoneal rupture in 4 of 8 cases of abscesses of the left lobe; 1 of the 3 deaths in the series was from intraperitoneal leakage. In the left lobe, rupture occurs more often on the inferior surface (*Cases* 2 and 4) as opposed to that in the right lobe (*Case* 1) where the abscess tends to point on to the superior or anterior surface. In both places a slower pace of abscess development and leakage makes for localization by adhesions, with improvement in the outlook.

Wilmot (1962) described three forms of clinical presentation of intraperitoneal rupture of amoebic abscess:—

1. Sudden perforation with signs of widespread peritoneal soiling, carrying the highest mortality.
2. A gradual leak with localized abscess.
3. A gradual process without localization, causing chronic generalized peritonitis.

The first category, which is typified by *Case.*
2, and 4, is unfortunately the most frequently s
and the differentiation from other forms of p
tonitis presents some difficulty. The large liver
Case 2 and the preceding diarrhoea would fo
attention on hepatic amoebiasis, but in *Case* 1
diagnosis was far from clear and suspicion fell
cholecystitis with a calculous basis. In the m
chronic type a preceding history of repeated episo
of upper abdominal pain presenting with signs
peritonitis may give an indication of the diagno
but the complexity of the exercise is evinced by
observation of Vakil, Mehta, and Desai (1970) t
the uncomplicated abscess may still present w
abdominal rigidity, distension, and ileus.

The pitfalls in correct preoperative diagnosis h
been examined by Biggam and Ragab (1931),
(1955), and Singha (1959), with the follow
important observations:—

1. The preceding dysenteric illness is often lacki
as in *Cases* 1, 3, and 4.
2. A history of prolonged ill-health may be missi
especially in non-endemic areas, while in ende
areas the common association of intercurrent dise
would blur the picture.
3. The abdominal pain is not confined strictly
the right hypochondrium prior to rupture (*Case*
and 4).

In general, it would appear that a high index
suspicion, sometimes in spite of atypical features
the most important factor in arriving at a p
operative diagnosis. Laboratory investigations s
as examination of stools for amoebae and a white-
count are unhelpful, but serological tests for amoe
asis may provide confirmatory evidence.

The literature shows no agreement on the choice
the appropriate method of treatment. A few clinici
have favoured surgical intervention (Hulke, 18
Self, 1955; Singha, 1959), but most have prefer
conservative measures, involving repeated aspirat
of the abscess and the soiled abdomen, supported
anti-amoebic and antibiotic chemotherapy (Ludl
1926; Chatterji, 1922a, b; Biggam and Ragab, 19
Chang and Robertson, 1934; Paul, 1959; Thak
1965). With a published mortality of 75 per c
the likelihood of 4 consecutive cases surviv
by chance is 0·3 per cent ($P<0\cdot05$), indicat
the significance of the results which have b
achieved.

The essential details of the method which has b
used in this series have been early operation p
ceded by intensive resuscitation, involving
judicious use of isotonic saline, Rheomacrod
blood, and adequate doses of hydrocortisone a
ampicillin followed later by the amoebicidal dr
metronidazole and emetine hydrochloride (we h
had to give larger doses than the generally accep
400 mg. thrice daily for 7 days). In additi
anaesthesia, whether general or local, has impro
in the past decade, as has to some extent the gene
nutrition of patients in southern Ghana.

The rationale for conservative treatment
discussed by Paul (1959), who observed that
escape of pus from an amoebic abscess cavity
extremely slow and ceased promptly with aspirati
Ludlow's (1926) results show a mortality of 11·1
cent for open operation and 2·3 per cent

conservative treatment. Chatterji (1922a, b) claimed a 1·6 per cent mortality for conservative measures. In these series, however, it is difficult to know whether all the cases had free pus in the peritoneal cavity as the abdomen was not opened. This is important in view of the observation of Vakil and others (1970) that uncomplicated abscesses still present with marked signs of peritoneal irritation. In the average tropical practice with less experience of the varied presentation of hepatic amoebiasis these difficulties of accurate diagnosis adding to the uncertainty of adequate removal by aspiration of thick glairy pus from both peritoneal and abscess cavities far outweigh the dangers of open drainage.

The important lesson from these facts is that the idea that amoebic abscesses should be regarded differently from other hepatic abscesses is perhaps not so tenable, at least when they rupture into the peritoneal cavity, now that surgery is safer and that metronidazole is available as a rapidly acting and non-toxic amoebicide. Restriction to oral administration is a disadvantage in very ill patients on parenteral fluid therapy, but with intensive resuscitation and supplemented by chloroquine during this period it is not a limiting factor. One important cause of failure of surgical treatment in the past has been the use of emetine hydrochloride during the resuscitation period, the myocardial toxicity of the drug prejudicing the chance of recovery from circulatory collapse (Adi, 1966).

NEW INSTRUMENTS FOR MICROVASCULAR SURGERY

By ROBERT ACLAND
DEPARTMENT OF PLASTIC SURGERY, THE LONDON HOSPITAL

SUMMARY

Instruments are described which have been developed for use in work on blood-vessels of less than 1 mm. in diameter. They include hand-rests, pedal-operated instruments, vessel clamps, and a counter-pressor.

THE instruments described here were designed on the basis of personal experience in anastomosing vessels of 0·5–0·8 mm. external diameter. In developing a satisfactory technique for such fine work the following obstacles to success were encountered, and steps were taken to overcome them:—

1. Even using an operating microscope it is difficult to visualize very small vessels clearly at a high magnification. Greater clarity can be obtained by the use of simple aids.

2. Tremor and other unwanted movement mask the capacity of the hands for fine manipulation. To overcome this, hand-rests and pedal-operated instruments have been developed.

3. Existing small-vessel clamps are too cumbersome for very fine work. A clamp of suitable dimensions has been developed.

4. It is difficult to hold the vessel edge steady in order to place the suturing needle precisely and to pass it through the vessel wall with the minimum of damage. A counter-pressure device has been developed to overcome this difficulty.

AIDS TO VISUALIZATION

For regular success in anastomosing very small vessels it is necessary to place sutures as close together as 3 or 4 per mm., taking extremely small bites of tissue. The difficulty of doing this accurately with vessel walls which are 6–8 cells thick, colourless, and translucent will be appreciated.

A very bright light is needed when working at the highest magnification of the microscope. A slightly overrun 50-W. bulb is preferable to the 30-W. bulb which is fitted as standard in the Zeiss microscope.

In order to see the faintly opalescent vessel ends clearly it is a great help to have a dark background behind them. A suitable background material can be made using a short length of dental matrix band made of flexible stainless steel, rounded at the corners, and blackened by the process used by instrument makers for aural instruments. Under the microscope this appears dark grey, and black suture material is clearly seen against it.

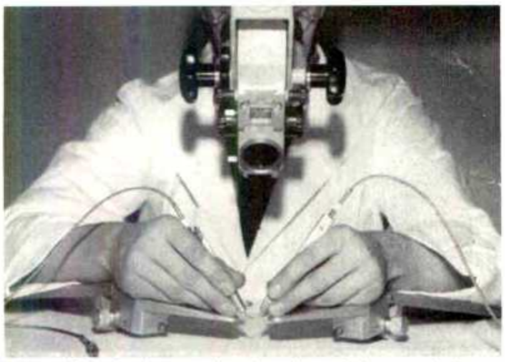

FIG. 1.—The hand-rests, showing the pedal-operated forceps (left hand) and scissors, and the optimal position of the hands.

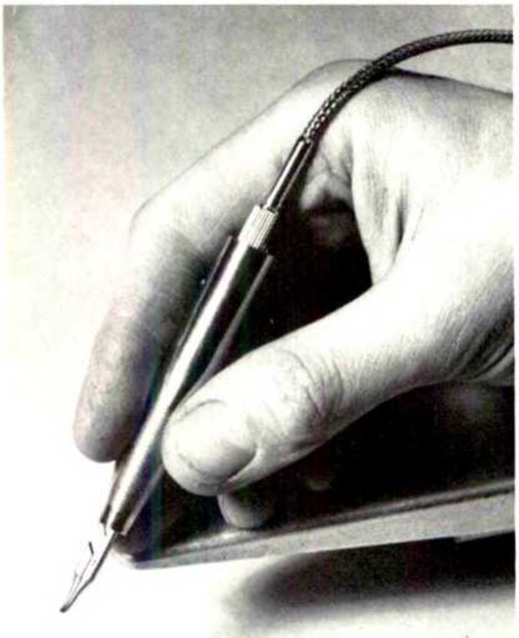

FIG. 3.—The pedal-operated needle-holder. The cable is seen above, right.

HAND-RESTS

The fingers have a remarkable capacity for fine manipulation, but this capacity is entirely masked by tremor unless the hands are resting on a solid supporting surface. The more distally the support extends, the more fully is tremor abolished.

The author's hand-rests (*Fig.* 1) consist of solid duralumin plates, 45 × 6·5 cm., which are hinged at wrist-level. They are used on a solid flat table on which they can be freely moved about. They support the elbows at table-level, slope upwards to support the wrists 5 cm. above the table, and continue beyond the hinge to a blunt point on which the finger-tips are supported 2–8 cm. above the table, this height being adjustable. Using these hand-rests it is possible to do fine work for long periods without fatigue.

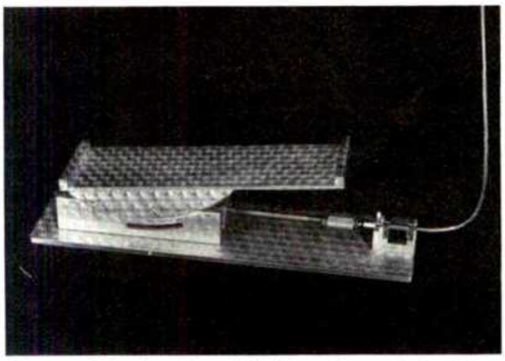

FIG. 2.—Side-view of a pedal, with a cable attached (right).

Work is in progress on a means whereby these hand-rests can be used in clinical procedures.

PEDAL-OPERATED INSTRUMENTS

There is one type of unwanted movement which is not controlled even with the use of hand-rests. When an instrument is opened or closed by reducing or increasing the pressure of the finger-tips upon it, a relatively coarse uncontrolled movement occurs because of imperfect synergism between the opposing fingers. The amplitude of this movement, which is increased by fatigue or anxiety, is commonly of the order of 0·25 mm. This is enough to be highly disturbing in such a delicate task as dissecting the adventitia off a small vein.

To overcome this difficulty a set of three instruments—scissors, forceps, and needle-holder—has been developed. These instruments are held and directed by the hand, but are opened and closed by the remote control of foot-pedals.

Several authors have described pedal-controlled microsurgical instruments, using differing systems of control. Buncke and Schulz (1966) and Acland (1969) used low-pressure hydraulic transmission, Salmon (1968) used compressed air, and the highly sophisticated instruments of Parel, Crock, O'Brien, Henderson, and Galbraith (1970) use electric power.

In the author's present instruments the control movement is transmitted from the pedal to the instrument by flexible lightweight 'Bowden' cables, 2 m. long. The inner moving wire is coated with PTFE, which greatly reduces the friction.

Each cable is attached to a foot-pedal (*Fig.* 2). The pedals do not hinge in the ordinary way but rotate on a curved surface, the centre of which is at an imaginary point corresponding to the position of the user's ankle-joint. This permits precise and variable control both upwards and downwards. The pedals have no spring, the upward movement being made by downward pressure with the heel.

The three present instruments are a modified jeweller's needle-point forceps, a modified Wecker's iris scissors, and a purpose-made needle-holder (*Fig.* 3).

Each instrument, with its attached cable coiled up, can be sterilized without harm in an ordinary autoclave. The instruments have the further advantages of being relatively robust, requiring no adjustment, and being easily assembled for use.

The value of these instruments is that for the beginner they greatly increase the precision and confidence of fine movements. The necessary foot co-ordination is easily acquired. However, it has to be said that with sufficient practice one can learn to do even the finest work without these aids, using such simple instruments as Castroviejo scissors and jeweller's forceps. The place of foot-operated instruments in microsurgery is therefore uncertain.

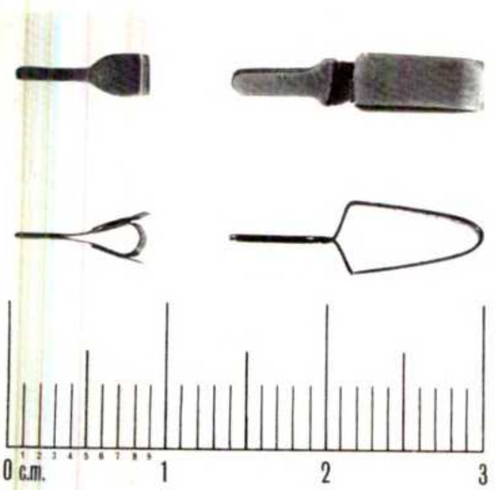

FIG. 4.—The author's artery clamp (left) with a Mayfield clamp (right).

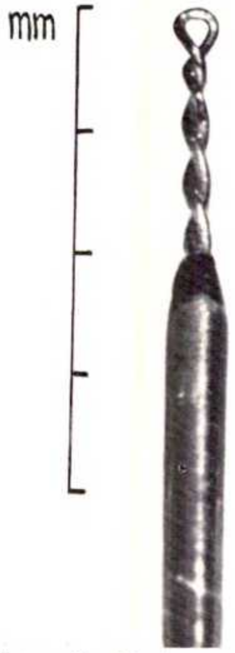

FIG. 5.—The Micro-loop counter-pressor.

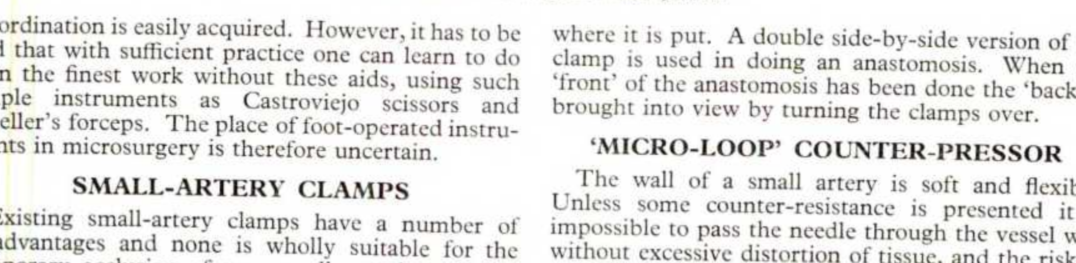

FIG. 6.—Method of using the counter-pressor.

SMALL-ARTERY CLAMPS

Existing small-artery clamps have a number of disadvantages and none is wholly suitable for the temporary occlusion of very small vessels. Clamps such as the Mayfield and Scoville Lewis are bulky and difficult to apply, and have a tendency to fall about in the wound under their own weight, to the detriment of the orderly conduct of the operation. In addition, they exert an unnecessary amount of pressure.

The author's clamp is illustrated in *Fig.* 4. It acts on the principle of the Bulldog type of office paper-clip. The clamp is 8 mm. long and weighs 65 mg. It is easily applied with a pair of slightly modified plain dissecting forceps, and has a strong tendency to stay where it is put. A double side-by-side version of the clamp is used in doing an anastomosis. When the 'front' of the anastomosis has been done the 'back' is brought into view by turning the clamps over.

'MICRO-LOOP' COUNTER-PRESSOR

The wall of a small artery is soft and flexible. Unless some counter-resistance is presented it is impossible to pass the needle through the vessel wall without excessive distortion of tissue, and the risk of tearing out adjoining sutures.

There are three ways of arranging counter-resistance. First, the vessel edges may be picked up with forceps. If this is done just at the point on the edge where the suture is to be, it both weakens the tissue where it needs to be strongest and prevents the taking of the smallest possible bite. If the vessel edge is picked up just to one side of the intended site of the next suture, sideways distortion of tissue occurs and irregular spacing of sutures results.

Secondly, the vessel may be manipulated in a 'no-touch' manner by exerting traction on the ends of the sutures already in place (O'Brien, 1970). This begs the question of how the first sutures are put in. In addition, such a practice is likely to cause enlargement of the needle-holes, which predisposes to thrombus formation.

Thirdly, counter-pressure may be made from within the vessel. A simple and effective counter-pressor (*Fig.* 5) consists of a single circular loop of electro-polished stainless-steel wire. The external diameter of the loop is 0·25 mm. The loop is fixed in the end of a rounded-off fine hypodermic needle which is mounted on a plain handle.

To pass a suture the counter-pressor is placed just inside the vessel (*Fig.* 6A) and the needle is passed through the vessel wall and through the loop. When the needle is a little way through the loop, the loop is withdrawn and placed on the outside of the vessel (*Fig.* 6B) to provide counter-pressure at the point where the needle is brought out.

The advice is often given 'never to touch the intima' on account of the danger of damaging the endothelium and thereby provoking thrombus formation. However this may be, this instrument has been used regularly by the author in anastomosing femoral arteries of rats (diameter 0·6 mm.) without any subsequent thrombus formation attributable to its use.

Acknowledgements.—I wish particularly to thank the following people:—

Professor M. W. Thring, Head of the Department of Mechanical Engineering at Queen Mary College, London, for making the facilities of his department available to me, and Mr. C. W. Ford, Mr. B. Morris, and Mr. H. Slater of his staff for their untiring work in the development of most of the instruments described here.

Mr. T. H. Tarbuck of Dixey Instruments Ltd. and Mr. T. Davis of his staff for their work in developing the needle-holder.

Mr. T. Katch of the U. N. Co., Tokyo, for his help in developing the cables.

The laboratory staff of the Dental Institute, The London Hospital, for their help in many ways.

My friends and colleagues at Princess Margaret Hospital, Swindon, where this work began.

This work was completed during the tenure of a research grant from the Medical Research Council, and the development work at Queen Mary College, London, was supported by a grant from the Nuffield Foundation.

WOUND ANTIBIOTICS IN GASTRO-INTESTINAL SURGERY

COMPARISON OF AMPICILLIN WITH PENICILLIN AND SULPHADIAZINE

By T. A. M. STOKER and HAROLD ELLIS

SURGICAL UNIT, WESTMINSTER HOSPITAL, LONDON

Summary

Ampicillin was compared with a penicillin and sulphadiazine combination as a topical wound application in patients undergoing biliary or gastro-intestinal surgery in a controlled study. Eleven of the 53 patients having a topical application of penicillin and sulphadiazine developed wound sepsis (20·8 per cent) compared with 4 of the 59 patients receiving ampicillin (6·8 per cent). This difference is significant ($P < 0·01$).

The incidence of wound sepsis following surgical operations is still regrettably high. Although only rarely associated with mortality, wound infection causes prolongation of convalescence, unpleasant dressings, ugly scars, increased risk of wound breakdown, and the production of a dangerous locus of infection within the surgical ward.

Heavily contaminated wounds and those whose surfaces are soaked by pus during the course of operation are, not surprisingly, associated with a high rate of infection, but numerous reports reveal that sepsis is also particularly common in routine surgical procedures in which the gastro-intestinal and biliary tracts are opened (Committee on Trauma, 1964). Since contamination of the wound at the time of operation is the main cause of suppuration, there has been considerable recent interest in the use of anti-bacterial agents placed in the wound at operation (Nash and Hugh, 1967; Rickett and Jackson, 1969; Mountain and Seal, 1970).

Penicillin and sulphadiazine powder has been used for this purpose for many years, and the present report compares its efficacy with ampicillin powder in patients undergoing gastro-intestinal or biliary-tract surgery.

MATERIALS AND METHODS

Patients undergoing operative procedures in which either the alimentary or biliary tract was to be opened were randomly distributed to receive either Penicillin G (1 MU.) and sulphadiazine (2 g.) powder or ampicillin (1 g.) powder topically into the laparotomy wound after closure of the peritoneum. No powder was given to those patients with a history of sensitivity to any of these compounds. Skin preparation in every case was carried out with iodine in spirit. In those cases requiring a peritoneal drain this was brought out through a separate stab incision. Wounds were assessed on the tenth postoperative day unless there was need for earlier examination because of, for example, pain, fever, or early discharge from hospital.

Wound infection was defined as the presence of pus which discharged spontaneously or needed to be released, according to the criteria of Lundqvist (1964). A swab was taken for bacteriological culture from any wound discharge. Special note was made of any systemic antibiotic therapy used over the operative period, and this comprised in every case a 5–6-day course of ampicillin. Patients undergoing elective colonic surgery received a 5-day course of phthalylsulphathiazole, 2 g. 6-hourly by mouth, supplemented in the last 48 hours by oral neomycin, 0·5 g. 6-hourly. Any special feature relating to the patient or to the operative procedure was also recorded.

Table I.—THE INCIDENCE OF WOUND INFECTION IN RELATION TO THE TYPE OF OPERATIVE PROCEDURE AND THE USE OF A TOPICAL ANTIBIOTIC

TYPE OF OPERATION	AMPICILLIN		PENICILLIN AND SULPHADIAZINE		NO ANTIBIOTIC	
	No. of Patients	No. of Wound Infections	No. of Patients	No. of Wound Infections	No. of Patients	No. of Wound Infections
Appendicectomy	6	2	4	1	0	
Large- or small-bowel surgery	16	1	17	5	2	1
Biliary-tract surgery	18	0	16	3	1	0
Gastroduodenal surgery	19	1	16	2	0	
Total	59	4	53	11	3	1

RESULTS

During the period of study, 121 consecutive patients were subjected to operations involving the opening of the alimentary or biliary tract. Three patients who had had previous reactions to antibiotics received no local therapy. Of the 118 patients receiving topical antibiotics, 6 were subsequently excluded because of death or reoperation during the first 10 postoperative days. Of the 112 patients remaining for study, 15 developed wound infection (14 per cent). Eleven of the 53 patients who had penicillin and sulphadiazine powder in the wound developed infection (20·8 per cent) compared with 4 of the 59 patients who received topical ampicillin (6·8 per cent). This difference is significant ($P < 0{\cdot}01$). One of the 3 patients who had no topical antibiotic because of hypersensitivity became infected.

The incidence of infection considered in relation to the type of operative procedure is set out in *Table I*. It can be seen that the two series of patients are well matched in this respect. Operations on the appendix have the greatest proportion of infections, followed by those on the large and small intestines.

The use of antibiotics systemically and as pre-operative bowel preparation was also reasonably distributed between the two groups. Forty-six patients had had systemic chemotherapy (ampicillin), with 4 postoperative wound infections; 24 had received topical ampicillin, 21 had had penicillin and sulphadiazine, and 1 had not had topical therapy. There were 2 wound infections in the group receiving topical ampicillin and 2 in the group having penicillin and sulphadiazine. Twenty-five patients had received bowel preparation with phthalylsulphathiazole and neomycin, with 3 postoperative wound infections; 11 of these had received topical ampicillin, 13 had had topical penicillin and sulphadiazine, and 1 had received no local therapy. One patient who had had topical ampicillin, 1 receiving penicillin and sulphadiazine, and the 1 patient who had received no topical therapy became infected.

Bacteriology.—Bacteria were cultured from the pus obtained from 11 of the 16 infected wounds, and in every case the infection was due to a Gram-negative organism. The organism in the case which had received no wound antibiotic was sensitive to both ampicillin and sulphonamides and might have been suppressed by either powder. In 4 of the 7 patients in the penicillin and sulphadiazine series the infecting organism was sensitive to ampicillin and resistant to sulphonamides. Two of the three organisms in the ampicillin series were resistant to ampicillin and all were resistant to sulphonamides.

DISCUSSION

In the early days of antibiotics it was hoped that the use of these agents as a prophylactic would abolish sepsis from the surgical wards, but this dream was soon shattered as report after report appeared showing that the use of various antibiotics seemed to have no effect at all on sepsis rates or even potentiated the growth of resistant organisms (Ellis, 1969). Most of these studies can be criticized in that antibiotic therapy was commenced after operation, whereas Linton (1961) has stressed that prophylaxis, if it is to be used, must commence before the operation has begun so that an adequate antibiotic level is present in the tissues at the time that bacterial inoculation takes place. Experimentally, Burke (1961) has demonstrated that systemic antibiotics have no effect on primary staphylococcal wound sepsis if the bacteria producing the infection have been in the tissues for longer than 3 hours before therapy is commenced. Bernard and Cole (1964), in a carefully controlled investigation of patients undergoing gastro-intestinal and biliary-tract surgery, showed that a penicillin, methicillin, and chloramphenicol combination in which the first dose was given 1 or 2 hours preoperatively and the second during operation resulted in a 5 per cent infection rate, compared with a 25 per cent rate in untreated controls. Similar results have been reported using cephaloridine in elective gastro-intestinal operations (Polk and Lopez-Mayor, 1969), and combined carbenicillin and gentamicin begun within 2 hours of surgery (Bloom, 1969).

Most surgeons are averse to the use of systemic antibiotics as a prophylactic measure, but the value of local chemotherapy has aroused considerable interest recently. By this means an extremely high concentration of antibiotic in the wound is achieved at the time when potential bacterial contamination takes place, the concentration of antibiotic being far higher than could be obtained by systemic administration (Ryan, 1967) and yet being without the disadvantages and potential dangers of a full systemic antibiotic course. Matsumoto, Hardaway, Dobek, and Noyes (1967) showed convincingly that a spray of oxytetracycline in heavily contaminated crush wounds in experimental animals had a dramatic effect on mortality: 67 per cent of their control group died compared with only 1 per cent in the treated group. It is interesting that the same dosage of oxytetracycline given systemically reduced the mortality to only 51 per cent.

A number of clinical trials on the use of antibiotics instilled directly into the wound have now been published and their results have been encouraging. Nash and Hugh (1967) used ampicillin powder in the abdominal wound following large-bowel surgery; 3 per cent became infected in the treated group and 41 per cent in the untreated patients. Moylan and Brockenbrough (1968) reduced their rate of wound infection from 19·8 to 9·7 per cent when wounds were irrigated with 1 per cent kanamycin following enterotomies; the control group in this study had the wound irrigated with saline. Bacterial swabs taken at the end of the operation showed a positive culture in all but 1 patient where sepsis later occurred, thus confirming the importance of contamination at the time of surgery. Rickett and Jackson (1969) reported a double-blind trial with the use of topical ampicillin in appendicectomy wounds. There was a 3 per cent infection rate in those patients in whom 500 mg. ampicillin were placed in the wound compared with a 24 per cent infection rate in those receiving lactose powder. This study can be criticized because it may well be that lactose itself encourages wound infection by its presence in the tissues. Mountain and Seal (1970) compared patients undergoing appendicectomy who either received or did not receive topical ampicillin; the sepsis rate in the treated group was 9 per cent compared with 24 per cent in the untreated group.

Sufficient evidence seems to have accumulated which indicates that topical antibiotics can significantly reduce wound infection in alimentary-tract surgery; the problem would now seem to be which is the most effective agent. In this study we have compared penicillin and sulphadiazine powder with ampicillin. Penicillin with a sulphonamide has been a popular topical combination for many years and does indeed provide protection against a wide spectrum of the bowel organisms. However, in modern surgical practice ampicillin has an even wider spectrum of activity with less chance of bacterial resistance to it. Our own findings confirm the greater effectiveness of topical ampicillin in reducing local infection. An incidence of infection of 20·9 per cent was found in patients receiving penicillin and sulphadiazine powder compared with 6·8 per cent in the ampicillin-treated group. Moreover, it is interesting that of the infected wounds in the former group from which bacteria were obtained on culture, 4 out of 7 were ampicillin-sensitive.

Since a number of patients are, or claim to be, sensitive to a variety of antibiotics it is obviously important to determine the efficiency of a variety of agents as topical applicants, and there has been renewed interest in the use of local wound antiseptics (Edlich, Custer, Madden, Dajani, Rogers, and Wangensteen, 1969). Studies of this nature need to determine not only the efficiency of such agents in reducing local infection, but also any effect they might have on wound healing. We have conducted a trial of noxythioline (a chemical compound which undergoes slow decomposition to liberate free formaldehyde) as a topical application in a controlled trial against ampicillin but have found it less effective (Stoker and Ellis, 1971).

Acknowledgement.—We wish to thank Messrs. Beechams Ltd. for generously supplying the antibiotics used in this trial.

KIDNEY PRESERVATION FOR TRANSPORTATION

EXPERIMENTAL ANALYSIS OF OPTIMAL PERFUSATE COMPOSITION

By GEOFFREY M. COLLINS, LIONEL C. J. HARTLEY, and GORDON J. A. CLUNIE

DEPARTMENT OF SURGERY, UNIVERSITY OF QUEENSLAND, AND PRINCESS ALEXANDRA HOSPITAL, BRISBANE

SUMMARY

Previous experiments have demonstrated that canine kidneys can be preserved for 24 hours or more following initial perfusion with a solution of intracellular composition (C3) and subsequent ice storage. In the present study the composition of C3 was varied to determine the role of each of the major constituents. The efficacy of the solution was found to depend more on magnesium sulphate than on the potassium content, although potassium assumed a greater importance in perfusates free of magnesium. No variation in composition produced a significant improvement in the results obtained with solution C3 itself.

INITIAL cold perfusion followed by ice storage is, by virtue of simplicity, the method preferred in most transplant centres for the storage of human cadaveric kidneys. Although the success of this technique may be ascribed largely to profound depression of metabolism upon cooling (Levy, 1959), it is clear that perfusate composition is also of considerable importance. One such perfusate, solution C3, formulated to resemble intracellular fluid, would appear to be the best so far developed for both canine and human kidney preservation (Collins, Hartley, and Clunie, 1971a, b; Woods, Holley, and Pheteplace, 1971). The present study was undertaken to define more precisely the role of each of the major constituents of this perfusate.

MATERIALS AND METHODS

The experimental protocol has been described previously (Collins, Shugarman, and Terasaki, 1969). Canine kidneys were stored in iced saline slush after an initial perfusion from a height of 100 cm. with 150 ml. of the cold solution under test, and were reimplanted in the donor 24 hours later, contralateral nephrectomy being carried out at that time. Saline and mannitol diuresis were induced during all operative procedures, and the function of the stored kidneys was assessed by daily measurements of serum creatinine. In the present study serial modifications of solution C3 were tested, varying the composition with respect to sodium, potassium, magnesium, and glucose (*Table I*). The *p*H ranged from 7·05 to 7·15 at 37°C. and the osmolarity from 300 to 330 mosmol per l. In addition to the electrolytes, all the perfusates contained procaine hydrochloride, 0·94 g. per l., glucose,* 23·5 g. per l., and heparin, 5000 U. per l. Statistical analysis of the results was performed using Student's *t*-test.

RESULTS

A total of 64 canine kidney preservation experiments was performed, comparing 9 variations of perfusate composition (*Table I*). The maximum serum creatinine levels reached within the first week after reimplantation of the stored kidneys are recorded in *Tables II* and *III*.

Table I.—COMPOSITION OF PERFUSATES

PERFUSATE	ELECTROLYTE CONTENT (mmol. per l.)						
	Na	K	Mg	SO_4	PO_4	Cl	HCO_3
C3	9	107	28	28	54	14	9
C3 (sucrose)	9	107	28	28	54	14	9
C3 (sodium)	116	—	28	28	54	14	9
C3 (extra magnesium)	3	50	86	86	17	5	3
C3 (no magnesium)	9	107	—	—	54	14	9
Sodium phosphate	128	—	—	—	73	—	—
Sodium phosphate + magnesium	128	—	28	28	73	—	—
Sodium/potassium phosphate + magnesium	64	64	28	28	73	—	—
Potassium phosphate + magnesium	—	128	28	28	73	—	—

In the first group the composition of C3 was modified by either substitution of sucrose for glucose or alteration in the magnesium content. Serum creatinine levels (*Table II*) rose on average to 2·4 ± 0·7 mg. per cent with C3 as the perfusate, and to 2·7 ± 1·2 mg. per cent when sucrose was substituted for glucose, a difference which was not significant ($P > 0{\cdot}05$). Alteration of the magnesium content, however, had a more noticeable effect. When the perfusate contained an increased amount of magnesium sulphate (90 mmol. per l.), with a corresponding reduction in the concentration of the other electrolytes, the average serum creatinine level for the group rose to only 2·2 ± 0·7 mg. per cent, a value which was significantly lower ($P < 0{\cdot}05$) than the mean for the group in which the perfusate was C3 without magnesium, where the maximum serum creatinine was 3·9 ± 2·8 mg. per cent. With sodium phosphate solution (*Table III*) the maximum creatinine was 7·7 ± 5·0 mg. per cent, but the addition of magnesium sulphate (30 mmol. per l.) produced a significant reduction ($P < 0{\cdot}05$) to 2·7 ± 0·9 mg. per cent.

The second series of experiments (*Table III*) was intended to define the importance of the sodium to potassium ratio in the perfusate by substitution of sodium for the potassium in C3, and by utilization of a simplified perfusate containing, in addition to magnesium sulphate, either sodium phosphate, potassium phosphate, or a mixture of the two in equal amounts. In the presence of magnesium sulphate (30 mmol. per l.) alterations in the ratio of sodium to potassium had little effect on the extent of the rise in serum creatinine. The lowest maximum serum creatinine levels were achieved when the perfusate contained both sodium and potassium, as with the C3 solution or the sodium/potassium/phosphate mixture. In these groups the average maximum creatinine levels recorded were 2·4 ± 0·7 mg. per cent in each case. Individually, sodium phosphate or potassium phosphate together with magnesium sulphate resulted in slightly higher maximum creatinine levels of 2·7 ± 0·9 mg. per cent and 3·0 ± 0·5 mg. per cent respectively. These differences, however, were not significant ($P > 0·05$). In the *absence* of magnesium sulphate, on the other hand, a potassium-containing solution appeared to be superior to a purely sodium-containing one. Thus, the average maximum serum creatinine level recorded for the group perfused with sodium phosphate alone was 7·7 ± 5·0 mg. per cent compared with 3·9 ± 2·8 mg. per cent for the group in which C3 without magnesium served as the perfusate. Owing to rather large standard deviations within these groups this difference just failed to reach statistical significance ($P > 0·05$).

---

* In solution C3 (sucrose) glucose was replaced iso-osmotically with sucrose (*Table I*).

Table II.—KIDNEY FUNCTION AFTER INITIAL PERFUSION AND ICE STORAGE FOR 24 HOURS

PERFUSATE	MAXIMUM SERUM CREATININE (mg. per cent)			DEATH FROM URAEMIA
	Individual	Mean	S.D.	
C3	1·5, 2·1, 3·8, 2·5, 2·2, 3·3, 1·8, 1·2, 2·8	2·4	0·7	0/9
C3 (sucrose substitution)	1·5, 4·8, 1·6, 4·1, 2·7, 2·1, 2·7, 2·3	2·7	1·2	0/8
C3 (no magnesium)	3·5, 3·2, 9·4,* 1·9, 3·6,† 1·9‡	3·9	2·8	1/6

* Died from uraemia.

† Died from peritonitis.

‡ Died from wound dehiscence.

Died from pneumonia.

DISCUSSION

Undoubtedly the most important single factor contributing to the success of hypothermic kidney storage is the marked reduction in metabolism produced by cooling (Levy, 1959). The efficacy of the method is thus proportional to the reduction in temperature achieved (Stueber, Kovacs, Koletsky, and Persky, 1958). In order to achieve rapid cooling (Markland and Parsons, 1963) it is the normal practice to perfuse the kidney soon after removal with a volume of cold electrolyte solution. This procedure has the added theoretical advantages of the elimination of some antigen in the form of retained blood and providing a basis for assessment of organ viability in terms of the uniformity and quality of perfusion (Belzer and Kountz, 1970). The composition of the perfusate used has usually been based on extracellular fluid, in which the principal cation is sodium, and has frequently contained in addition some colloid in the form of either protein or dextran (Cleveland, Lee, Prout, and Hume, 1964; Dempster, Kountz, and Jovanovic, 1964; Sells and Pena, 1970). Recently, however, we have shown experimentally and in man that a perfusate resembling intracellular fluid, solution C3—4, yields better results (Collins, Shugarman, Terasaki, Braf, Sheil, and Williams, 1970; Collins and others, 1971a, b), and this finding has been amply confirmed by others (Collste, Bjorken, Collste, and Groth, 1970; Liu, Humphries, Stoddard, and Moretz, 1970; Woods and others, 1971). We are unable to explain the failure of certain groups to repeat our experimental results (Kulatilake, O'Donoghue, and Shackman, 1970; Smellie, Marshall, and Hadjiyannakis, 1970), but believe that the proved efficacy of the C3 perfusate when applied to the preservation of human cadaveric kidneys (Collins and others, 1971b) goes some way towards answering the criticism raised by Frost, Ackerman, Finch, and Manlove (1970) that the method would be ineffective after a period of warm ischaemia.

Table III.—KIDNEY FUNCTION AFTER INITIAL PERFUSION AND ICE STORAGE FOR 24 HOURS

PERFUSATE	MAXIMUM SERUM CREATININE (mg. per cent)			DEATH FROM URAEMIA
	Individual	Mean	S.D.	
C3 (sodium)	2·5, 3·0, 3·2, 1·7, 3·0, 2·5	2·7	0·5	0/6
Sodium phosphate	6·6, 7·8,* 16·0,† 4·6, 3·4	7·7	5·0	1/5
Sodium phosphate + magnesium	3·4, 1·3, 3·1,‡ 4·0, 1·8, 2·9, 2·5	2·7	0·9	0/7
Sodium/potassium phosphate + magnesium	3·3, 2·3, 1·5, 2·9, 2·2	2·4	0·7	0/5
Potassium phosphate + magnesium	2·8, 3·3, 3·3, 2·1, 3·6, 2·8	3·0	0·5	0/6

* Died from wound dehiscence.

† Died from uraemia.

‡ Died from ureteric obstruction.

The initial choice of the composition of solution C3, which is rich in potassium and magnesium, as a perfusate for hypothermic kidney storage was based on a number of considerations. A substantial proportion of cellular energy production is utilized by the membrane ionic active-transport mechanisms (Whittam and Ager, 1964). The level of cellular respiration is directly related to the concentration of sodium in the environment (Burck and Petruch, 1966). It would therefore seem logical to endeavour to suppress energy requirements during hypothermic storage by a reduction in the concentration of sodium in the extracellular fluid, using a perfusate rich in potassium and poor in sodium. This type of perfusate would have the added advantage of preventing the loss of intracellular potassium and gain of sodium which are known to occur when active-transport mechanisms are suppressed by cold (Whittam and Davies, 1953; Keeler, Swinney, Taylor, and Uldall, 1966). Similar ionic shifts are known to occur in hibernating animals (Haggag, Raheem, and Khahl, 1965), but are limited by the unusual efficiency of the cell-membrane ionic pumps in these animals at low temperatures (Willis, 1966). A further interesting observation made during hibernation is that the plasma-magnesium levels are increased (Haggag and others, 1965; Pengelley and Chaffee, 1966), and this would tend to support the inclusion of magnesium in a perfusate for hypothermic storage.

In the present study the importance of each of the components of solution C3 was tested by serial modifications of its composition. Substitution of sucrose for glucose in iso-osmolar proportions produced no significant deterioration in the results (*Table II*), implying that exogenous glucose does not provide a useful substrate during hypothermic kidney storage. Alteration of the electrolyte content, on the other hand, seemed to influence the results to a greater extent. Magnesium sulphate was the component of greatest importance. Its inclusion in the C3 perfusate in concentrations above 10 mmol. per l. (Collste and others, 1970) results in consistently good 24-hour kidney preservation. The optimum level would appear to lie in the range of 30–90 mmol. per l. The beneficial effects of magnesium in organ preservation have been described previously (Kamiyama, Webb, and Ecker, 1970), and have been attributed to metabolic inhibition and the ability of magnesium to prevent loss of intracellular potassium. This effect may explain why in the present study the rise in serum creatinine following the use of a perfusate containing magnesium sulphate was low, regardless of the sodium to potassium ratio. When the perfusate contained no magnesium, however, there was a suggestion that the potassium content assumed a greater importance, the maximum creatinine levels in the group perfused with C3 without magnesium being lower than those in the group perfused with sodium phosphate alone. This difference failed to reach statistical significance because of the large standard deviations in the results for both groups. However, taken together with other evidence for the importance of an elevated potassium content in perfusates for organ storage (Keeler and others, 1966; Abouna, 1968; Calman, Bell, MacPherson, Wood, and Quin, 1970), the difference between these two groups may well be meaningful. It is interesting to note that the highest creatinine values followed perfusion with a potassium phosphate/magnesium sulphate solution in which the potassium concentration was 128 mEq./l., and it may be that too high a potassium concentration is deleterious. The lower potassium concentration of 107 mEq./l. in C3 and 64 mEq./l. in the sodium/potassium phosphate mixture may approach more closely the levels of 30–50 mEq./l. which have been found by others to be optimal for continuous perfusion (Abouna, 1968; Calman and others, 1970). *In vitro* studies of canine renal cortical respiration at present in progress in our laboratory tend to support the contention that the potassium concentration should not be too high.

The canine kidney preservation model upon which this and most other studies have been based has been invaluable as a proving ground for storage techniques intended ultimately for clinical use. Unfortunately, the many uncontrollable factors in dog kidney transplantation lead to variability in results, and the resolution of the method is therefore limited to rather broad comparisons between perfusates and storage techniques which differ substantially in their efficacy. Thus, attempts to define more precisely the optimum composition of perfusates with such a method will probably be unrewarding. From the present series of experiments it would appear to be difficult to improve on solution C3, the effect of which seems to be based largely on the magnesium and to a lesser extent the potassium content. However, an increase in the magnesium and a reduction in the potassium concentrations deserve further examination in a more sensitive model. We are currently investigating *in vitro* preservation methods which may provide a better tool for initial assessment of the value of individual constituents of perfusates for hypothermic kidney preservation.

THE VALUE OF FRUSEMIDE IN 110 CONSECUTIVE PROSTATECTOMIES

By C. R. WILLIAMS*

SENIOR SURGICAL REGISTRAR, UROLOGICAL UNIT, SELLY OAK HOSPITAL, BIRMINGHAM

SUMMARY

One hundred and ten patients undergoing open prostatectomy had an induced diuresis using frusemide. The results of this treatment are reviewed. Seventy-one patients (65 per cent) presented as emergencies with acute retention, while the remainder presented with chronic retention or prostatism. The average age was 69 years, and 25 patients (23 per cent) were aged 75 years or more. Only rarely was a patient refused operation because of confinement to bed or failing mental faculties. Blood-loss, fluid and electrolyte balance, and postoperative urinary infection were studied in detail, and the following points are emphasized:—

1. The average postoperative 24-hour urinary output was 4·5 litres, 40 per cent of which was passed in the first 3 hours when the danger of clot retention is greatest.
2. Clot retention was eliminated as a problem, and bladder wash-outs were not necessary.
3. The average blood replacement was 1·05 U., and the average fall in postoperative haemoglobin level was 1·1 g.
4. The postoperative urinary infection rate was low, being 8 per cent at 1 week after operation.
5. A low morbidity was recorded and the mortality was 0·9 per cent.

A vigorous diuresis induced by frusemide after suitable fluid loading is both effective and safe. It is a distinct advance over previous methods used.

THE immediate complication after prostatectomy is haemorrhage, and its possible sequel, clot retention. In general, the threat of this complication is present only in the first few hours after operation. The other important complication, urinary infection, is potentiated by excessive bleeding and poor bladder drainage necessitating interference with the catheter. Any method which ensures a free flow of urine will reduce these hazards. A large urinary secretion will dilute and prevent the clotting of blood that is being shed in the immediate postoperative period. Also, by removing the environment which is favourable to bacterial growth, urinary infection may be prevented.

Osmotic diuretics have been extensively used in prostatic surgery. McKelvie in 1962 and Rickwood and Thorne in 1967 reported good results using intravenous urea. Jameson in 1969 described the use of mannitol and intramuscular frusemide in 80 cases. Recently, Essenhigh and Eustace (1969) have described the use of frusemide administered intravenously in a larger dose in a series of 50 cases.

The use of frusemide, a non-mercurial diuretic of low toxicity, after suitable fluid loading to produce a physiological bladder wash-out would appear to be particularly attractive. Frusemide is a distinct advance over intravenous urea or mannitol because of its ease of administration, its rapid action, and the predictability of its effect. Frusemide acts mainly by reducing sodium reabsorption in the distal tubules and it may also increase the glomerular filtration rate, even when renal function is impaired (Kerr and Robson, 1965). It was decided to carry out a trial of frusemide in patients undergoing prostatectomy.

MATERIALS AND METHODS

During a 9-month period 110 consecutive prostatectomies were carried out; all of the patients were given frusemide. This series of patients was unselected. Very occasionally a patient was refused operation because of either a complete lack of mobility or failing mental faculties. The age range was 50–96 years, the average age being 69 years.

Table I.—ASSOCIATED DISEASE

Associated Disease	*No. of Patients*
Hypertension	46
Chronic bronchitis	14
Coronary thrombosis	5
Cerebrovascular accident	3
Auricular fibrillation	2
Aortic stenosis	1
Congestive cardiac failure	1
Angina pectoris	2
Deep venous thrombosis	1
Severe arteriosclerosis	4
Diabetes mellitus	2

All of these patients were managed in a busy urological unit. Sixty-five per cent presented as emergencies with acute painful retention, 8 per cent had chronic painless retention, and the remaining 27 per cent were admitted for elective surgery because of prostatism. The patients in this study exhibited an impressive array of concomitant 'medical' disease (*Table I*). *Table I* shows that a severe degree of cardiovascular or pulmonary disease, a frequent finding in this age-group, is not in itself a contra-indication to prostatectomy.

Preliminary assessment of the patients included estimation of haemoglobin, blood-urea, and electrolytes, culture of urine, and intravenous pyelography. Blood-urea was normal in 86 per cent, over 50 mg. per 100 ml. in 10 per cent, and over 100 mg. per 100 ml. in 4 per cent. Urinary infection was present in 17 per cent of patients on admission to hospital.

The type of prostatectomy to be performed was decided by cystoscopy and rectal examination. Millin prostatectomy was performed in 79 patients (72 per cent), and transvesical prostatectomy in the minor degree of cellulitis. Two patients developed auricular fibrillation, which was controlled by digoxin. One patient aspirated a small amount of stomach content whilst under anaesthesia and was retained on a positive-pressure respirator for 12 hours postoperatively, recovering without incident thereafter. Vasectomy was not performed, and 3 patients developed a mild epididymo-orchitis after discharge from hospital; all settled rapidly on antibiotics.

---

* Present address: Walsgrave Hospital, Coventry.

Strictures occurred in 2 patients. One patient had prolonged catheterization and developed a stricture in the penile urethra which was easily dilated. The other patient, who had the prostatic cavity packed at operation for severe haemorrhage, developed a bladder-neck stricture after 6 months which necessitated excision. In 1 patient a bladder stone was missed at cystoscopy, and this precipitated retention 6 months after prostatectomy when it became impacted in the urethra and had to be removed.

There has been no instance of suprapubic fistula formation, and all the patients have satisfactory control of micturition, except for 1 man of 82 years who has stress incontinence; this man had been incontinent for 10 years preoperatively. No patient developed symptoms or signs of either deep venous thrombosis or pulmonary embolism.

Mortality.—No patient died as an immediate result of the operation. One patient, having made an initially satisfactory recovery, died in hospital 3 weeks after operation from acute pancreatitis. The mortality in this series was therefore 0·9 per cent.

There have been 3 late deaths. Two of these patients had carcinoma of the prostate and were aged 81 and 96 years, and the other patient had carcinoma of the bladder and was aged 82 years. These 3 patients died in their own homes approximately 4 months after discharge from hospital, having remained ambulant until shortly before death and free of the burden of an indwelling catheter.

DISCUSSION

The principle of inducing a diuresis after prostatectomy is well known but previous methods using intravenous urea or mannitol have not been entirely satisfactory. The response to intravenous urea and mannitol is not sufficiently predictable: intravenous urea may cause thrombophlebitis and mannitol may cause renal tubular damage or hypokalaemia. The use of frusemide is simple, effective, and would appear to have no contra-indications. Initial fears that frusemide may have some diabetogenic effect have proved unfounded (Schaefer, 1964). Two diabetics in the present series made a smooth postoperative recovery.

The most immediate problem of bleeding in the first few postoperative hours is reduced by an adequate diuresis, and clot retention has not been a problem in this series. Bladder wash-outs have not been necessary. Five patients had small blood-clots aspirated from the catheter with a suction syringe, no foreign substance being introduced into the bladder. This could probably have been avoided if a further dose of frusemide, 40 mg., had been given when the urine became heavily blood-stained. Eight patients were given such an extra dose of frusemide, with rapid clearing of the urine. Rickwood and Thorne (1967), using an intravenous urea technique, found that 45 per cent of their patients needed at least one bladder wash-out at some stage because of catheter blockage.

Blood-loss during and after prostatectomy may be underestimated by the surgeon. Salvaris (1960) estimated a mean overall loss of 1000 ml. in 30 patients. Goldman and Samellas (1961) estimated an average loss of 1050 ml. Over 50 per cent of the total blood-loss occurs in the postoperative period. The presence of a large amount of blood-clot in the bladder appears to encourage prolonged oozing from the prostatic bed, possibly by preventing the prostatic capsule from contracting down. The diuresis, by preventing the accumulation of blood-clot, reduces postoperative oozing, and the urine rapidly becomes clear of any gross blood-staining. In this series blood-loss was estimated by clinical observation and by estimation of the haemoglobin level. The average blood replacement was 1·05 U., and the average postoperative fall in haemoglobin was 1·1 g. Thirty patients did not require blood transfusion.

The incidence of postoperative urinary infection in this series (8 per cent) is low. The rapid clearing of blood from the urine and the elimination of clot retention prevent the formation of a favourable 'culture medium' in the bladder. O'Grady and Cattell (1966) suggest that a high urinary flow rate reduces infection by a mechanical washing-out effect. A minimum of interference with the catheter and early removal of the catheter also reduce the postoperative infection rate. The generally reported incidence of postoperative urinary infection has been between 15 and 100 per cent, including those authors using a no-catheter technique (Spencer, 1967). Salvaris (1960), reviewing a large series of prostatectomies, found that of 40 per cent who had postoperative urine cultures recorded, nearly all had an infection. Allan and Coorey (1966) found urinary-tract infection to be present in almost 100 per cent of their patients following operation, and this had fallen to 8 per cent after 1 year.

Table VI.—MORTALITY OF PROSTATECTOMY

AUTHOR	NO. OF CASES	ACUTE RETENTIONS (per cent)	MORTALITY (per cent)
Salvaris (1960)	1200	25	4·2
Stearns (1961)	500	35	0·66
Allan and Coorey (1966)	1000	69	5·2
Cooper, Ashmalla, and Cobb (1966)	302	22	0·99
Rickwood and Thorne (1967)	132	64	5·0
Spencer (1967)	132	60	6·1
Jameson (1969)	80	25	1·25
Williams (1972)	110	65	0·9

Morbidity from the operation was negligible, and no complications were attributable to the method of fluid loading or to the diuretic agent used. Postoperative mental confusion and chest infection have not been a problem. There has been no instance of deep venous thrombosis or pulmonary embolism. Dehydration is not well tolerated by the elderly and may lead to any of these complications. It is felt that a rapid fluid turnover and the maintenance of a positive fluid and electrolyte balance are important factors in preventing complications.

The mortality of prostatectomy which has been recorded in the literature is shown in *Table VI*, and has ranged from over 6 per cent to 0·6 per cent, which was obtained by Stearns (1961) in a series of rigidly selected cases. The mortality of 0·9 per cent in this series is low and compares favourably with any published series of open prostatectomies or transurethral prostatectomies, for which the accepted mortality is around 1 per cent (Mitchell, 1970).

Acknowledgements.—I am greatly indebted to Mr. Bernard Price for allowing me to operate on and manage these patients who were under his care. The nursing staff of the urological unit, particularly Sister A. Phillips, Sister B. Corridan, and house-surgeon Dr. David Higginson, have all given untiring and invaluable help. Dr. Jordan Sikorska and Dr. John Davies have administered all the anaesthetics with their habitual skill. Finally, I would like to thank Miss Joan Teesdale, theatre superintendent, and her staff for their co-operation.

THE EFFECT OF ORAL SUPPLEMENTATION OF ZINC SULPHATE ON PRIMARY WOUND HEALING IN RATS

BY U. I. LAVY
GIST-BROCADES N.V. RESEARCH AND DEVELOPMENT—HAARLEM, NETHERLANDS (P.O. BOX 523)

SUMMARY

The effect of oral supplementation of zinc sulphate on primary wound healing of abdominal wounds was studied in normal rats receiving a standard diet. Daily oral administration of 40 mg. of zinc sulphate ($ZnSO_4.7H_2O$) per rat for 13 days postoperatively resulted in a 35–36 per cent increase in the bursting strength of sutured incision wounds. This increase was statistically significant and corresponded to a gain of about 13 days in healing time. The same daily dose of zinc did not result in a significant increase of wound-bursting strength measured on the sixth day after operation.

IN recent years there has been much interest in the effect of zinc supplementation in the acceleration of wound healing. So far, the effect in man has been demonstrated for secondary healing of open wounds (Pories, Burget, Henzel, Smith, and Strain, 1966; Pories, Henzel, Caris, Rob, and Strain, 1967), leg ulcers (Carruthers, 1969; Husain, 1969; Greaves and Skillen, 1970), leg ulcers in sickle-cell anaemia (Sergeant, Galloway, and Gueri, 1970), and bed-sores (Cohen, 1968). Although the results of zinc supplementation on primary healing of sutured wounds in man have not, to our knowledge, been reported, such a use could also be of importance (Groundwater and Macleod, 1970).

Most of the reported studies on the effect of zinc supplementation in normal animals have been done with rats. Strain, Pories, and Hinshaw (1960), who used zinc methionine, and Pories and others (1966) and Morton and Malone (1969), working with zinc sulphate, demonstrated an acceleration in wound healing of excised skin wounds of rats. On the other hand, O'Riain, Copenhagen, and Calnan (1968), Groundwater and Macleod (1970), and Sandstead, Lanier, Shepard, and Gillespie (1970) found that systematically administered zinc did not affect the strength of sutured incision wounds in rats.

The discrepancy between the reports about the effect of zinc supplementation on the healing of open excision and sutured incision wounds in rats has led to the present study.

MATERIAL AND METHODS

Female Wistar rats, derived from the specific pathogen-free (S.P.F.) colony of TNO, Zeist/Netherlands, were used. The body-weights of the rats ranged from 170 to 200 g. The standard diet contained about 37 mg. of zinc per kg.* The rats underwent operation under aseptic conditions and ether anaesthesia. A standard incision, 5 cm. long, was made in the midline through the skin and linea alba. The wound was closed with six interrupted through-and-through 00 silk sutures.

In a preliminary experiment the rats were killed on the sixth day after operation and the bursting strength of the wound was measured by the method of Prudden, Nishihara, and Batter (1957), using increasing air pressure in a balloon placed inside the abdominal cavity. One group of rats received a daily oral dose of 40 mg. zinc sulphate ($ZnSO_4.7H_2O$) in 2 ml. of water per rat, and another group served as a control.

---

* Hope Farms' RMH/TM rat pellets.

In the main series of experiments the rats were killed with ether 13 days after operation and the remaining sutures were removed. The whole of the ventral surface was excised and the bursting strength of the wound was measured, using the principle of Wolarsky and Prudden (1962). The specimen was secured firmly over a trapezoidal hole in a Perspex box so that the box was made air-tight. An air-stream, increasing the pressure by 10 mm. Hg per 5 seconds, was led into the box until wound disruption occurred. The resulting fall in pressure constituted a clear end-point. The maximal pressure attained at the moment of bursting could be read conveniently by means of a float on top of the mercury column in a manometer which was connected with the box. The float was provided with a small steel brush so that it stayed in position after the mercury had fallen, but it could be moved down again with the aid of a magnet at the end of the experiment.

Table I.—BURSTING STRENGTH OF ABDOMINAL WOUNDS IN RATS TREATED WITH ZINC SULPHATE IN AQUEOUS SOLUTION AND IN CONTROL RATS ON THE SIXTH DAY AFTER OPERATION

GROUP	NO. OF ANIMALS	MEAN BURSTING STRENGTH (mm. Hg) ± STANDARD ERROR	PERCENTAGE BURSTING STRENGTH
Control	10	84 ± 5·4	100
Zinc-treated	10	79 ± 13·6	94

The difference between the groups is not statistically significant: $P > 0{\cdot}35$ (method of Welch, 1947).

Table II.—BURSTING STRENGTH OF ABDOMINAL WOUNDS IN RATS TREATED WITH ZINC SULPHATE IN AQUEOUS SOLUTION AND IN CONTROL RATS ON THE THIRTEENTH DAY AFTER OPERATION

GROUP	NO. OF ANIMALS	MEAN BURSTING STRENGTH (mm. Hg) ± STANDARD ERROR	PERCENTAGE BURSTING STRENGTH
Control	13	217 ± 16·7	100
Zinc-treated	13	292 ± 17·5	135

The difference between the groups is statistically significant: $P < 0{\cdot}0025$ (Student's t-test; one-sided tail probability).

Two sets of experiments were arranged. In the first set, consisting of two experiments, the influence of zinc supplementation was investigated. In both experiments the rats were randomly divided into two groups. From the day of operation each rat in the treatment group was given a daily oral dose of 40 mg. zinc sulphate dissolved in water or suspended in 1 per cent amylum. The control animals received a dose of water or 1 per cent amylum only. The experiment with the amylum suspension was carried out as part of an investigation which included other water-insoluble compounds. The results were analysed statistically using Student's t-test (Gosset, 1908) and the method of Welch (1947).

The aim of the second set of experiments was to establish the relation between time and healing of sutured incision wounds in normal untreated rats. Ninety-five rats underwent operation and were assigned randomly to nine groups. A group of rats was killed every 3 days after operation and the tensile strength of the wounds was measured as described. The results were tested statistically for linearity and regression.

RESULTS

1. The daily oral supplementation with 40 mg. zinc sulphate per rat for 6 days did not result in a significant change in the bursting strength of the wounds (*Table I*).

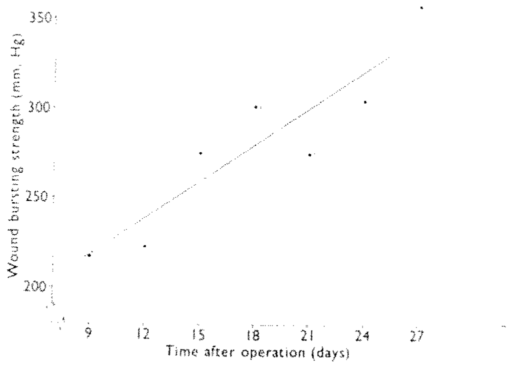

FIG. 1.—Relation between time and bursting strength of sutured abdominal incision wounds in untreated normal rats.

Table III.—BURSTING STRENGTH OF ABDOMINAL WOUNDS IN RATS TREATED WITH ZINC SULPHATE IN A 1 PER CENT AMYLUM SUSPENSION AND IN CONTROL RATS ON THE THIRTEENTH DAY AFTER OPERATION

GROUP	NO. OF ANIMALS	MEAN BURSTING STRENGTH (mm. Hg) ± STANDARD ERROR	PERCENTAGE BURSTING STRENGTH
Control	10	273 ± 20·9	100
Zinc-treated	9	371 ± 8·3	136

The difference between the treated and untreated group is statistically significant: $P < 0{\cdot}0005$ (method of Welch (1947); one-sided tail probability).

Table IV.—BURSTING STRENGTH OF ABDOMINAL WOUNDS IN UNTREATED RATS AT DIFFERENT TIMES AFTER OPERATION

DAY AFTER OPERATION	NO. OF ANIMALS	BURSTING STRENGTH (mm. Hg) ± STANDARD ERROR
3	11	12 ± 5·1
6	11	123 ± 8·7
9	11	217 ± 13·8
12	11	223 ± 24·1
15	11	276 ± 18·1
18	11	302 ± 16·9
21	6	276 ± 31·0
24	11	306 ± 18·1
27	7	359 ± 37·1

2. Forty mg. zinc sulphate, given orally in daily doses for 13 days, resulted in a 35–36 per cent increase in the bursting strength of the sutured abdominal incision wounds. This increase was highly significant (*Tables II, III*).

3. The results of the study of the time–healing relation are given in *Table IV*. The figures for bursting strengths of the wounds indicate three phases of healing: no increase in wound strength during the first 3 days after operation, then a fast increase

during days 3–9, and finally a slow prolonged increase.

By means of a regression analysis of the data on wound strength from the ninth day after operation onwards, it was established that the wound strength showed a significant increase with time which was linear ($F_{\text{regr.}} = 25{\cdot}2$, d.f. 1 and 61; $F_{\text{lin.}} = 0{\cdot}84$, d.f. 5 and 61). This plot is presented in *Fig.* 1. The drawn line represents $\hat{y} = 155{\cdot}41 + 6{\cdot}95x$. This straight line can be used to determine the meaning of the increase in bursting strength in terms of healing time. The treated rats had a wound strength which was 35–36 per cent greater than that of the control animals on day 13; the controls did not reach a comparable level in wound strength until day 25·6. This means that the treated animals had a time-gain in wound healing of 12·6 days in the present experiment. The one-sided lower confidence limit by $\alpha = 0{\cdot}05$ is 6·2 days.

DISCUSSION

The results of our study demonstrate that in addition to a well-established effect on secondary wound healing, zinc supplementation given orally to rats on a normal diet increases the rate of primary wound healing.

Several other workers have failed to demonstrate a beneficial effect of parenteral zinc supplementation on primary wound healing in normally fed rats (O'Riain and others, 1968; Groundwater and Macleod, 1970; Sandstead and others, 1970). Murray and Rosenthal (1968) treated skin wounds in rats locally without favourable results, but they did mention that the suitability of this form of administration may be disputed.

A possible reason why the positive effect of zinc supplementation on primary wound healing has escaped the attention of previous authors seems to be that the duration of the treatment period between operation and testing is an important factor. Most of the previous work, including experiments on the effects of materials other than zinc on primary wound healing (Prudden and others, 1957; Rosenthal, 1968) has been carried out with measurement of wound strength taking place on the sixth or seventh day after operation, apparently since these days lie in the phase of rapid healing. However, Groundwater and Macleod (1970) measured wound strength on days 4, 7, and 10 after operation, and Sandstead and others (1970) did so on day 12. Sandstead and Shepard (1968), using zinc-deficient rats, observed that the tensile strength of wounds in zinc-deficient rats was not lower than that in control rats unless tensiometry was performed on day 12 instead of day 6. In our preliminary experiments we were also unable to demonstrate any effect of zinc supplementation on day 6 after operation. Since we did find a difference on day 13 the effect of zinc on wound strength must have taken place in the intervening period. The conclusion that the slow phase of healing is affected rather than the rapid phase seems obvious, but additional measurements between days 6 and 13 in zinc-treated rats would be necessary to prove this.

It should be noted, however, that there are some differences between the conditions of our experiment and those employed by other authors that may add to the discrepancy in the outcome of zinc supplementation. For example, our oral dose, the equivalent of 9·06 mg. of metallic zinc daily per rat, was larger than the parenteral doses used by Groundwater and Macleod (1970) and by Sandstead and others (1970). The intraperitoneal doses used by O'Riain and others (1968) were even higher, but they reported considerable mortality in all dose groups. A further point of difference is in the surgical technique. Whilst we measured the bursting strength after incisions through the entire abdominal wall, O'Riain and others (1968) and Sandstead and others (1970) made skin incisions only and measured the tensile strength. On the other hand, Groundwater and Macleod (1970) also measured the bursting strength of sutured linea alba wounds. Since in our experiment no increase in wound strength was noted on day 6, we believe the duration of the treatment period to be a very important factor. It is perhaps of interest to note that in a study with excised pilonidal sinus wounds of human patients, Pories and others (1967) also found that oral zinc supplementation only began to accelerate healing significantly after the fifteenth day.

The interpretation of the increase in wound strength in terms of a gain in healing time contributes to the evaluation of the significance of zinc supplementation. Any increase in strength would be of little clinical importance if the untreated patient reached the same stage within a short time.

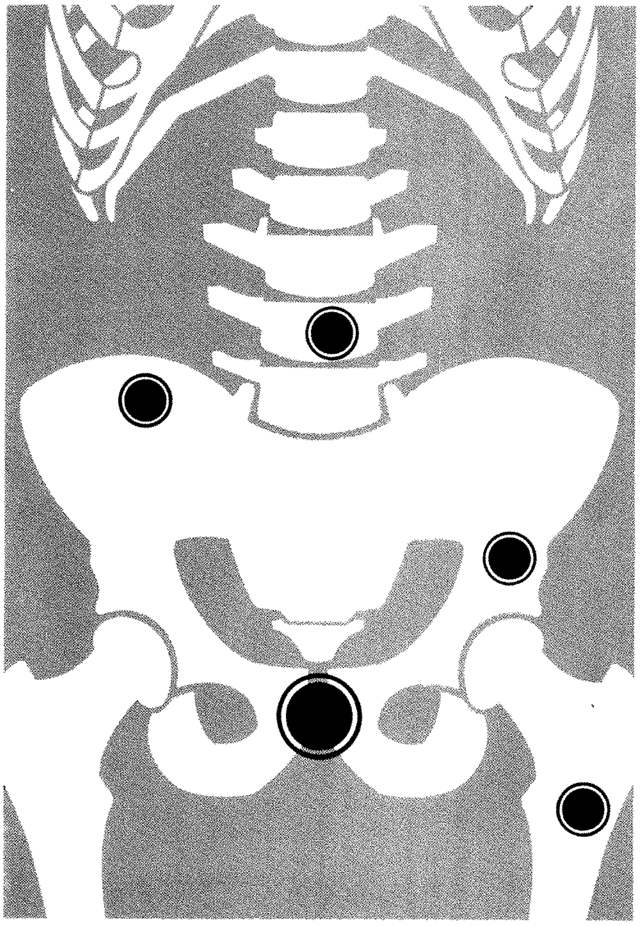
Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



Response is rapid. **Honvan** is a practical alternative to surgery in acute urinary retention caused by prostatic carcinoma.

Gastric tolerance of **Honvan** is good and side effects comparatively rare.

Honvan is available for both intravenous and oral administration.

a selective cytotoxic action

ACUTE INTRAMURAL ABSCESS OF THE PYLORIC ANTRUM—LOCALIZED PHLEGMON

BY GORDON GILLESPIE AND GORDON H. MACPHERSON
STOBHILL GENERAL HOSPITAL, GLASGOW

SUMMARY

A case of acute 'localized' phlegmonous gastritis is described. The predominant clinical features were persistent abdominal pain and a tender mass in the epigastrium. Complete recovery followed partial gastric resection.

ACUTE phlegmonous gastritis, or 'carbuncle' or 'erysipelas' of the stomach as it was called by early writers, was first described by Cruveilhier in 1820. This rare condition results from bacterial infection of the stomach wall by pathogenic organisms. Until 1947, 355 cases had been described in the world literature (Guzzeta and Southwick, 1947). Starr and Wilson (1957) collected a further 25 cases reported over the next 10 years. Few references to this unusual condition have appeared since then. Acute phlegmonous gastritis may occur in either diffuse or localized form and of the reported cases the diffuse variety is by far the more common. We report here a case of acute localized phlegmonous gastritis which presented some unusual features.

CASE REPORT

A 26-year-old married woman presented to the Casualty Department of Stobhill General Hospital, Glasgow, on 8 Aug., 1970, with epigastric pain of 1 week's duration. The pain had increased in severity and had been unrelenting since onset. There had been no vomiting, bowel upset, or urinary symptoms. The menstrual cycle was normal. In particular, there had been no previous dyspepsia and until the onset of symptoms the patient had been in good health. The only previous admission to hospital was 13 years previously when she had had surgical removal of a swallowed needle from the small bowel.

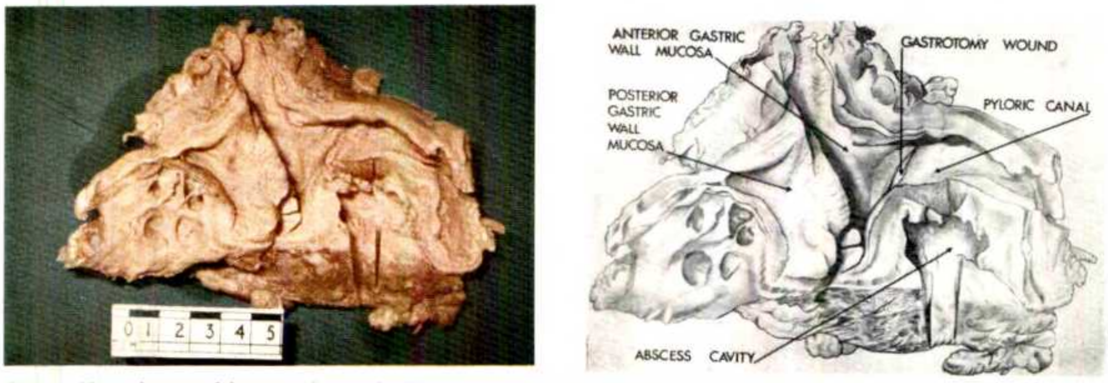

FIG. 2.—Mucosal aspect of the resected stomach. The posterior wall of the stomach has been opened to show the intramuscular multilocular abscess cavity in the antrum producing a narrowing of the pyloric canal. The vertical gastrotomy wound can be seen on the anterior wall.

Examination revealed a distressed, thinly built woman in whom a tender mass was palpable in the epigastrium. The mass was mobile up and down, but not from side to side. She was afebrile. A plain radiograph of the abdomen revealed no abnormality other than a paucity of gas shadows. A chest radiograph was likewise negative. After 24 hours' observation the pain persisted and the tender mass remained.

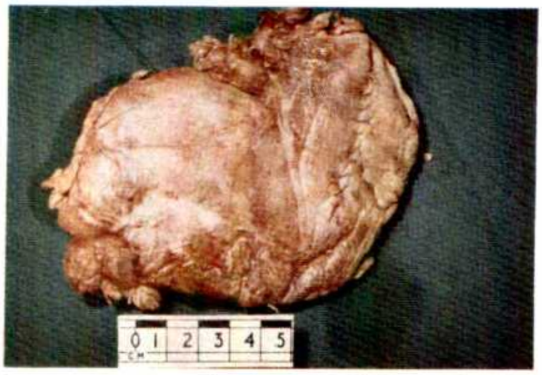

FIG. 1.—Anterior wall of the resected stomach from the serosal aspect. The pylorus is on the left and the body of the stomach with a sutured vertical gastrotomy wound is visible on the right. Note the yellow line of fibrinous exudate along the subpyloric border and the injected appearance of the serosa over the antrum.

At laparotomy on 9 Aug. the pyloric antrum was found to be inflamed on its serosal surface with a thin line of fibrinous exudate extending along the subpyloric border for a distance of approximately 6 cm. (*Fig.* 1). The antrum was mobile and was found to be the seat of an intraluminal tumour measuring approximately 4–5 cm. in diameter. The remainder of the serosal aspect of the stomach appeared normal and there was no other intra-abdominal lesion. A 5-cm. gastrotomy wound was made on the anterior wall of the unaffected body of the stomach to allow inspection of the mucosal aspect. A spherical mass covered by congested but intact mucosa was found occupying the antrum. The mucosa of the body of the stomach appeared normal. A presumptive diagnosis of leiomyoma of the antrum was made and, in view of the sessile nature of the swelling and the grossly narrowed communication remaining as the pyloric canal, a Billroth-I partial gastrectomy was performed.

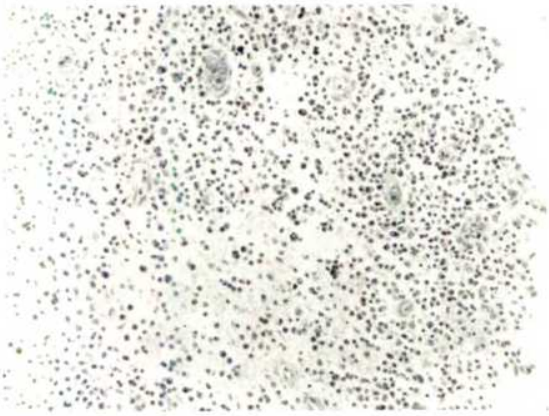

FIG. 3.—Photomicrograph showing pyogenic granulation tissue bordering the abscess cavity on the right. H. and E. (× 160.)

Following operation the patient recovered rapidly and was discharged 12 days after surgery. Further investigations were as follows: Wassermann reaction and Kahn test, negative; postoperative maximal pentagastrin test, peak 30-minute acid output, 1·1 mEq.; plasma proteins, 6·6 g. per cent; haemoglobin, 14·6 g. per cent; white cell count, 6000 per c.mm.; blood-film, normal.

PATHOLOGY.—A partial gastrectomy specimen with a recent gastrotomy incision, 5 cm. long, showed focal haemorrhage and acute inflammatory exudate over the distal third of the serosa (*Fig.* 1). On the cut surface the wall of the stomach enclosed a multilocular abscess, measuring 4–5 cm. in diameter and containing green pus (*Fig.* 2). The abscess projected into the pyloric antrum and resulted in a narrowing of the pyloric canal. The overlying mucosa was congested and stretched. There was no evidence of mucosal ulceration or scar tissue. There were no other pathological lesions present in either the mucosa or the wall of the stomach.

HISTOLOGY.—A multilocular pyogenic abscess was present in the muscle coat of the pyloric antrum. The abscess wall was made up of organizing granulation tissue, and the loculi contained acute inflammatory exudate (*Fig.* 3).

The muscular arteries adjacent to the abscess showed moderately severe endarteritis. The muscle around the abscess was almost completely replaced by fibrous tissue except for a thin layer just below the submucosa where it was infiltrated by chronic inflammatory cells and eosinophils. Apart from a moderate degree of lymphocytic and plasma-cell infiltration of the lamina propria, the mucosa was virtually normal. The serosa over the abscess was thickened owing to fibrosis.

In the multiple sections which were examined there was no evidence of any granulomatous lesion or of active or old healed gastric ulcer. Special stains for fungi and micro-organisms, including acid- and alcohol-fast bacilli, were negative.

DISCUSSION

Acute phlegmonous gastritis occurs in two principal forms: diffuse and localized. In each case the pathological process consists of an exudative fibrinopurulent inflammation of the full thickness of the gastric wall, involving particularly the submucosa and probably commencing there. Microscopy reveals extensive infiltration of all layers of the gastric wall with mixed inflammatory cells. The lesion is produced by a true infection of the stomach wall by pyogenic organisms, usually haemolytic streptococcus but occasionally other organisms. In the commoner diffuse variety of the disease the inflammatory process extends throughout the entire anatomical confines of the stomach, while less commonly focal involvement of the stomach occurs. Predisposing factors to the infection noted in some cases are hypochlorhydria due to alcoholism or chronic gastritis from other causes, and a concurrent infective process elsewhere in the body. The clinical features of phlegmonous gastritis have been reviewed by Starr and Wilson (1957) and by Smith, Garrett, and Herrick (1962) and include epigastric pain, vomiting, high fever, tachycardia, and leucocytosis. Males are affected three times more often than females and 80 per cent of cases occur between 30 and 60 years of age. In the diffuse variety toxaemia and general peritonitis rapidly supervene. Starr and Wilson (1957) classified the disease as chronic if the history revealed a prolonged illness of more than a few weeks' duration and there was an absence of fever or leucocytosis.

Difficulty in making a preoperative diagnosis in this condition and the rapid progress of the disease usually preclude orthodox investigations of the upper alimentary tract. However, it would appear that on some occasions the diagnosis has been made by plain radiographs which may demonstrate submucosal gas (Weens, 1946; Welch and Jones, 1947), and on others by gastroscopy (Mouter, Corent, and Wolfsohn, 1949).

The clinical, operative, and histological findings in the present case suggest that the condition observed was acute localized phlegmonous gastritis with an abscess of the pyloric antrum. The diagnosis was not made before operation and it is of interest that the finding of a persisting tender epigastric mass was the feature which prompted surgery. Unusually, the patient was afebrile and showed none of the features of toxaemia. While nothing is known of her gastric secretory function before surgery, the finding of an acid response to a maximal dose of pentagastrin in the postoperative period confirmed that she was not achlorhydric.

The correct treatment for this condition has been debated over the years. The mortality rate for the disease was reported by Eliason and Murray-Wright (1938) as 84 per cent. These authors suggested treatment by gastrostomy and transmucosal drainage of the abscess. Cutler and Harrison (1940) and Millar and Nushan (1952) recommended a conservative policy. However, Starr and Wilson (1957), reviewing 25 cases reported in the period 1947–57, found a mortality rate of 48 per cent. Ten deaths occurred among 15 patients who were treated conservatively, whereas 6 of 8 patients who had undergone gastric resection survived. More recently, Smith, Garrett, and Herrick (1962) have reported 2 further survivors following partial and total gastric resection, and both remained symptom-free at 5 years after operation. It would appear, therefore, that where the diagnosis is made, resection of the involved area of stomach offers the best choice of therapy for acute phlegmonous gastritis, and that subtotal

MORTALITY IN MISSILE WOUNDS OF THE HEAD

By ADELOLA ADELOYE

NEUROSURGERY UNIT, DEPARTMENT OF SURGERY, UNIVERSITY OF IBADAN, IBADAN, NIGERIA

SUMMARY

In a series of 250 patients with missile wounds of the head treated at the University College Hospital, Ibadan, Nigeria, 35 died after admission, a mortality of 14 per cent. Forty-three per cent of the deaths occurred within a week of wounding and were predominantly due to severe anatomical damage; among the 34 per cent who died at least 4 weeks after wounding there was evidence of intracranial infection. Surgical operation did not improve the outcome in the group with severe anatomical damage. A serious disturbance of the level of consciousness on admission, namely coma, was a bad prognostic sign.

DURING the First and Second World Wars it was estimated that 40–50 per cent of deaths from war wounds were due to missile injuries of the head (Olivecrona, 1940; Campbell, Kuhlenbeck, Cavenaugh, and Nielsen, 1958). In Nigeria between 1964 and 1970, during part of which period a civil war was being fought, 250 patients with missile injuries of the head were admitted to the Neurosurgery Unit of the University College Hospital, Ibadan, Nigeria. Thirty-five of these 250 patients died after arrival at hospital, a mortality of 14 per cent. The purpose of the present paper is to record our observations on the characteristic features of this group of fatal cases and to examine some of the factors noted which could influence the mortality rate in missile wounds of the head.

MATERIALS AND METHODS

The 250 patients included in this series were all Nigerians. Three civilians were admitted before July, 1967, after which period, as a result of the outbreak of civil war, the admissions were mostly soldiers. During the war, 15 other civilians were admitted who either had been injured in combat areas or had accidentally been shot in the head by game guns during hunting.

The soldiers either were referred to University College Hospital, Ibadan, from the military hospitals to which they had first been evacuated from the war front or were admitted directly to University College Hospital from the Army Medical Reception Stations close to the war front. The journey from these stations often spanned several days; rarely it took just over 24 hours on the few occasions when wounded soldiers were air-lifted to Ibadan. Civilians were admitted to hospital much sooner after sustaining an injury than soldiers. Similarly, some civilians were referred from other hospitals, and the rest were admitted directly without passing through a peripheral hospital.

The surgical management of these patients has been outlined elsewhere (Adeloye and Odeku, 1970). The wounds were thoroughly débrided under general anaesthesia. Scalp wounds were excised, and where the missile was lodged in the subgaleal space the skull was usually trephined in search of associated intracranial damage. The dura was opened in all cases of tangential skull injuries, and in all instances where the brain had been penetrated, in-driven bone fragments, haematomata, and accessible missiles and metallic fragments along the wound track were removed. Postoperatively, penicillin, streptomycin, and sulphadiazine were given routinely for about a week; pain was controlled with acetylsalicylic acid; phenytoin sodium and phenobarbitone were administered prophylactically.

Swabs for bacteriological studies were obtained from wounds in which infection was suspected. There was, however, the difficulty of distinguishing with the naked eye between necrosis and infection of the brain. Only 3 of the fatal cases were subjected to necropsy owing to the military regulations which prevailed during the civil war.

CLINICAL FINDINGS

The 35 patients who died were all soldiers. They were all males with ages ranging from 19 to 30 years, except for 1 female of 16 years who was described as a 'soldier in the rebel army'.

The *time interval* between injury and arrival at University College Hospital in the whole series of 250 patients was on average 13 days. For the 35 fatal cases this time interval varied from 1 day to 28 days, with an average duration of 4·7 days. Twenty-four of these fatal cases were admitted within 1 week of sustaining their head injuries, 50 per cent of the 24 arriving 1 day after injury. Five were admitted during the second week, and the rest were admitted to hospital 3–4 weeks after their injuries.

Missile Type.—In the whole group of 250 patients, 140 injuries resulted from bullets, 102 were due to metallic fragments dispersed from bombs, mines, and hand grenades, and in 8 instances the nature of the offending missile was not specified. Twenty-two (15·7 per cent) of the bullet wounds, 10 (9·9 per cent) of the injuries caused by metallic fragments, and 3 wounds in which the missile type was undefined were all fatal.

Type of Head Wounds.—No death was recorded among the patients who sustained scalp injuries alone. On the other hand, the mortality was greatest among the patients with through-and-through brain wounds in which the brain damage was maximal. The tangential skull wounds were slightly more lethal than the penetrating brain wounds (*Table I*). It is pertinent to observe that most of the tangential wounds were inflicted by bullets, which caused more fatality than metallic fragments in this series.

Anatomical Loci of the Wounds.—Head wounds in which relatively large areas of the brain suffered damage were the most lethal. These included the through-and-through brain wounds especially, and the extensive tangential and penetrating wounds which involved more than one anatomical region of the head. It would appear from *Table II* that isolated wounds of the front of the head—the frontal and the orbitocranial wounds—carried the least mortality.

Table I.—TYPE OF HEAD WOUNDS

TYPE OF WOUND	TOTAL NO. OF CASES	MISSILE TYPE		NO. OF DEATHS			MORTALITY (per cent)
		Bullets	Metallic Fragments	Operation performed	No Operation	Total	
Scalp wounds alone	25	14	11	—	—	—	0
Tangential skull wounds	92	70	22	11	2	13	14·1
Penetrating brain wounds	104	46	59	10	3	13	12·5
Through-and-through brain wounds	15	10	5	3	2	5	33·3
Unspecified	14	—	5	2	2	4	28·5
Total	250	140	102	26	9	35	14

Respiratory distress	5
Grunting respiration	
Stertorous breathing	
Cheyne-Stokes respiration	
Fever	5
Pneumonia	3
Generalized convulsions	3
Pallor	2
Bilateral conjunctivitis	2
Chemosis	1
Foul-smell	1
Bleeding mouth	1

General Condition of the 35 Fatal Cases on Admission.—The general physical signs exhibited by these patients on admission are shown in *Table III.* The starvation and the relatively immobile decubitus of the patients during the several days intervening between injury and arrival at University College Hospital would account for the respiratory manifestations which were commonly encountered. The respiratory distress consisted of grunting or stertorous respiration, and in 1 instance, Cheyne–Stokes respiration was observed. Two of the 3 patients with convulsions were admitted the day after injury; 1 of them died in status epilepticus a few hours after admission.

None of the patients had peripheral circulatory failure, the blood-pressures ranging from 110/70 to 160/110 mm Hg.

Level of Consciousness of the 35 Fatal Cases on Admission.—The patients were allocated into one of five categories of level of consciousness, ranging from the comatose to the fully conscious, depending on their response to verbal call or command and to the application of painful stimuli.

The patient was *comatose* when there was no response at all to any form of stimulation; *stuporose* when he responded to painful stimulation but only in an inappropriate manner; *drowsy* when he responded correctly to painful stimulation by withdrawing the appropriate part of the body which was stimulated, and, where the language barrier could be broken, he responded to a call or a command. The drowsy patient lapsed into somnolence on cessation of these stimuli. The *confused* patient was abusive or wanted to be left alone during the course of physical examination. He was intermittently restless and disorientated.

On admission, 14 patients were comatose, 5 were stuporose, 6 were drowsy, and 6 were confused. The remaining 4 patients, who were fully conscious on admission and were thus able to relate their own stories, gave a history of post-traumatic amnesia varying from 3 hours to 4 days.

Those patients with severe disturbance of consciousness were admitted sooner than the rest. Thus, the patients admitted in coma or in stupor were all admitted within 1 week of sustaining their head injuries: 12 were admitted 1 day after injury, 3 were admitted on the second day, and 1 each arrived on the third, fourth, and sixth days respectively after sustaining their head wounds. The only exception was a comatose patient who arrived 8 days after injury.

Neurological deficits were described in 24 of these patients. These consisted of hemiparesis or hemiplegia (18) with facial palsy of an upper motor neuron type (6), paraplegia with bilateral extensor plantar response (4), and paraplegia with paresis of one arm (2).

Neck stiffness was elicited in 11 patients.

Associated Wounds.—In the entire series of 250 patients, missile wounds in other parts of the body besides those of the head were encountered in 53 patients, an incidence of 21 per cent. Among the 35 fatal cases only 3 (8·6 per cent) had associated wounds, none of which was serious enough to threaten life. These comprised a penetrating wound of the hand with fractured metacarpals, facial lacerations, and a right clavicular fracture.

EFFECTS OF SURGICAL TREATMENT ON SURVIVAL

Nine of the 35 fatal cases died before any operative treatment was undertaken. The rest had neurosurgical débridement of their wounds at University College Hospital. In 5 of the latter group some inadequate surgical procedures had been carried out by doctors at the war front who had sutured the scalp wounds in every patient except 1, who, in addition, had had a limited débridement of his intracranial wound at a military hospital before referral to University College Hospital.

Time of Operation at University College Hospital.—Fifteen of the fatal cases had their operation within 1 week of injury, 4 were operated on in the second week, 4 in the third week, 2 in the fourth week, and 1 in the fifth week.

Table IV.—Time of Death after Operation

Time of Death after Operation	*No. of Patients*
Within 1 week	12
1–2 weeks	1
2–3 weeks	—
3–4 weeks	5
After 4 weeks	8
Total	26

Time of Death after Operation.—In the entire series, 192 patients were treated neurosurgically. Of these, 26 died, an operative mortality of 13·5 per cent. Twelve (46 per cent) of those who had an operation survived for 3 hours to 7 days (*Table IV*). All these had severe *anatomical damage*, and none had established overt intracranial infection. However, in 1 patient from whom an intracerebellar bullet was removed 10 days after sustaining a penetrating brain wound, a pocket of pus was encountered around the bullet. In another who was admitted 3 days after his injury, maggots were found at the bottom of his wound. Three of the 12 patients had generalized convulsions before operation. These fits occurred 24 hours, 2 days, and 3 days respectively after injury. In none of the 12 patients was there any improvement in the level of consciousness after operation.

Among those who survived for more than 3 weeks, *infection* was the main cause of death. In the 5 patients who survived for 3–4 weeks after operation there was heavy infection of the wounds, which suppurated and yielded a mixed bacteriological growth. After the third postoperative week, the longer the survival, the more extensive was the infection, which could involve every compartment of the intracranial chamber as well as the subgaleal space extracranially. The organisms obtained on bacteriological studies were *Pseudomonas pyocyaneus*, *Staphylococcus pyogenes*, and *Proteus vulgaris* (each occurred three times), and infection with coliforms was encountered on two occasions. In the patients with intracranial infection the tendency was for the level of consciousness to improve postoperatively, and when these patients developed convulsions, they occurred late.

TIME INTERVAL BETWEEN INJURY AND DEATH

Most of the deaths (43 per cent) occurred during the first week after injury. Another peak incidence of mortality (34 per cent) was recorded 4 weeks after sustaining head injury (*Table V*). The deaths in the first week were due to neuronal (anatomical) damage, and those occurring later were predominantly due to overwhelming intracranial suppuration. Between these two peak periods, death resulted from a combination of anatomical damage and intracranial infection.

Table V.—Interval between Injury and Death

Time of Death after Injury	No Operation	Operation performed	Total No. of Deaths	Incidence (per cent)
Within 1 week	8	7	15	43
1–2 weeks	1	4	5	14
2–3 weeks	—	1	1	3
3–4 weeks	—	2	2	6
After 4 weeks	—	12	12	34
Total	9	26	35	100

Nine patients died without operation. All of them were admitted to hospital either in coma or in stupor, and died within 1 week of injury, except for 1 patient who arrived 6 days after sustaining his head wound and died 3 days after admission. There was no evidence of overt infection in these patients, and severe anatomical damage seemed the probable cause of death. This was confirmed at autopsy in 2 patients.

One unique cause of death was severe erythema multiforme (Stevens–Johnson's syndrome) which occurred in 1 patient who died 47 days after sustaining his head injury and 38 days after operation. This patient had a course of penicillin, streptomycin, and sulphadiazine for a week immediately after his operation, and he also had phenytoin sodium and phenobarbitone continuously postoperatively. The patient was only on these anticonvulsants when he developed his fatal erythema multiforme.

All the deaths occurred during the first admissions of the patients, except in 2 patients who died of brain abscesses. These 2 patients were readmitted 4 and 6 weeks after they had left hospital respectively; both were in stupor, with nuchal rigidity, fever, and Jacksonian epileptic fits. Intracranial suppuration was suspected clinically and they both died shortly after admission. Autopsy confirmed the presence of intracerebral abscesses.

DISCUSSION

The reported mortality in battle casualties from head wounds has varied according to the type of case studied. Acutin (1940), from examinations of the dead, estimated that 30–40 per cent of men with head wounds in the Finnish campaign died on the battlefield, and among those evacuated the mortality was 27 per cent. On the other hand, fatality rates for cases who reached base or forward hospitals have been much less and have variously been reported at 10·9 per cent (Gaynor and Gruwitz, 1945), 13·2 per cent (Jefferson, 1919), 13·9 per cent (Pilcher and Angelucci, 1942), 15·9 per cent (Terian, 1943), and 17 per cent (Munslow, 1946). The variability in mortality figures is hardly surprising since it reflects the type of cases selected for referral to these hospitals, the timing and type of the initial and the definitive surgical treament, and the nature of the aftercare of the wounds.

In general, certain factors, a number of which have been exemplified by this series, have a bearing on the survival of patients with missile wounds of the head. Rifle bullets were more deadly than bullets from civilian game guns and small metallic fragments dispersed from grenades, bombs, and mines. These rifle bullets travel at a greater velocity than both shrapnel and the relatively low-velocity missiles encountered in civilian practice, and thus cause more extensive tissue damage (Raimondi and Samuelson, 1970). The surprisingly low figure recorded by Wolf (1940) of 10 deaths out of 343 craniocerebral wounds subjected to surgery during the First World War was probably because 80 per cent of these wounds were caused by splinters from grenades, bombs, and mines, and only 20 per cent were due to rifle bullets.

Frontal wounds seemed to be less dangerous than wounds in other parts of the cranium. Cushing (1918) observed that occipital cases tended to do less well after operation than frontal ones. Despite the mental disturbance which he noted in patients with frontal wounds, as far as survival was conerned, 'they have usually done well'. Among the casualties with penetrating brain wounds sustained during the bombing of Hawaii in 1941, Cloward (1942) described patients with large gaping frontal wounds oozing brain matter who were found to be conscious, rational, and co-operative. Schorstein (1944) reported only 1 death out of 8 patients with orbitofrontal gunshot wounds who were treated with débridement and in 3 cases with fascia lata graft of the dura.

The freedom of simple scalp wounds from fatality is generally and universally recognized (Cushing, 1918; Horrax, 1919; Jefferson, 1919). In the other categories of head wounds there is a progressive increase in the mortality-rates with increase in the extent and severity of the brain damage sustained. Horrax (1919) reported the lowest mortality of 5·8 per cent among patients with tangential skull injury without dural laceration, and the highest mortality of 80 per cent in through-and-through brain wounds in which large areas of the brain had suffered damage. In tangential skull wounds with lacerated dura the shattered bone fragments are driven intracranially, lacerating blood-vessels and brain tissue over a much wider area than the size of the gutter of the scalp wound would lead one to suspect. In this respect, tangential skull wounds are more dangerous than the penetrating brain wounds in which the missile carves out a neater and narrower path in the brain before coming to rest. Jefferson (1919) reported a mortality of 41·1 per cent in tangential skull wounds with in-driven bone fragments, and 34·8 per cent in penetrating brain wounds; in the latter category when the ventricle was penetrated the mortality rose to 75 per cent, the same incidence as Jefferson (1919) reported for through-and-through brain wounds. These various observations were confirmed in our series.

Missile wounds occurring elsewhere in the body in association with head injuries and other concomitant diseases such as pneumonia or gas gangrene were found to be contributory to death in most series (Cushing, 1918; Horrax, 1919; Gaynor and Gruwitz, 1945; Ascroft, 1947). Indeed, Ascroft (1947) recorded associated wounds in 33 per cent of fatal cases as opposed to the 20 per cent incidence in survivors. On the other hand, in our series, as in that of Jefferson (1919), no death was attributable to severe associated missile wounds.

Two clinical physical signs of grave prognostic significance which have been noted in patients with missile wounds of the head are rise in temperature and coma on admission. Pilcher and Angelucci (1942) found that a rise of temperature above 103° F. (39° C.) was an ominous sign. Cushing (1918) observed during the First World War that 5 out of every 6 patients admitted in coma or stupor died, whereas only 1 out of every 21 patients who were conscious on admission and capable of giving a history died. The importance of coma as a grave prognostic sign was again emphasized during the Second World War by Miller (1942) and Eden (1943) in connexion with high mortality from missile wounds of the head during the North African campaign.

There is hardly any controversy about the role of anatomical or neuronal damage and of intracranial infection and haemorrhage in the causation of death in missile wounds of the head. Prior (1944), a pathologist working in a hospital near the front line, performed post-mortem examinations on soldiers who had died on the battlefield. He found that the injury was usually gross in cases who had died from skull wounds; where the injury was of lesser degree, death was from intracranial suppuration or intracranial haemorrhage. As to the temporal relationship of these factors, neuronal damage and intracranial haemorrhage were the main causes of mortality in the first few days, with haemorrhage being particularly important in the first 24 hours. After 5 days, sepsis began to become important, with progressive increase in incidence with the passage of days. Where the period of time between injury and admission to hospital was long, infection was more prevalent than the other causes of death (Jefferson, 1919). In a series of fatal head wounds described by Ascroft (1947) the causes of death were neuronal damage (41 per cent), intracranial sepsis (40 per cent), intracranial haematoma (13 per cent), and others (6 per cent).

One of the problems of attributing the cause of death to intracranial haematoma is that of defining what constitutes significant haematoma. Small and Turner (1947) noted that a small haematoma was such a common finding along the missile track that one would expect it in penetrating wounds. Similarly, Gillingham (1947) observed that it was rare to find any large intracranial clot either at operation or at autopsy. Schorstein (1947), in the North African and Italian campaigns, found that only 83 of 2000 patients (4·2 per cent) had intracranial haematoma. At the other extreme, Lewin and Gibson (1956) reported the unusually high incidence of 46 per cent for intracranial haematoma among British casualties in the Korean war. Where it was found, the incidence of intracranial haematoma increased with earlier hospital care (Barnett and Meirowsky, 1955). The fact that we did not find intracranial haemorrhage to be an important cause of death in the present series was presumably because such patients died almost immediately after injury and failed to reach hospital, and also because of the incomplete autopsy examination of those who died after admission.

It is important to know what role surgical treatment can play in reducing mortality in missile injuries of the head. Although early surgery is desirable in these patients (Guleke, 1941), it has been shown that the time interval between injury and surgical treatment is less important to ultimate survival than meticulous specialized care in the investigation, operation, and after-treatment of the patients (Cairns, 1940; Terian, 1943). Since these patients travel well prior to surgery (Ascroft, 1943; Money and Nelson, 1943; Gaynor and Gruwitz, 1945), in the absence of adequate surgical facilities, further evacuation is preferable to incomplete 'débridement' (Campbell, 1945). When a large number of these patients have to be dealt with there may be difficulty in selecting those who would benefit most from the available surgical care. Miller (1942) and Eden (1943), realizing that coma was a bad prognostic sign, preferred to leave aside the deeply unconscious patient and they operated on the more promising ones in whom it was important to prevent the development of intracranial infection, the other important cause of mortality besides severe anatomical damage. Pilcher and Angelucci (1942) found that in 61·5 per cent of the fatal cases in their series, death occurred within 24 hours of injury, and they thought it unlikely that the lives of these patients could have been saved by any therapeutic procedure. At University College Hospital, Ibadan, where we operated on all those who could stand the procedure, patients with severe brain damage who came in comatose or stuporose did not benefit from débridement, on the whole. Yet despite these observations, in peace or in war it is never absolutely right to abandon comatose patients with head wounds to their fate, for it is known that the poorest cases on admission sometimes do surprisingly well later. In addition, Campbell and others (1958), who set out in a study of 24 fatal missile wounds of the head to establish the clinical criteria of mortal brain wounds, were unable to indicate which wounds were apt to be definitely fatal and therefore better left alone.

COMPARATIVE EVALUATION OF PREOPERATIVE AND OPERATIVE RADIOLOGY IN BILIARY-TRACT DISEASE

By D. J. GRUNDY,* P. A. KING, AND G. LLOYD†

CHELSEA AND KENSINGTON GROUP, ST. MARY ABBOTS HOSPITAL, LONDON

SUMMARY

In 100 consecutive patients with an abnormal cholecystogram a study was carried out to compare the value of the 4-day Telepaque test, intravenous cholangiography, and operative cholangiography. Of the 100 patients, 87 were shown at operation to have stones in the gall-bladder and 22 to have stones in the common bile-duct. In 4 of the latter patients, stones were absent from the gall-bladder.

Operative cholangiography was the most accurate investigation in the diagnosis of a stone in the common duct; the operative cholangiogram gave definite evidence of stones in the duct in 20 of the patients, and was abnormal in some respect in all of the patients with a stone in the common duct. It is concluded that this investigation should be performed on all patients undergoing cholecystectomy.

The 4-day Telepaque test demonstrated stones in the gall-bladder in 30 per cent of the patients with a non-functioning gall-bladder on oral cholecystography, thus materially improving the diagnosis of gall-bladder stones preoperatively. Of duct stones, however, only 32 per cent were shown by the 4-day Telepaque test, and 59 per cent were demonstrated by intravenous cholangiography. In view of the risk associated with Biligrafin, and to a lesser extent with large doses of Telepaque, it is concluded that neither of these tests is desirable prior to cholecystectomy in

the good-risk patient, provided that a satisfactory technique of operative cholangiography is used. They should be reserved for the poor-risk patient, when the presence or absence of duct stones may influence the decision to operate.

THE importance of radiological assessment of the bile-ducts as well as the gall-bladder prior to cholecystectomy is well recognized. In recent years interest has been centred on methods of decreasing the percentage of residual stones and on avoiding unnecessary exploration of the common bile-duct. The incidence of residual stones in the bile-duct after cholecystectomy without operative cholangiography varies in different series, from 2 per cent (Colcock and Liddle, 1958) to 20 per cent (Hicken, McAllister, and Call, 1954). The average incidence is probably 5 per cent (Le Quesne, 1960). Operative cholangiography diminishes the residual stone rate from 5 to 0·4 per cent (Ferguson and Estes, 1967), whilst providing criteria for exploration of the common bile-duct.

Two methods of demonstrating stones in the bile-ducts preoperatively were developed in the 1950's, namely, intravenous cholangiography using Biligrafin (Frommhold, 1953), and the 4-day Telepaque test, as described by Salzman and Warden (1958) and Salzman, Spurck, Kier, and Watkins (1959).

The present paper describes a prospective study which was undertaken in order to evaluate each of these techniques, individually and together, in the diagnosis of stones in the gall-bladder and bile-ducts.

MATERIALS AND METHODS

The study was performed on 100 consecutive patients with an abnormal cholecystogram demonstrated in the course of investigation for suspected gall-stones. A cholecystectomy was performed in all of these patients. No patient was jaundiced at the time of operation. There were 28 males and 72 females in the series, with ages ranging from 23 to 81 years, and with an average age of 52 years. Stones were present in the gall-bladder and/or the common bile-duct in 91 per cent.

The cholecystogram was considered to be abnormal if it fell into one of the following categories:—

1. Unequivocal evidence of stones in the gall-bladder.
2. A 'non-functioning' gall-bladder, i.e., no opacification on an examination which was repeated on the following day.
3. A 'poorly functioning' gall-bladder, i.e., poor opacification on an examination repeated on the following day.

After the initial cholecystographic examination the following investigations were performed on all the patients: a 4-day Telepaque test, an intravenous cholangiogram with tomography, and an operative cholangiogram.

Cholecystogram.—A standard technique was employed, using 3 g. of Telepaque (iopanoic acid). In the absence of adequate opacification the examination was repeated the following day after a second dose of Telepaque.

4-Day Telepaque Test.—Telepaque (1 g.) was given three times a day for 4 days, during which time the patient took a relatively fat-free diet. On the morning of the fifth day a film was taken of the gall-bladder area, the patient having fasted overnight.

Intravenous Cholangiogram.—A film was taken 20 minutes after an intravenous injection of 20 ml. of Biligrafin forte (iodipamide methylglucamine), and tomograms were obtained 30 minutes to 1 hour after injection, when optimal filling of the ducts was to be expected.

Operative Cholangiogram.—The patient, on an Eric Samuel tunnel, was tilted 15° to the right to deflect the image of the common bile-duct from that of the vertebral column. After careful digital and visual examination of the biliary tract, the cystic duct was cannulated using a transparent polythene catheter (size PE 205) filled with saline and connected to a syringe by a pyelostomy nozzle with a tap. Introduction of air-bubbles was prevented by initial aspiration of bile into the syringe. Three successive films were taken using the pull-through technique described by Samuel (1959) after the injection of water-soluble contrast medium (45 per cent Hypaque or 60 per cent Urografin). The first injection was of small volume in order to demonstrate the normally narrow terminal segment of the common bile-duct and to avoid obscuring stones in this region by intraduodenal contrast. The gall-bladder was removed whilst the films were being developed. The latter were studied by the surgeon, the criteria for exploration of the common bile-duct being as follows:—

1. Filling defects in the ducts.
2. Dilatation of the common bile-duct (diameter greater than 11 mm.).
3. Failure of contrast to flow into the duodenum on the second film.

Postoperative T-tube Cholangiogram.—A T-tube was inserted after exploration of the common bile-duct, and a cholangiogram was carried out through this on the tenth to twelfth postoperative days.

RESULTS

Operation showed that of the entire 100 patients, stones were found in the gall-bladder in 87. Stones were removed from the common bile-duct in 22; in 4 of these patients stones were absent from the gall-bladder. We have no reason to believe that any patient has developed residual stones.

Cholecystography demonstrated unequivocal evidence of stones in the gall-bladder in 50 patients (group A), a 'non-functioning' gall-bladder in 45 (group B), and a 'poorly functioning' gall-bladder in 5 (group C).

The 4-day Telepaque test confirmed the presence of stones in the gall-bladder in all 50 patients in group A, and in addition showed unequivocal evidence of stones in the gall-bladder in 15 of the 50 patients in groups B and C, including all 5 patients in group C; i.e., the test increased the positive diagnosis of stones in the gall-bladder by 30 per cent. In addition, in the whole series the Telepaque test demonstrated stones in the common bile-duct in 7 patients (*Fig.* 1).

The results of intravenous cholangiography are shown in *Table I*. The value of intravenous cholangiography in the diagnosis of stones in the gall-bladder could not be estimated as this investigation often immediately followed the 4-day Telepaque test, but there is no evidence that it was more effective than the 4-day Telepaque test alone. Stones were demonstrated in the common bile-duct in 14 patients, including all 7 who had been shown to have stones by the 4-day Telepaque test. These findings were verified at operation in 13 patients. Failure of Biligrafin to concentrate was noted in 2 patients: 1 patient who had recently been jaundiced and another who had a cholecystocolic fistula but with no history of ascending cholangitis. There was one major reaction to Biligrafin (immediate hypotension) and the number of unsatisfactory examinations was 7, including 2 patients who were subsequently found to have a stone in the duct.

Table I.—RESULTS OF INTRAVENOUS CHOLANGIOGRAPHY

Result	*No. of Cases*
Stones demonstrated in common bile-duct	14
Normal common bile-duct demonstrated	79
Major reaction to Biligrafin	1
Failure of Biligrafin to concentrate	2
Total No. of unsatisfactory Biligrafin examinations	7

Table II.—FINDINGS ON OPERATIVE CHOLANGIOGRAPHY

Finding	*No. of Cases*	
'Definite' stones in common bile-duct	22	(Stone found in 20)
Suggestion of stones in common bile-duct	4	Stone found in 2 Stenosis of ampulla in 1 No abnormality in 1
Dilated duct but no filling defect	4	Stenosis of ampulla in 1 No abnormality in 1 Duct not explored in 2
Unsatisfactory films	2	
Normal films	68	

Table III.—SUMMARY OF OPERATIVE FINDINGS

	PRESENT SERIES	LE QUESNE (1960)
No. of common bile-ducts explored	32 out of 100 (32 per cent)	34 out of 109 (31 per cent)
No. of common bile-ducts explored in which stones found	22 out of 32 (68 per cent)	21 out of 34 (62 per cent)

The operative cholangiogram was considered to show definite evidence of stones, i.e., a filling defect, often with other abnormalities, in 22 patients, including the 13 referred to above. Stones were found and removed in 20. In a further 8 patients the operative cholangiogram was considered abnormal—although showing no filling defect—and stones were found in 2 cases. The findings in these 8 patients are shown in *Table II*. Stones in the duct were palpated in 13 of the 22 patients who showed evidence of stones, and in 6 of the remaining 9 the operative cholangiogram demonstrated stones which had been unsuspected on either preoperative assessment or operative palpation. Flow of contrast into the duodenum on the first or second film was observed in 84 patients; stones were present in 15 of these. In the remaining 16 patients, in whom duodenal flow was not seen or was present only on the third film, stones were shown in 7. *Table III* shows that the percentage of bile-ducts explored (32) and the percentage with stones (22) were very similar to those of Le Quesne (1960). Of the 10 patients in whom stones were not found, 4 had a dilated common bile-duct, 2 had ampullary stenosis, 1 had gritty debris in the bile and a history of jaundice, and 1 had a thickened bile-duct. The operative cholangiogram erroneously suggested duct stones in the remaining 2 patients.

Postoperative T-tube Cholangiogram.—This did not reveal any residual stones, and no patient has subsequently been seen with a stone over periods ranging from 2 to 8 years.

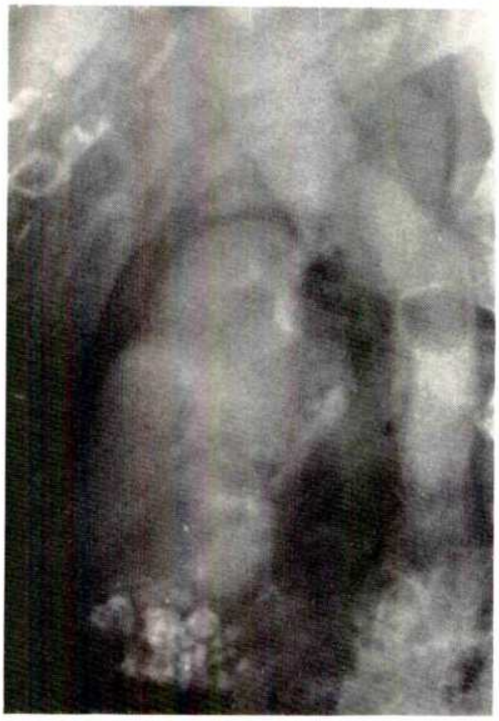

FIG. 1.—The 4-day Telepaque test, showing radiolucent and radio-opaque stones in the gall-bladder, and radiolucent stones rimmed by contrast in a dilated common bile-duct. The cholecystogram merely demonstrated the radio-opaque stones and a 'non-functioning' gall-bladder.

Deaths.—There were 2 deaths in the series. One was an 81-year-old woman who had had many stones removed from the common bile-duct and who died 8 days postoperatively with a diagnosis of cerebrovascular accident. The other was a 68-year-old woman who died suddenly 15 days postoperatively with a diagnosis of pulmonary embolism, autopsy being refused.

DISCUSSION

The original work on excretion cholecystography was done by Graham and Cole in 1924. Telepaque was introduced in 1951 by Dunne, Jensen, and Hughes, and Biligrafin in 1953 by Frommhold. Operative cholangiography was described in 1931 by Mirizzi, but our technique and interpretation are based on the work of Le Quesne (1960).

Cholecystography is widely accepted as a safe and accurate investigation in the diagnosis of stones in the gall-bladder. This is borne out by the present series. There was positive evidence of stones in 50 patients. In the remainder of the patients the diagnosis was based on an inability to demonstrate contrast medium in the gall-bladder. This study confirms that the repeated failure to demonstrate the gall-bladder on cholecystography is reliable evidence of the presence of gall-bladder pathology, but it also shows that in many such patients definite positive evidence of stones is provided by a 4-day Telepaque test. In this study the latter test was the most successful in providing conclusive evidence of stones in the gall-bladder. If definite evidence of the presence of stones is required before advising cholecystectomy, the 4-day Telepaque test will give such information in some 30 per cent of patients with a so-called 'non-functioning' gall-bladder. The test is safe, provided that there is no serious impairment of hepatic function (Teplick, Myerson, and Sanen, 1965). However, Canales, Smith, Robinson, Remmers, and Sarles (1969) have since described 4 cases of renal failure due to large doses of Telepaque in patients with no clinical or laboratory evidence of hepatic dysfunction. Telepaque causes nausea in 14–18 per cent of patients, and diarrhoea, usually mild, in 38 per cent (Healey and Grainger, 1965). We did not find these reactions a serious problem.

Turning to the diagnosis of stones in the common bile-duct, the 4-day Telepaque test was disappointing in that it only demonstrated stones in 7 (32 per cent) out of 22 patients with such stones, and, furthermore, in all these 7 patients the stones were demonstrated by intravenous cholangiography. From the literature (Salzman and others, 1959) and the present series it is clear that occasionally the 4-day Telepaque test will outline a common-duct stone in a patient in whom it either cannot be demonstrated by intravenous cholangiography or in whom it is less well shown by this means.

Intravenous cholangiography demonstrated stones in the common bile-duct in slightly over half (59 per cent) of the patients in whom they were present, but major reactions with hypotension and renal failure have been described in patients with diminished hepatic function (Craft and Swales, 1967), and Ansell (1970) has quoted a mortality of 1 in 5000. The investigation is time-consuming for the radiography department, and if tomography is performed it involves a considerable number of films, but its usefulness is apparent in the elderly or poor-risk patients when the presence or absence of stones may influence the decision to operate. There is little point in performing an intravenous cholangiogram if this decision has already been taken.

In view of the evidence which has since come to light concerning the toxicity of Biligrafin and Telepaque, it follows that the combined techique of a 4-day Telepaque test followed by an intravenous cholangiogram would not be recommended in any patient in the future.

It is clear from the present study, as shown by other workers previously (Le Quesne, 1960; Ferguson and Estes, 1967), that operative cholangiography is undoubtedly the best method of demonstrating stones in the common bile-duct. In our series the operative cholangiogram was interpreted as showing stones in 22 patients, and stones were removed in 20, which represents an accuracy rate of 92 per cent. It is, of course, possible that stones were present in the duct of some of the patients in whom the cholangiogram was considered to be normal. This is unlikely, as the criteria of normality of the operative cholangiogram were essentially the same as those of Chapman, Curry, and Le Quesne (1964), who showed that a normal operative cholangiogram can be relied on with confidence as indicating a stone-free duct. In our opinion this examination should be used routinely, for not only does this make for speed and efficiency in the procedure but it may reveal totally unexpected stones. It is a completely safe examination, but does require the services of a radiographer in theatre for about half an hour. We did not perform post-exploratory cholangiography, partly because of the difficulty in excluding air-bubbles. Elimination of this procedure seems justified by the absence of residual stones on subsequent T-tube cholangiograms.

Immediately available on request
the up-to-date manual on **Thrombolytic Therapy**

This manual describes how highly purified streptokinase (Kabikinase), potentiates the body's natural ability to dissolve thrombi.

It discusses the respective roles of thrombolysis and anticoagulation, and defines the place for Kabikinase Thrombolytic Therapy in :

venous thrombosis "... 30 per cent of ill medical and surgical patients develop thrombi. . . ." There are comments on clinical detection, diagnostic procedures and sequelae ;

pulmonary embolism "... the cause of death of 1 in 200 hospital admissions." The "at risk" patient is identified ;

acute arterial thromboembolism – the results of thrombolysis are discussed ;

chronic arterial occlusive disease – recent work is described.

Reference is made also to :

Thrombolysis for coronary thrombosis, clotted haemodialysis shunts, occlusion of retinal vessels, meningitis and ventriculitis.

Early treatment of deep vein thrombosis preserves valvular function and should avert the post-phlebitic leg.

Medical embolectomy for pulmonary embolism is now the first line of attack.

Thrombolytic therapy is facilitated by the Kabikinase Standard Dosage Scheme.

MEDIASTINOSCOPY

AN ANALYSIS OF 320 CONSECUTIVE CASES

By J. GUNSTENSEN and J. D. WADE

DEPARTMENT OF THORACIC SURGERY, ROYAL INFIRMARY, EDINBURGH

SUMMARY

Three hundred and twenty consecutive cases of mediastinoscopy are analysed.

1. Mediastinoscopy is a safe procedure and causes little disturbance to the patient.
2. The preoperative assessment of patients with presumably resectable bronchial carcinoma was the main indication for mediastinoscopy, and its use was associated with a fall in the non-resectability rate at thoracotomy from 28 to 15 per cent over two 3-year periods.
3. The policy of exclusion from exploratory thoracotomy of patients with bronchial carcinoma and mediastinal lymph-node metastases is discussed in relation to the histological nature of the lesion and the site and extent of the mediastinal node involvement.
4. It is concluded that there is a case for offering resection to selected patients with limited mediastinal node invasion from bronchial carcinoma.
5. The value of mediastinoscopy as a diagnostic procedure for mediastinal and pulmonary hilar masses and for undiagnosed pulmonary opacities is shown.

MEDIASTINAL lymph-node metastases and invasive growth of the mediastinum are the commonest causes of failure to carry out resection at thoracotomy for bronchial carcinoma (Reynders, 1964). Daniels (1949) had introduced routine scalene-node biopsy in the preoperative investigation of bronchogenic carcinoma in order to spare some patients the risk and discomfort of an exploratory thoracotomy. Harken, Black, Clauss, and Farrand (1954) extended the scope of the investigation by unilateral exploration of the superior mediastinum through a supraclavicular incision. Radner (1955) suggested a method of digital exploration of both sides of the upper mediastinum through a suprasternal incision, the same incision through which Carlens (1959) explored the superior mediastinum in immediate relationship to the front and sides of the trachea and proximal main bronchi, introducing the mediastinoscope (*Fig.* 1) which permitted specimens of the mediastinal tissues to be obtained under direct vision.

TECHNIQUE

The investigation is carried out under general anaesthesia with endotracheal intubation. The patient is supine with a pillow under the shoulders to extend the neck. Slight elevation of the upper half of the body relieves venous congestion. A 4-cm. transverse incision is made half-way between the laryngeal prominence and the upper border of the manubrium. The sternohyoid and sternothyroid muscles are separated in the midline, and the pretracheal fascia below the thyroid gland is incised to expose the trachea. With the finger the loose space between the pretracheal fascia and the front and sides of the trachea is opened up and the mediastinal structures are palpated; abnormal glands are assessed for hardness and mobility. Thereafter the Carlens mediastinoscope is introduced (*Fig.* 2), and with the aid of a suction dissector the subcarinal, the tracheobronchial, and the right and left paratracheal lymph-nodes, if present, are dissected and specimens are removed under direct vision. Bleeding is controlled by diathermy coagulation.

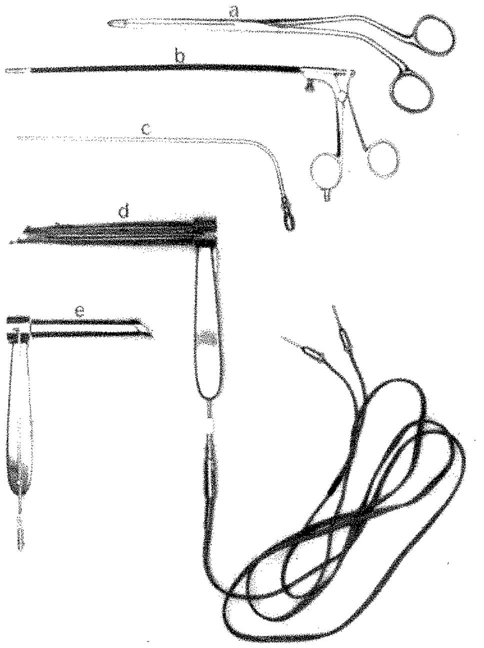

FIG. 1.—The Carlens mediastinoscope. a, Dissector. b, Biopsy forceps. c, Suction dissector. d, e, Adult and child mediastinoscopes.

INDICATIONS FOR MEDIASTINOSCOPY

Although mediastinoscopy was initially introduced as a means of detecting superior mediastinal node metastases of bronchial carcinoma, the indications for the procedure now fall into two main groups:—

1. Bronchogenic carcinoma: Mediastinoscopy is used for (*a*) the preoperative assessment of patients with presumably resectable carcinoma, and (*b*) the histological diagnosis of carcinoma in patients believed to have non-resectable tumours.

2. Intrathoracic disease other than bronchial carcinoma: Mediastinoscopy is used for the histological diagnosis of (*a*) mediastinal and pulmonary hilar masses, and (*b*) pulmonary lesions of unknown aetiology.

MATERIAL

During the 3-year-period 1968–70, 545 patients with bronchogenic carcinoma were seen at the Cardiothoracic Unit, Royal Infirmary, Edinburgh. One hundred and seventy-seven (32 per cent) of them were found to have presumably resectable tumours and they were all submitted to mediastinoscopy. The remaining 368 patients had accepted contra-indications to resection, such as positive scalene nodes, cerebral metastases, hepatic metastases, poor respiratory function, phrenic nerve paralysis, or vocal cord paralysis. Most patients over the age of 70 years with bronchial carcinoma have been considered unsuitable for resection even in the absence of a specific contra-indication. One hundred and three of the patients who were not considered for resection had mediastinoscopy in order to obtain histological confirmation of the diagnosis. The remaining patients were not subjected to mediastinoscopy because the histological diagnosis had been obtained by other means or because they were too ill for operative investigation.

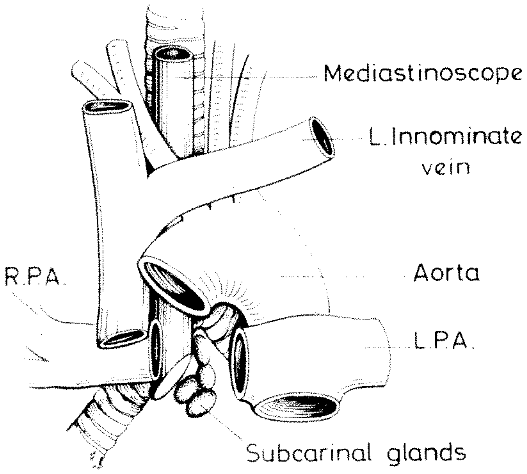

FIG. 2.—The mediastinoscope in position.

Forty-two patients with mediastinal masses or pulmonary lesions of unknown aetiology were investigated by mediastinoscopy.

RESULTS OF 320 CONSECUTIVE MEDIASTINOSCOPIES

Preoperative Assessment of Patients with Presumably Resectable Bronchial Carcinoma.—One hundred and seventy-seven patients fell into this group and 43 (24 per cent) of them were found to have mediastinal lymph-node metastases. *Fig.* 3 shows the distribution of glandular metastases for left- and right-sided lesions respectively.

Fourteen of the 82 patients with left-sided bronchial carcinoma had metastases in the mediastinal nodes. One patient with a lower lobe squamous carcinoma and metastases limited to the subcarinal lymph-nodes underwent exploratory thoracotomy, but the tumour was not resectable because of invasion of the descending thoracic aorta. The other 13 patients with positive mediastinal nodes were not submitted to thoracotomy. The 68 patients without mediastinal lymph-node metastases had exploratory thoracotomy. Resection was carried out in 59, and in 2 of these, subcarinal lymph-node metastases were found which might have been detected at mediastinoscopy. Nine patients had exploratory thoracotomy without resection. The reasons for not undertaking resection are shown in *Table I*.

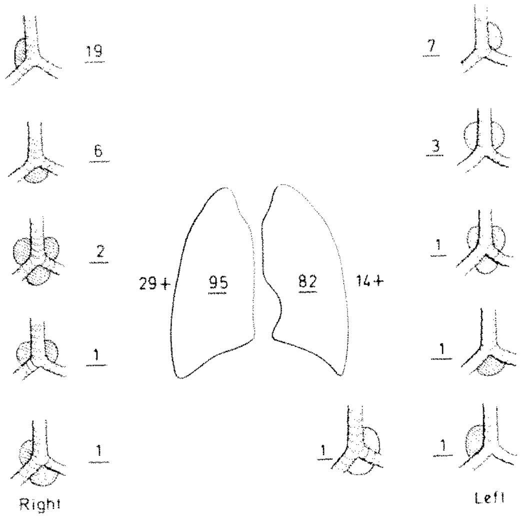

FIG. 3.—The distribution of mediastinal lymph-node metastases in 177 cases of presumably resectable bronchial carcinoma.

Table I.—CONTRA-INDICATIONS TO RESECTION IN BRONCHIAL CARCINOMA WITH NEGATIVE MEDIASTINOSCOPY

CONTRA-INDICATION	NO. OF CASES	
	Right Pulmonary Tumour	Left Pulmonary Tumour
Mediastinal lymph-node metastases	4	1
Pericardial invasion	3	3
Pleural metastases	1	2
Chest-wall invasion	1	—
Superior caval invasion	1	—
Respiratory function sufficient for lobectomy which had been planned, but too low to permit pneumonectomy which was necessary	—	2
Invasion of descending thoracic aorta	—	1
Total	10	9

Twenty-nine of the 95 patients with right-sided tumours were shown to have mediastinal lymph-node metastases. Two patients with well-differentiated squamous carcinoma in the right upper lobe and metastases only in the right paratracheal lymph-nodes were submitted to pneumonectomy, with clearance of all visible tumour. The remaining 27 patients with positive nodes did not have thoracotomy. The 66 patients without mediastinal node involvement underwent thoracotomy, and the tumour was resected in 56, 1 of whom was shown to have subcarinal node metastases. The reasons for not carrying out resection in 10 patients are shown in *Table I*.

The total number of thoracotomies carried out was 137 and resection was undertaken in all but 20 (15 per cent).

The Histological Diagnosis of Carcinoma in Patients believed to have Non-resectable Tumours.—Mediastinoscopy was carried out in 103 such patients and provided the only proof of the diagnosis in 33 (32 per cent).

Intrathoracic Disease other than Bronchial Carcinoma.—This group of patients had mediastinal masses of unknown aetiology or undiagnosed pulmonary opacities. A histological diagnosis was obtained in 20 of the 42 patients. The findings are summarized in *Table II*.

Table II.—HISTOLOGICAL DIAGNOSIS OF LESIONS OTHER THAN BRONCHIAL CARCINOMA

Diagnosis	*No. of Patients*
Mediastinal and hilar masses	
Sarcoidosis	8
Reticulosis	4
Neurofibroma of vagus nerve	1
Secondary testicular tumour	1
Total	14
Pulmonary lesions	
Tuberculosis	3
Alveolar cell carcinoma	1
Sarcoma	2
Non-specific inflammation	22
Total	28

COMPLICATIONS OF MEDIASTINOSCOPY

The incidence of complications was low: a total of 8 complications occurred in the 320 patients. One required thoracotomy to control bleeding from a tear in the left innominate vein. In another patient removal of tissue from a tumour mass in the right paratracheal region caused brisk haemorrhage from the superior vena cava. A blood-loss of 900 ml. occurred before the bleeding was controlled with a gauze pack in the mediastinum for 30 minutes. Minor pneumothorax was caused on two occasions when tissue was taken from the anthracotic right lung instead of the right paratracheal lymph-nodes. Left recurrent nerve palsy occurred on three occasions. Twice this was due to the diathermy which was used to control bleeding which followed dissection in the left paratracheal region, and on the third occasion a patient who developed vocal cord paralysis shortly after mediastinoscopy was shown at thoracotomy to have invasion of the lymph-nodes in relation to the left recurrent nerve at the aortic arch. There was one instance of tumour invasion of the suprasternal wound 3 months after mediastinoscopy in a patient with extensive neoplastic involvement of the mediastinum.

DISCUSSION

Mediastinoscopy is a safe procedure. Only two serious complications occurred in 320 consecutive investigations, although they were carried out by a number of clinicians of varying experience. A study of the 137 patients who underwent thoracotomy showed that involved glands were missed in 8 patients, in 5 of whom the glandular metastases precluded resection. In 2 of these 5 patients the glandular metastases were situated in front of the great vessels —an area not accessible at mediastinoscopy.

Table III.—COMPARISON OF THE MANAGEMENT OF PATIENTS WITH BRONCHIAL CARCINOMA SEEN AT THE CARDIOTHORACIC UNIT, ROYAL INFIRMARY, EDINBURGH, OVER TWO 3-YEAR PERIODS

	3-YEAR PERIOD 1964–6	3-YEAR PERIOD 1968–70
Total No. of patients with bronchial carcinoma	652	545
No. of patients with presumably resectable lesions	291 (44 per cent)	177 (32 per cent)
No. of patients excluded from thoracotomy because of positive mediastinoscopy	—	40
No. of patients undergoing resection	210	117
No. of patients undergoing only exploratory thoractomy	81	20
Non-resectability rate as a percentage of total thoracotomies	28	15
No. of resections frustrated because of mediastinal glandular metastases	30	5

The investigation is carried out under general anaesthesia immediately after bronchoscopy; the general disturbance is small and many patients have been discharged home the day afterwards with no untoward results. Use of frozen-section histology has permitted a decision on management to be made within a few hours of mediastinoscopy. Thoracotomy has usually been carried out within 48 hours, but on the occasions when operation was delayed for administrative or other reasons, oedema and hyperaemia of the mediastinal and hilar structures caused minor inconvenience.

The presence of mediastinal node metastases indicates a poor prognosis in patients with bronchial carcinoma and most authors regard it as a contra-indication to exploratory thoracotomy. Accepting this, with 3 exceptions which are discussed later, our own non-resectability rate at thoracotomy dropped from 28 per cent in the 3 years 1964–6 to 15 per cent in the years under review (*Table III*). A greater reduction in the non-resectability rate has been recorded by others: from 40 to 10 per cent (Reynders, 1964), and from 23 to 6 per cent (Pearson, 1968). An examination of the causes of failure to resect the tumour at thoracotomy showed that the presence of mediastinal glandular metastases was the main reason in 30 (37 per cent) out of 81 patients in the 3-year period 1964–6, in comparison with 5 (25 per cent) out of 20 patients in the 3 years 1968–70. Prior to 1968 mediastinal glandular invasion was not considered a contra-indication to resection if the involved glands could be removed. The findings of invaded glands at mediastinoscopy does not mean that they cannot be removed, and Konrad and Schulte (1969) were able to resect the tumour and the invaded mediastinal glands in 50 per cent of patients in whom invaded glands had been detected by mediastinoscopy. Konrad and Schulte, however, made the point that they did not know what the chances of prolonged survival were in these patients.

There is considerable variation in the survival rates reported after resection for bronchial carcinoma in the presence of mediastinal glandular metastases, as shown by the following: 4-year survival rates of 8 per cent (Bergh and Schersten, 1965) and 9 per cent (Nohl, 1962); 5-year survival rates of 16 per cent (Belcher and Anderson, 1965) and 17 per cent (Collier, Blakemore, Kyle, Enterline, Kriley, and Johnson, 1957). This makes it difficult to evaluate the importance of mediastinal lymph-node metastases.

The extent and distribution of lymph-node metastases in our series of patients were shown to be different for the two sides. A higher proportion of positive nodes was detected in right-sided bronchial carcinoma than in the left-sided lesions (*Fig.* 3). The difference between the two sides is accounted for by the frequency of right paratracheal node metastases in comparison with left paratracheal node involvement. The right paratracheal nodes are commonly the first extrapulmonary nodes to be involved from carcinoma of the right upper lobe (Nohl, 1956), whereas left upper lobe tumours reach the left paratracheal nodes only after passage through the left tracheobronchial nodes under the arch of the aorta. This region is not easily accessible to mediastinoscopy. The subcarinal nodes may become involved early from left or right lower lobe tumours.

A study of the relation of the cellular nature of the tumour to the survival rate after resection in the presence of mediastinal glandular metastases shows that resection for squamous carcinoma with mediastinal metastases may offer a chance of prolonged survival. Le Roux (1968), recording the experience of this unit, reported a 14 per cent 3-year survival rate after resection for squamous carcinoma with mediastinal glandular metastases, but he does not mention the extent or site of the involved mediastinal lymph-nodes. Three of our 43 patients with positive mediastinal nodes as the only contra-indication to thoracotomy had well-differentiated squamous carcinoma. Resection was successfully undertaken in 2 of these patients who had right upper lobe tumours and only right paratracheal node metastases. Local invasion of the aorta prevented resection in a third patient with well-differentiated squamous carcinoma in the left lower lobe and metastases limited to the subcarinal lymph-nodes. During the 3-year period under review, patients with poorly differentiated squamous carcinoma in the mediastinal lymph-nodes were not considered for thoracotomy. Megavoltage X-ray treatment for inoperable squamous carcinoma of the bronchus confined to the chest resulted in a 3-year survival rate of 7 per cent if the mediastinum was involved (Deeley and Singh, 1967), which is half of the survival rate recorded by Le Roux (1968) after resection for squamous carcinoma with mediastinal metastases.

The 3-year survival rate after radiotherapy for anaplastic carcinoma (including oat-cell carcinoma) with mediastinal metastases was 2 per cent (Deeley and Singh, 1967). Le Roux (1968) reported a 10 per cent 3-year survival rate after pneumonectomy for similar tumours with mediastinal glandular metastases. These figures suggest that resection offers a better chance of survival than radiotherapy even if the mediastinum is involved, but a further survey of the literature reveals conflicting results due mainly to difficulties in histological classification. Those authors who have regarded anaplastic carcinoma as an entity distinct from oat-cell carcinoma have reported 5-year survival rates after resection varying from 0 per cent (Paulson, 1957; Barrett, Day, O'Rourke, Chapman, Sadeghi, Perry, and Tuttle, 1963) to 25 per cent (Kirklin, McDonald, Clagett, Moersch, and Gage, 1955) and 27 per cent (Clagett, 1960). In view of this confusion we would suggest that resection should be attempted in some patients with anaplastic carcinoma even in the presence of mediastinal node metastases, since radiotherapy appears to be of limited value.

Oat-cell carcinoma responds as well to radiotherapy as to surgery (Miller, Fox, and Tall, 1969). There is little to be gained by resection of oat-cell carcinoma if the mediastinal glands are involved.

The position with regard to adenocarcinoma is confused. In this series 13 patients had adenocarcinoma of the lung. There were no mediastinal metastases in 12 of these, and they all underwent resection. Only 1 patient was not offered thoracotomy, as mediastinoscopy had revealed extensive mediastinal metastases. Barrett and others (1963) reported a 5-year survival rate of 40·7 per cent after pneumonectomy for adenocarcinoma, but Le Roux (1968) recorded that all but 2 of 35 patients with adenocarcinoma which was managed by pneumonectomy died within 5 years whether or not glands were invaded at the time of thoracotomy. In a small number of patients Deeley and Singh (1967) had an 11 per cent 5-year survival rate for inoperable adenocarcinoma which was treated by radiotherapy. Since pneumonectomy for adenocarcinoma appears to give a poorer chance of prolonged survival than radiotherapy it is debatable whether resection should be undertaken if positive mediastinal nodes are found.

With three exceptions, positive mediastinal nodes in 43 patients were regarded as a contra-indication to surgery. For the past 6 years the operative mortality for exploratory thoracotomy without resection in this unit has been 3 per cent. This is not regarded as a prohibitive figure and therefore to deny thoracotomy to patients with squamous or anaplastic carcinomas because they have mediastinal node metastases irrespective of the site and extent of the mediastinal involvement possibly impairs the chance of survival for an undue number of patients. It is suggested that patients with only right paratracheal node metastases from a right carcinoma (squamous or anaplastic) or with subcarinal node metastases from a right or left carcinoma should be considered for surgery.

Those with contralateral or left paratracheal node metastases should not be offered resection. No additional patients with left-sided tumours would have been offered resection if such a policy had existed in the past 3 years (*Fig.* 3). Twenty-six patients with right-sided lesions had only right paratracheal and/or subcarinal node metastases. Six of them had oat-cell carcinoma, which is probably not worth resecting in the presence of mediastinal node invasion, leaving 20 patients with squamous or anaplastic carcinoma who might have been offered resection; in fact 2 of them underwent pneumonectomy. Thus, 18 patients, nearly half of the total number of 40 patients who were not considered for resection because of positive findings at mediastinoscopy, were possibly denied curative resections.

Mediastinoscopy provided a histological diagnosis in all 14 patients with mediastinal or pulmonary hilar masses. The investigation is of particular value in the diagnosis of sarcoidosis, and Hristov (1969) reported that the investigation gave histological confirmation of the diagnosis in 96 per cent of cases, whereas other biopsy techniques were effective in only 15–26 per cent. A positive histological diagnosis was obtained in 6 out of 28 patients with atypical pulmonary opacities. We do not think that a negative finding at mediastinoscopy is of value in excluding malignancy as a cause of an undiagnosed pulmonary opacity, as was suggested by Sarin and Nohl-Oser (1969).

Acknowledgement.—We are grateful to Mr. A. Logan for permission to publish these results and for his help in the preparation of this paper.

ARGENTAFFIN-CELL TUMOUR OF MECKEL'S DIVERTICULUM

A REPORT OF 2 CASES AND REVIEW OF THE LITERATURE

BY E. L. JONES, H. THOMPSON, AND J. ALEXANDER WILLIAMS

DEPARTMENTS OF PATHOLOGY, THE MEDICAL SCHOOL AND GENERAL HOSPITAL, BIRMINGHAM, AND NUTRITIONAL AND METABOLIC UNIT, THE GENERAL HOSPITAL, BIRMINGHAM

SUMMARY

Two patients with argentaffin carcinoma (carcinoid tumour) of Meckel's diverticulum are described and the literature is reviewed. Only 45 previous cases have been reported.

In both patients the primary tumour had metastasized by the time the diagnosis was made. The first patient developed the carcinoid syndrome 3 months after removal of the tumour but he is alive and well over 5 years later.

The findings in these 2 patients add further support to the view that a carcinoid in a Meckel's diverticulum behaves like that in the small bowel rather than that in the appendix, with an appreciable (21 per cent) incidence of metastasis. The recommended treatment, therefore, should be similar to that of small intestinal carcinoid, namely, wide excision of intestine with a wedge of mesentery. Furthermore, prophylactic resection of Meckel's diverticulum is recommended whenever possible to eliminate the possibility of subsequent development of this tumour.

CARCINOID tumour (argentaffin carcinoma) occurring in a Meckel's diverticulum is rare. Since Oberndorfer's report in 1907 of 2 carcinoid tumours in the tip of a Meckel's diverticulum of a 68-year-old man, 45 additional cases have been reported. The literature has recently been reviewed by Weitzner (1969).

This report is of 2 patients who developed carcinoid tumours of Meckel's diverticulum, 1 of whom subsequently developed the carcinoid syndrome and is alive and well 5 years after the primary tumour was removed. This case appears to be the first reported example of the carcinoid syndrome resulting from a primary Meckelian carcinoid tumour in a male.

CASE REPORTS

Case 1.—A 69-year-old man presented with 1-year history of diarrhoea, becoming worse in the last 4 months with the passage of approximately six stools per day. The stools were unusually pale but occasional blood-streaking was observed. There were no other gastro-intestinal symptoms and no weight-loss. The blood-pressure was 130/80 mm. Hg, and no abnormal signs were detected on examination of all systems.

INVESTIGATIONS.—The haemoglobin was 16·2 g. per 100 ml. (109 per cent), the white blood-count was 8100 cells per $mm.^3$, and the differential count was normal. The erythrocyte sedimentation rate was 4 mm. per hour. Barium radiographic examination of the large bowel showed the presence of diverticula in the sigmoid and descending colon, and a barium follow-through examination of the small bowel showed a coarsening of the mucosal pattern of the mid-portion of the small bowel, giving a fixed distorted area close to the ascending colon.

The radiological picture was interpreted as being consistent with lymphosarcoma, Crohn's disease, or carcinoid.

LAPAROTOMY.—An indurated mass of ileum was found matted to the ascending colon. Fixity to the posterior abdominal wall made removal difficult and one fixed node was left behind where it was densely adherent to the superior mesenteric vessels and the third part of the duodenum.

A hemicolectomy and distal ileostomy were performed, from which the patient made an uncomplicated recovery.

PATHOLOGY.—The specimen consisted of caecum and ascending colon, 15 cm. in length, with 89 cm. of terminal ileum. A complex Meckel's diverticulum was located 35 cm. from the ileocaecal valve. A greyish-white tumour mass, 1·5 cm. in diameter, involved the neck and wall of the diverticulum (*Fig.* 1). The mesenteric tissues close to the diverticulum were indurated and infiltrated by deposits of greyish-white tumour, drawing together several loops of small intestine.

Histologically, the tumour consisted of cords and solid clumps of small uniform cells (*Fig.* 2) with occasional acinar or 'pseudo-rosette' formations. The nuclei were round or oval with prominent nucleoli and infrequent mitotic figures. The cytoplasm was eosinophilic and

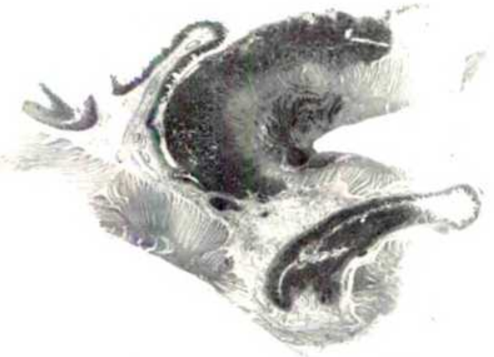

FIG. 1.—Section through Meckel's diverticulum showing tumour mass involving the neck and wall of the diverticulum. H. and E. (× 2.)

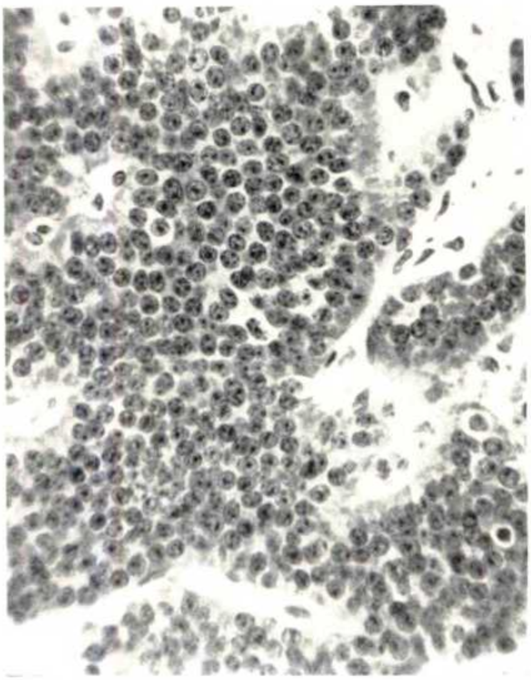

FIG. 2.—Solid clumps of uniform oval cells with occasional acinar differentiation (top left). H. and E. (× 450.)

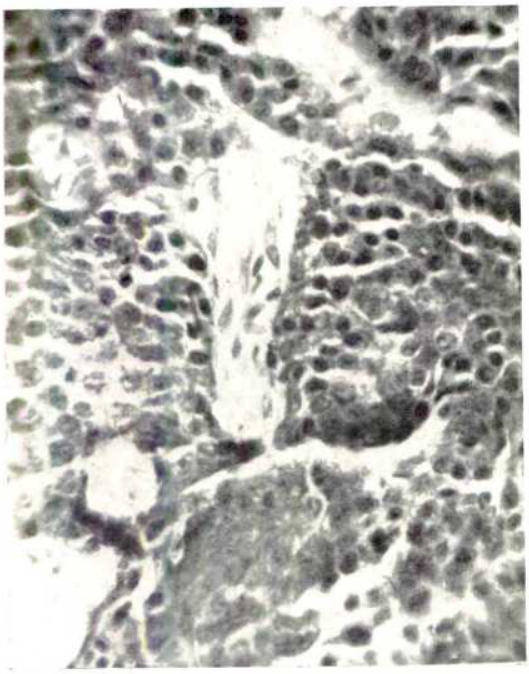

FIG. 3.—Cytoplasm of tumour cells showing dark granules. Diazo. (× 450.)

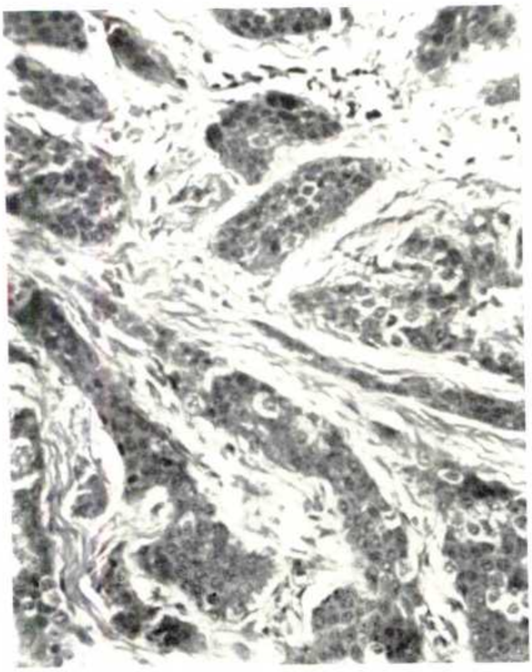

FIG. 4.—Small cords of tumour cells separated by dense fibrous trabeculae. Haematoxylin and van Gieson's. (× 250.)

finely granular. The tumour widely infiltrated the submucosa, muscularis externa, and serosa. Histochemical staining techniques for argentaffin granules demonstrated positive black granules in Masson-Fontana and brown granules in diazo-stained sections (*Fig.* 3). Metastatic deposits involved the adjacent mesentery and mesenteric lymph-nodes. The deposits in the mesentery were surrounded by dense fibrous trabeculae (*Fig.* 4).

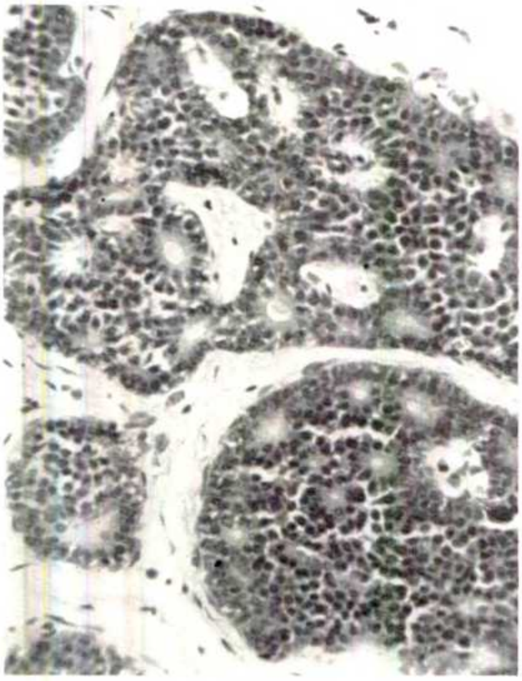

FIG. 5.—Omental metastasis of argentaffin carcinoma showing a well-developed 'pseudorosette' formation. H. and E. (× 250.)

A diagnosis of a moderately well-differentiated argentaffin carcinoma of Meckel's diverticulum was made.

POSTOPERATIVE COURSE.—After recovery a 24-hour collection of urine was found to contain less than 8 mg. of 5-hydroxyindole-acetic acid (HIAA).

FOLLOW-UP EXAMINATION.—Three months later there was evidence of 'flushing' after meals and the patient continued to pass three or four loose stools per day; these features were suggestive of the carcinoid syndrome. Serum estimation of 5-hydroxytryptamine (HT) was 372 ng. per ml. and the platelet HT was 2278 ng. per 10^9 platelets.

Over the following 5 years these symptoms have not worsened. Five years later the patient was readmitted to hospital with acute retention of urine, and a retropubic prostatectomy for benign prostatic hypertrophy was performed.

INVESTIGATIONS.—On the second admission the haemoglobin was 14·6 g. per 100 ml. (100 per cent), E.S.R. was 10 mm. per hour, and W.B.C. was 10,000 per mm.^3 Urine HIAA was 73 mg. per 24 hours.

OPERATION.—A laparotomy was performed and some of the multiple peritoneal nodules were removed for biopsy. Assessment of the liver was not possible because of dense omental adhesions.

HISTOLOGY.—The omental biopsy specimen was infiltrated by trabecular and acinar deposits of argentaffin carcinoma showing well-developed tubules (*Fig.* 5) and acinar differentiation. Argentaffin granules were seen in Masson-Fontana stained sections. Deparaffinized unstained sections mounted in a fluorescent-free medium were examined for autofluorescence with a Reichert Zetopan microscope fitted with Fluorlux ultra-violet illumination equipment. All the tumour cells showed a vivid, golden-yellow, granular fluorescence of the cytoplasm (*Fig.* 6) which is characteristic of HT.

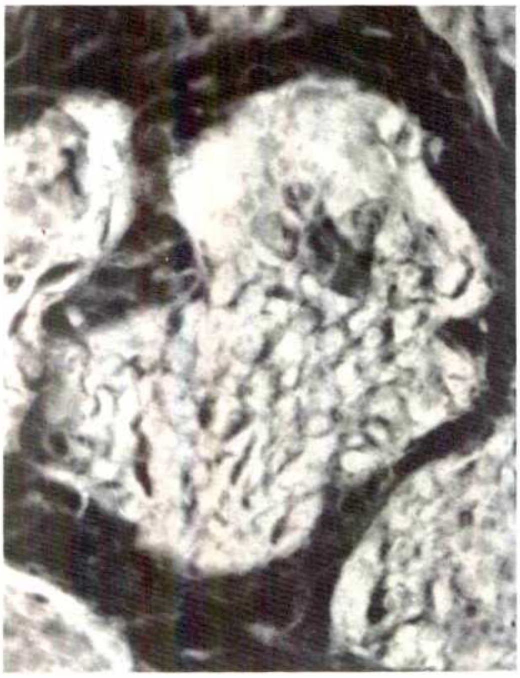

FIG. 6.—Clumps of tumour cells showing (golden-yellow) autofluorescence in ultra-violet light. Unstained. (× 790.)

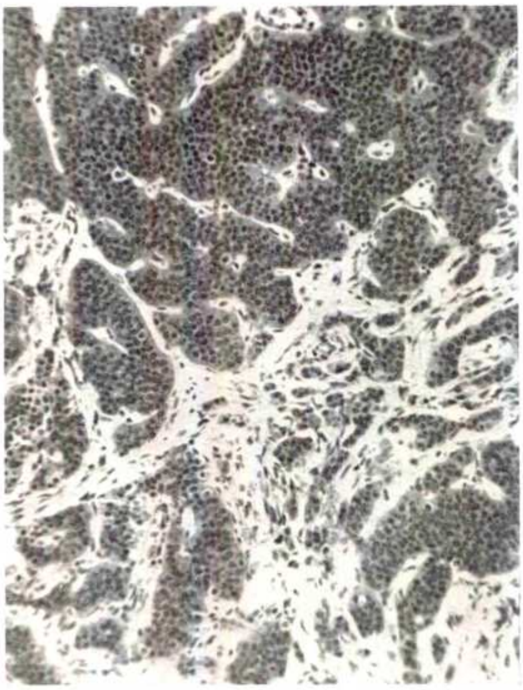

FIG. 7.—Omentum infiltrated by trabecular 'scirrhous' type of argentaffin carcinoma. H. and E. (× 150.)

FOLLOW-UP EXAMINATION.—The patient made a good recovery from the prostatectomy, and on examination 6 months later was well, in spite of flushing and six or seven daily bowel actions.

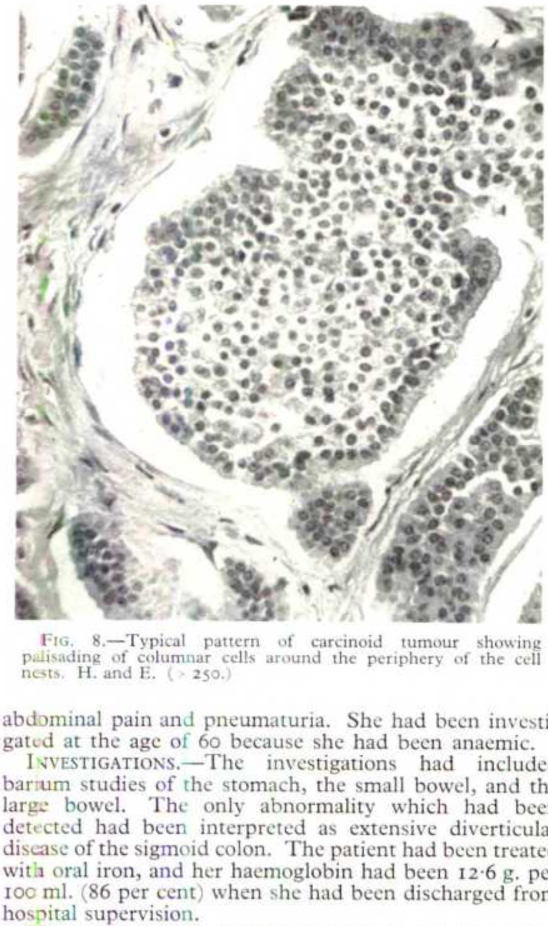

FIG. 8.—Typical pattern of carcinoid tumour showing palisading of columnar cells around the periphery of the cell nests. H. and E. (× 250.)

Case 2.—A 64-year-old woman presented with a 3-month history of intermittent diarrhoea and colicky lower abdominal pain and pneumaturia. She had been investigated at the age of 60 because she had been anaemic.

INVESTIGATIONS.—The investigations had included barium studies of the stomach, the small bowel, and the large bowel. The only abnormality which had been detected had been interpreted as extensive diverticular disease of the sigmoid colon. The patient had been treated with oral iron, and her haemoglobin had been 12·6 g. per 100 ml. (86 per cent) when she had been discharged from hospital supervision.

When the patient presented again as an emergency admission 3 years later her haemoglobin was 12·8 g. per 100 ml. (88 per cent), W.B.C. was 12,000 per mm.^{3}, and E.S.R. was 29 mm. per hour. A plain radiograph of the abdomen showed that gas was present in the urinary bladder, and a pyelogram showed caliceal hydronephrosis on the right with a normal left kidney. Cystoscopy supported the suspicion of a vesicocolic fistula. Barium examination of the rectum demonstrated a stricture of the sigmoid colon through which barium would not pass; a connexion was demonstrated between the stricture site and the bladder. The blood-urea was 46 per 100 ml., and urine culture grew a heavy growth of monilia and *Staphylococcus aureus*. The blood-pressure was 230/110 mm. Hg.

LAPAROTOMY.—Laparotomy revealed a mass in the sigmoid colon and nodules in the omentum. The small intestine was interpreted as being normal. A diverting transverse colostomy and omental biopsy were performed.

HISTOLOGY.—The omental biopsy specimen was infiltrated by a trabecular 'scirrhous' type of argentaffin-cell carcinoma (*Fig.* 7).

POSTOPERATIVE INVESTIGATIONS.—Assessment of HIAA showed excretion of 14·7 and 26 mg. on two separate 24-hour specimens.

A presumptive diagnosis of carcinoid tumour of the colon was made, and 6 weeks later a planned resection of the sigmoid colon was attempted despite technical difficulty due to fixity of the sigmoid colon. An estimated blood-loss of 2 litres during the operation was replaced, but her blood-pressure fell to 120 mm. Hg systolic and could not be restored, despite further rapid transfusion and the maintenance of the central venous pressure at 16 cm. of saline. The patient died within 12 hours of the operation.

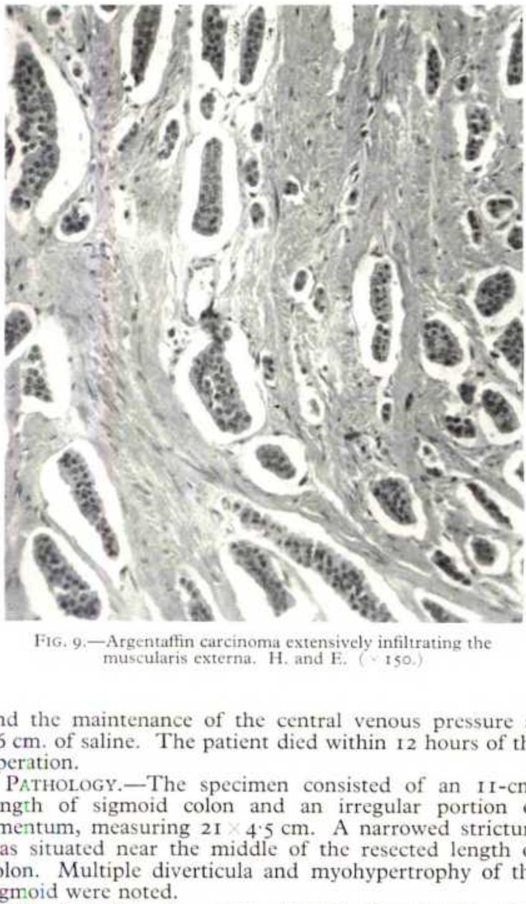

FIG. 9.—Argentaffin carcinoma extensively infiltrating the muscularis externa. H. and E. (× 150.)

PATHOLOGY.—The specimen consisted of an 11-cm. length of sigmoid colon and an irregular portion of omentum, measuring 21 × 4·5 cm. A narrowed stricture was situated near the middle of the resected length of colon. Multiple diverticula and myohypertrophy of the sigmoid were noted.

Histologically, the colon showed diverticulitis with secondary deposits of argentaffin carcinoma in the serosa. The omentum was infiltrated by multiple deposits of argentaffin carcinoma.

NECROPSY.—The peritoneal cavity contained 1500 ml. of blood and serous fluid. A nodule of yellowish-white tumour tissue, 2 cm. in diameter, was situated at the orifice of a Meckel's diverticulum at a level approximately 75 cm. from the ileocaecal valve. Metastatic deposits of greyish-white tumour tissue were found in the pelvic lymph-nodes and measured up to 1 cm. in diameter.

The liver (weight, 1090 g.) did not contain secondary deposits, but multiple tumour nodules up to 1·5 cm. wide were found on the right diaphragm.

HISTOLOGY.—The plaque-like tumour situated at the mouth of the Meckel's diverticulum consisted of solid nests and cords of round, uniform cells, showing a tendency to columnar palisading at the periphery of the nests (*Fig.* 8). The cytoplasm was eosinophilic and granular. Positive argentaffin granules were seen in sections stained by the Masson-Fontana and diazo methods.

The tumour was penetrating all layers of the wall and was diffusely infiltrating the muscularis externa (*Fig.* 9).

A diagnosis of a well-differentiated argentaffin carcinoma in Meckel's diverticulum was made.

DISCUSSION

Argentaffin carcinoma of the ileum is a rare tumour. MacDonald (1956) found only 74 examples out of 26,401 necropsies and 418,166 surgical specimens.

More recently, Brookes, Waterhouse, and Powell (1968) described 168 cases of malignant disease of the small intestine reported to the Birmingham Regional Cancer Registry in a 10-year survey (1950–9). The types of tumours found in the Birmingham Regional Cancer Registry series included 55 adenocarcinomas (32 per cent), 56 sarcomas (33 per cent), 32 carcinoid tumours (19 per cent), and in 25 cases (15 per cent) there was no definite histological diagnosis. Of the 32 carcinoid tumours, 28 were situated in the ileum, 2 in the jejunum, and 2 in the duodenum.

During the period 1958–67, 78 further carcinoid tumours of the small intestine have been reported to the same registry. Sixty-three of these 78 tumours were situated in the jejunum and ileum, 2 of which were in a Meckel's diverticulum.

The occurrence of an argentaffin-cell tumour in a Meckel's diverticulum is very rare, and to date there are only 45 other documented cases reported in the literature (*Table I*), although Anthony and Drury (1970) refer to 1 other example which was seen among 100 cases of argentaffin carcinoma of all sites found during a 12-year-period from 1956 to 1968 from the files of the Central Middlesex Hospital, Bland-Sutton Institute of Pathology, Middlesex, and St. Mark's Hospital, London.

Most carcinoids occurring in Meckel's diverticulum are unsuspected incidental findings at necropsy (19 out of 45,) or operation (25 out of 45). Nine (20 per cent) have shown invasion of the intestinal wall (Sanders and Axtell, 1964). Nine out of 44 (21 per cent) have shown metastases, the liver being involved in 8, mesenteric lymph-nodes in 4, lungs in 1, vertebrae in 1, and ileum in 1.

Three of the 8 patients with hepatic metastases developed the carcinoid syndrome; all were females, the majority (5 out of 9) of patients with disseminated tumour being women. This is unusual in view of the very low incidence to date of carcinoid in Meckel's diverticula in women and the apparent fairly equal occurrence of metastasizing carcinoids of the small intestine in both sexes. Thus, 36 of the patients were men and 9 were women. The fact that carcinoid of Meckel's diverticulum has been encountered four times as often in males than in females probably reflects the twofold (Wansbrough, Thomson, and Leckey, 1967) to threefold (Seagram, Louch, Stevens, and Wentworth, 1968) greater incidence of Meckel's diverticulum in males.

The size of the tumour was recorded in 32 cases and varied from 0·3 to 5·3 cm. The youngest case was a 14-month-old child and the oldest an 80-year-old man. Thirty-six patients were aged 50 or over. The average age was 55 years. Special stains for argentaffin granules in the tumour were positive in 21 of 23 cases in which they were performed. The carcinoid was ulcerated and was the source of the gastro-intestinal haemorrhage in 2 patients. Six of the diverticula showed diverticulitis. A double carcinoid was present in 2 of the diverticula (Oberndorfer, 1907; Traill, 1968).

Thirty-four (75 per cent) of the cases of carcinoid tumour in Meckel's diverticulum have been reported since 1950. Although this may suggest that the lesion is more prevalent than previously was suspected, it most probably reflects the more common practice of resecting normal diverticula found incidentally at surgery (Weitzner, 1969). Prophylactic resection of Meckel's diverticulum is recommended whenever possible in order to eliminate the potential site of this rare tumour.

Rigidity and collagenous fibrosis of the mesentery are frequently present in association with carcinoid tumour of the small intestine and cause obstruction by retraction and kinking, a complication known to surgeons for many years (Cooke, 1931; Grimes and Bell, 1949; Moertel, Sauer, Dockerty, and Baggenstoss, 1961). In both of the present cases there was extensive fibrosis and induration of the mesentery with indrawing of the coils of small intestine. Moertel and others (1961) and later Dockerty (1963) reviewed the same series of 209 cases seen at the Mayo Clinic over a period of 50 years. They noted that in only 1 out of 56 cases who presented with symptoms was the correct diagnosis made preoperatively. The commonest form of presentation was small intestinal obstruction in 49 cases, which was due to mesenteric fibrosis in 33 (67 per cent).

Metastases occurred in 21 per cent of Meckelian carcinoids, compared with 30 per cent of carcinoids of the small intestine (Moertel and others, 1961).

Although there are too few cases to draw valid conclusions, carcinoids in Meckel's diverticulum tend to behave more like small intestinal than appendiceal carcinoids. For this reason the recommended treatment of carcinoids in this area is the same as that for similar tumours of the small intestine, namely, wide excision of the intestine with a wedge of mesentery.

In the report of Brookes and others (1968) 31 cases of small intestinal carcinoid tumour were followed up, with a 5-year survival rate of 41·9 per cent, and of 16 cases receiving radical surgery, 56 per cent survived 5 years. A similar 5-year survival of 52 per cent was found by Pagtalunan, Mayo, and Dockerty (1964). During the period reviewed by Brookes and others (1968) there were 47 cases of carcinoid tumour of the appendix reported to the same registry, and the 5-year survival rate was 91·5 per cent (43 cases).

In the literature on carcinoid tumours arising in Meckel's diverticulum very few of the cases have been reported some time after the diagnosis was made. Two of the women with disseminated carcinoid were alive for 10 and 24 months following surgery and cytotoxic therapy. None of the other patients has been known to develop metastases, although only 2 had been followed up for more than 5 years.

The findings in the present 2 cases are summarized in *Table II.* Both cases showed dissemination to the peritoneum and the mesenteric nodes. In *Case* 1 the symptoms of the carcinoid syndrome developed 3 months after the removal of the primary tumour. Despite this the man is alive and well 5 years later. A further operation for prostatic enlargement 5 years later revealed extensive omental secondaries, containing large quantities of HT, the presence of which was by confirmed histochemical staining reactions and positive autofluorescence in ultra-violet light. We believe this to be the first report of the carcinoid syndrome from a primary argentaffin carcinoma in a Meckel's diverticulum in a man. It is clear from the clinical progress in this case that the natural history of this tumour closely mimics the now well-recognized apparently slow growth-rate and good survival which are associated with other gastro-intestinal carcinoids despite early local invasion and metastases.

Table II.—CLINICAL FEATURES OF 2 PATIENTS WITH CARCINOID OF MECKEL'S DIVERTICULUM

CASE	AGE (years) AND SEX	SIZE (cm.)	SPECIMEN	METASTASES	COMMENT
1. J. T.	69 M.	1·5	Surgery	Mesentery, mesenteric lymph-nodes	Argentaffin reaction. Carcinoid syndrome present. Alive and well 5 years later.
2. G. A.	64 F.	2·0	Necropsy	Mesentery, mesenteric lymph-nodes, colonic serosa, diaphragm	Argentaffin reaction. Died following operation for sigmoid diverticulitis

Acknowledgements.—We are grateful to Dr. W. T. Cooke for permission to record the clinical details of both cases, to Miss D. J. Powell, Statistical Officer to the Birmingham Regional Cancer Registry, to the staff of the Histology Department, General Hospital, Birmingham, for technical assistance, and to Miss G. L. Parkinson for typing the manuscript.

THE EFFECTS OF INTERMITTENTLY APPLIED EXTERNAL PRESSURE ON THE HAEMODYNAMICS OF THE HIND-LIMB IN GREYHOUND DOGS

By S. SABRI, V. C. ROBERTS, and L. T. COTTON

DEPARTMENT OF BIOMEDICAL ENGINEERING, KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

The application of intermittent compression of 30 mm. Hg to the hind-limb of a greyhound results in an increase of about 400 per cent in the pulsatility of femoral vein flow and of 250 per cent in the peak femoral vein flow. This effect may result in adequate filling and emptying of the deep venous channels and sinuses of the lower limb of man, thereby preventing stasis in them. Intermittent compression of the calf seems, therefore, to have an obvious place in the prophylaxis of deep-vein thrombosis.

During exercise the skeletal muscle of the calf interacts with the valved veins of the lower limb to produce a mechanical blood pump. Exercise results in intermittent compression of the deep veins of the calf and thigh which displaces and maintains venous blood-flow towards the heart (Waterfield, 1931; Clark, Cotton, and Zarek, 1965). During the subsequent muscle relaxation, reflux of blood is prevented by the 'non-return' action of the venous valves. Thus, calf-muscle contraction is followed by a considerable drop in venous pressure at the ankle (Pollack and Wood, 1949; Henry and Gauer, 1950; Højensgard and Sturup, 1952). It has been suggested that the action of the muscle pump on the venous pressure and flow in the lower limb may be simulated by using rhythmical external compression of the calf, e.g., by applying pneumatic cuffs (Henry, Slaughter, and Greiner, 1955; Allwood, 1957; Loane, 1959). The resultant 'milking' of the venous channels reduces the venous pressure, thereby increasing the arteriovenous pressure gradients in the lower limb, which in turn promote the blood-flow (Henry and others, 1955; Allwood, 1957).

MATERIALS AND METHODS

Eight greyhound dogs, weighing 25–30 kg., were anaesthetized with intravenous Nembutal in a dose of 30 mm. per kg. body-weight and maintained with additional small doses as required. Both femoral veins were exposed and all their tributaries were ligated. Intermittent external pressure was applied to one limb using a standard half-leg inflatable plastic splint (Parke-Davis & Co.), while the other leg acted as control.

The first group of 5 dogs was used to investigate the effects of varying the interval between each successive compression on the haemodynamics of the hind-limb. Intermittent compression was achieved by connecting the splint to a Beaver respirator and the resultant variation in splint pressure was monitored with a Bell and Howell L221 transducer (*Fig.* 1). Blood-flows in the femoral veins were measured using a Nycotron 372 electromagnetic flow-meter and cuff flow-probes type PS. Following placement of the probes, a period of time was allowed for the flows to stabilize and then a train of equispaced compressive impulses, having a maximum value of 30 mm. Hg, was applied to the leg. The compression was then stopped, the pressure in the splint was reduced to zero, and the flows were allowed to restabilize. The whole procedure was then repeated for a further six settings of the respirator speed control. In this way the interval between successive compressions in each train was varied over the range of 1·45–4·15 seconds. Continuous recordings of blood-flow and splint pressure were traced by an ultra-violet recorder, and the mean, minimum, and peak femoral vein flows were calculated from the traces.

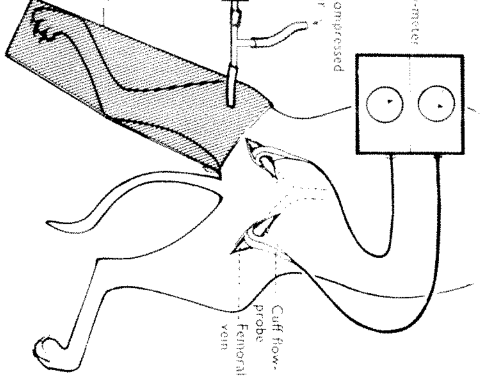

FIG. 1.—Experiment to determine the effects of intermittent compression of the leg on femoral vein flow in greyhounds. Compressed air is supplied from a Beaver respirator.

The second group of 3 dogs was used to investigate the effects of applying, for 60 minutes, a compressive impulse of 30 mm. Hg every 4 seconds. Continuous recordings of both the mean and pulsatile femoral vein blood-flows were made throughout the 60-minute period. Changes in both the mean and pulsatile femoral vein blood-flows were then taken from the traces at 5-minute intervals.

RESULTS

Table I shows the effects of varying the interval (T) between successive compressions of 30 mm. Hg on the mean [Q(mean)], peak [Q(max)], and minimum [Q(min)] femoral vein blood-flows in the experimental

Table I.—EFFECT OF VARYING THE INTERVAL (T) BETWEEN SUCCESSIVE APPLICATIONS OF AN EXTERNAL PRESSURE OF 30 mm. Hg. ON THE MEAN VOLUME FLOW RATE [Q(mean)] IN THE CONTROL (UNCOMPRESSED) LEG AND IN THE COMPRESSED LEG. ALSO GIVEN ARE THE MAXIMUM [Q(max)] AND MINIMUM [Q(min)] FLOWS IN THE COMPRESSED LEG

(compressed) limb. Also given is the mean flow [Q (mean)] in the control (uncompressed) limb. Intermittent compression produced small but haphazard changes in the mean femoral vein flow which were probably not significant. The results obtained from *Table I* are plotted in *Figs.* 2 and 3. The changes in pulsatility were calculated from the difference between the maximum and minimum femoral vein blood-flows [Q(max)] – [Q(min)]. It can be seen from *Figs.* 2 and 3 that the greater the interval between successive compression, the greater was the increase in both the pulsatility and in the peak femoral vein blood-flow. The best result in the experimental range occurred when a compression was applied once every 4 seconds, although mathematical analysis of the results shows that the effect should be maximal when a compression is applied about once every 45 seconds. Applying a compression every 4 seconds increased the pulsatility by about 400 per cent (*Fig.* 2) and the peak femoral vein flow by 250 per cent (*Fig.* 3).

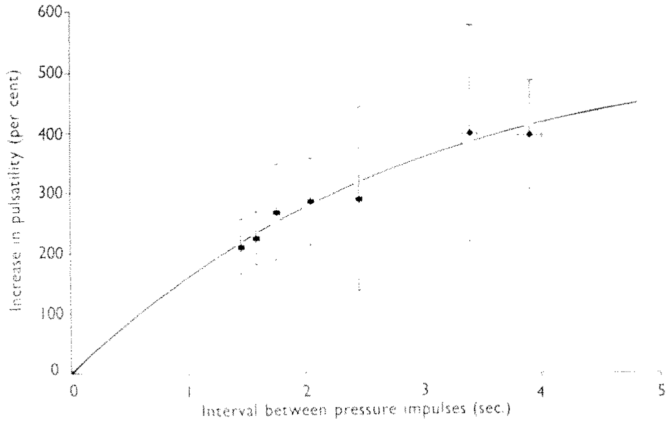

FIG. 2.—Graph showing how the increase in pulsatility of the venous flow varies with the interval between each compressive impulse (The vertical and horizontal bars represent ± 1 S.D. about the mean value.)

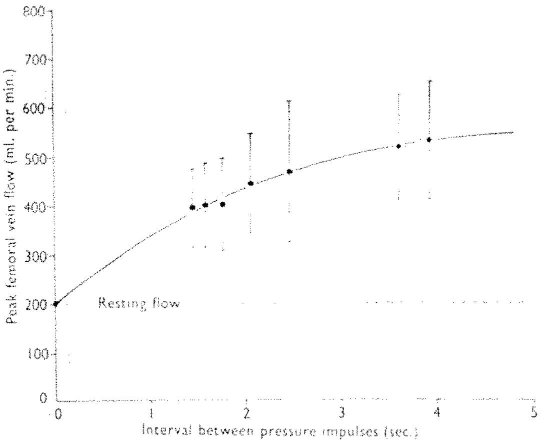

FIG. 3.—Graph showing the relationship between the peak femoral vein flow and the interval between the compressive impulses. Also shown is the resting flow. (The vertical and horizontal bars represent ± 1 S.D. about the mean value.)

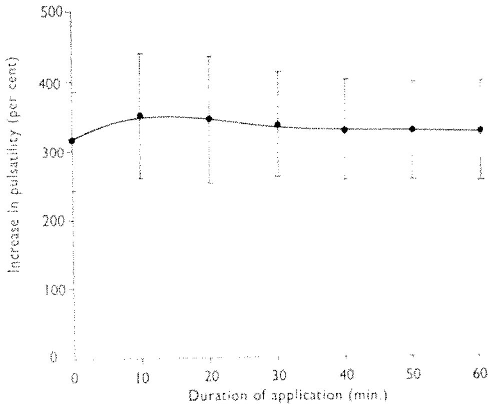

FIG. 4.—Graph showing how the effects of intermittent compression on the pulsatility of the venous flow are maintained over a period of 1 hour. (The vertical and horizontal bars represent ± 1 S.D. about the mean value.)

Table II shows the effects of applying, for a period of 60 minutes, a compression pressure of 30 mm. Hg once every 4 seconds. The results obtained from *Table II* were applied in *Fig.* 4, which demonstrates that the increase in pulsatility is maintained throughout the entire 60-minute period.

DISCUSSION

Venous stasis in the lower limb of resting recumbent patients (McLachlin, McLachlin, Jorg, and Rawlings, 1960; Cotton and Clark, 1965) is thought to be an important cause of thrombosis in the deep veins of the calf (Hadfield, 1950). Radiographic and anatomical studies have shown that venous blood stagnates in the thin-walled soleal sinuses which have been shown to be functionally isolated in the recumbent state (Gibbs, 1957; Sevitt and Gallagher, 1961; Cotton and Clark, 1965). Induction of anaesthesia and the associated inactivity of the calf muscles during operation aggravate remarkably the stagnation in these sinuses (Cotton and Clark, 1965; Clark and Cotton, 1968).

Arteriophlebographic studies have revealed that static compression of the lower limb results in an increase in the flow-rate in the deep veins of the leg but does not result in any filling of the soleal sinuses

* The compressive impulses were applied at the rate of 15 per minute with a maximum pressure of 30 mm. Hg. For each dog mean volume flow-rate [Q(mean)] in the control leg and in the compressed leg is given at 5-minute intervals. Also given are the maximum [Q(max)] and Q(min)] flows.

(Clark and others, 1965). The combination of electrical stimulation and external compression of the calf, however, results in a rapid filling of both the deep veins and the soleal sinuses (Cotton and Clark, 1965). It is therefore suggested that the increased pulsatility of venous blood-flow which is obtained by the combination of electrical stimulation and compression of the calf is a reflection of the degree to which the venous system of the calf is being emptied and refilled, and is thus a measure of the degree of stasis present.

Applying an intermittent compression of 30 mm. Hg 15 times per minute results in an increase of about 400 per cent in the pulsatility of the femoral venous flow. Furthermore, the results of this investigation have indicated that there is no concomitant increase in the mean femoral vein blood-flow of any significance, a finding which does not agree with that of Henry and others (1955), Allwood (1957), and Loane (1959), who showed that intermittent compression of the calf will increase the arteriovenous gradients and therefore increase the blood-flow in the limb.

The study of the effects of intermittent compression provides a useful method of investigating the haemodynamic causes of postoperative deep-vein thrombosis. For example, if a clinical trial designed to study the efficacy of this method were to indicate that peroperative intermittent compression of the leg was effective in preventing postoperative deep-vein thrombosis, then one could conclude that in all probability the damping of the flow pulsatility caused by induction of anaesthesia (Clark and Cotton, 1968) is the most important factor in the initiation of the thrombus in the deep veins of the leg.

THE EFFECT OF INTERMITTENTLY APPLIED EXTERNAL PRESSURE ON THE HAEMODYNAMICS OF THE LOWER LIMB IN MAN

By V. C. ROBERTS, S. SABRI, A. H. BEELEY, and L. T. COTTON
DEPARTMENT OF BIOMEDICAL ENGINEERING, KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

The effects of intermittently applied external pressure on blood-volume flow-rate in the femoral vein have been investigated in a series of 6 patients undergoing surgery for bilateral varicose veins. During the investigation, pressure was applied to the legs with the aid of an inflatable plastic splint, while blood-flow in the femoral veins was measured with an electromagnetic blood flow-meter.

The investigation has shown that intermittently applied pressure increases the pulsatility of the venous flow-wave while leaving its mean level largely unaltered. It has been shown that the increase in peak flow is directly proportional to the rate of pressure application, being maximal at about 10 mm. Hg per second. It has further been shown that the increase in both the pulsatility and the peak flow reaches a maximum when the interval between successive pressure applications is 1 minute.

IN the search for effective measures to prevent post-operative deep-vein thrombosis the use of statically applied external pressure has not been successful (Rosengarten, Laird, Jeyasingh, and Martin, 1970). The reason for this probably lies in the failure of external pressure, unless precisely controlled, to alter significantly the haemodynamics of the situation (Spiro, Roberts, and Richards, 1970; Sabri, Roberts, and Cotton, 1971a). More recently it has been suggested that the haemodynamics might be changed to more advantage by the use of intermittently applied external pressures (Sabri, Roberts, and Cotton, 1972). During this latter investigation it was shown in greyhounds that intermittently applied external pressure can significantly increase both the peak femoral vein flow and its pulsatility while leaving its mean level largely unaltered. These increases have been shown to vary with the interval between the compressive impulses, the effect being theoretically maximal when a pulse is applied every 45 seconds.

Other work on the effects of externally applied pressure has shown that the volume of blood ejected from the calf of supine subjects varies with the magnitude of the applied pressure, tending to a maximal value when the pressure is 40 mm. Hg (Roberts, 1971). Since this ejected volume must be constant for any given patient, the peak achieved by applying a pressure will depend on the speed with which the pressure is applied. This present investigation was therefore divided into two parts. In the first part the effect on the peak femoral vein flow of varying rates of pressure application was investigated, and in the second part the effects of varying the interval between successive compressive impulses on the peak flow were studied.

MATERIALS AND METHODS

Six patients undergoing surgery for bilateral varicose veins were asked for their informed consent and co-operation. General anaesthesia was induced and maintained with spontaneous respiration. Blood-flows in the femoral veins were measured with a Nycotron 372 electromagnetic flow-meter and Nycotron cuff flow-probes type PS, using a standard procedure reported previously (Spiro and others, 1970).

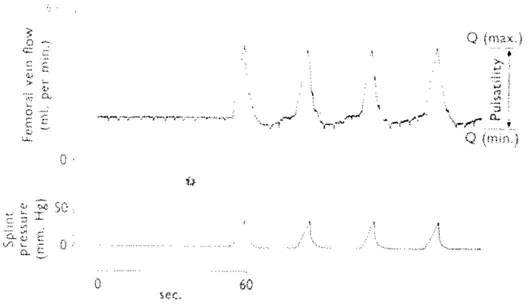

FIG. 1.—Two typical flow and pressure traces obtained during the investigation. The traces show that as pressure is applied to the leg the flow rises and then as the pressure is released falls to below its resting level. The flow then gradually rises to its previous resting level.

The patients were divided into two groups of 3. In the first group blood-flow was measured in one leg only while the leg was subjected to controlled compression with the aid of an inflatable, plastic, below-knee splint (Parke-Davis & Co.). Following placement of the flow-probe, a period was allowed for the flow to stabilize and pressure was then applied at a controlled rate until it had reached 50 mm. Hg. The pressure was released when the flow had fallen to its original resting level, and a period of time was then allowed for the flow to restabilize. This procedure was then repeated for several different rates of pressure application over the range 0·89 to 9·40 mm. Hg per second (i.e. the time taken for the pressure in the splint to reach 50 mm. Hg took between 56 and 5·3 seconds from the time that filling commenced, the higher filling rates producing the lower filling times).

In the second group of 3 patients blood-flows were measured in both the femoral veins. Following placement of the probes, a period of time was allowed for the flows to stabilize and then a train of equi-spaced compressive impulses was applied to the leg by means of an inflatable splint (*Fig.* 1). These were stopped, the flows were allowed to restabilize, and the procedure was repeated three times. The interval between successive compressions in each train was controlled, in four discrete steps over the range

18·0–55·7 seconds, by means of a modified Therepac pneumatic controller (Epac Ltd.). The compression rate was fixed at 6 mm. Hg per second and the pressure was released when it reached 30 mm. Hg. Thus, each compression lasted for approximately 5 seconds.

RESULTS

The results of the first part of the investigation are shown in *Table I*. For each subject the resting flow prior to compression [Q^R(mean)] is tabulated against the peak flow [Q(max)] achieved at each rate of pressure application (dP/dt). Also shown is the time taken for the flow to return to its resting level following release of the compression (T^R). The results from these 3 patients are summarized in *Fig.* 2, which shows the increase in peak flow as a function of the rate of pressure application.

both the control and compressed legs are given, as well as the maximum [Q(max)] and minimum [Q(min)] flows in the compressed limb. The period between successive compressions in each train (T) is also given.

Fig. 1 shows a typical pressure recording obtained during this investigation. The recording commences with a rest period during which no pressure is applied to the leg. The venous flow trace during this period is only very slightly pulsatile, a small dip occurring in synchronism with respiration. Following this rest period, a train of compressive impulses is applied to one leg and the pulsatility of the flow wave-form increases markedly. The pulsatility is defined as being the difference between the maximum [Q(max)] and minimum [Q(min)] flows, and in *Fig.* 3 the increase in pulsatility is shown as a function of the interval between the compressive impulses.

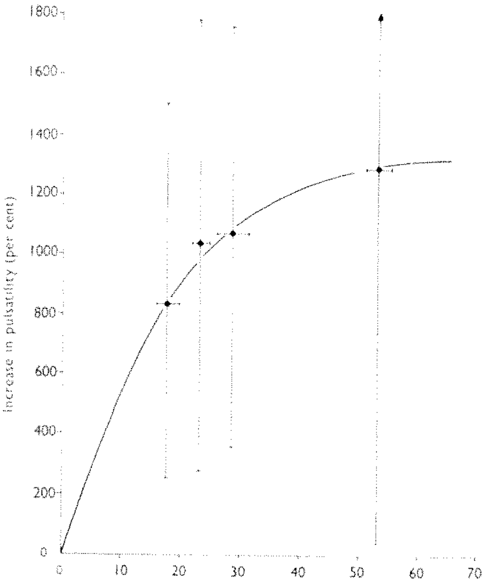

FIG. 3.—Graph showing the increase in pulsatility of the femoral vein flow-wave as a function of the interval between successive pressure impulses. (The vertical and horizontal bars represent ±1 S.D. about the mean value.)

In *Fig.* 4 the peak femoral vein flow achieved by intermittent compression is shown as a function of the interval between the pressure impulses (T).

DISCUSSION

In attempts to prevent postoperative deep-vein thrombosis, considerable attention has been focused on the role played by stasis of blood in the veins of the leg. Attempts at preventing this stasis by bandaging have, however, produced inconclusive and often conflicting results. More recently, the peroperative use of passive calf exercise, which increases both the mean level and the pulsatility of the venous flow (Roberts, Sabri, Pietroni, Gurewich, and Cotton, 1971), has been shown to reduce significantly the incidence of postoperative deep-vein thrombosis (Sabri, Roberts, and Cotton, 1971b). However, this work still leaves several questions unanswered, the chief of which concerns the role of flow pulsatility in the development of deep-vein thrombosis.

An investigation conducted in greyhounds into the effects of intermittently applied external pressure revealed that both the peak value and the pulsatility of the femoral vein flow could be increased, while the mean level was unchanged (Sabri and others, 1972). Furthermore, theoretical analysis of the results indicated that the maximum effect would be produced when the compressive impulses were applied every 45 seconds.

In the present investigation the original animal study has been extended to cover human subjects and the results obtained are very similar in many respects. It has been shown that the peak femoral vein flow can be increased sixfold and its pulsatility increased almost thirtyfold. These maximal values occur when the interval between successive compressions is about 60 seconds, a finding which appears to be related to the time required for the venous system to refill following release of leg compression, for as *Table I* shows it takes an average of 58·6 seconds for the flow to return to its normal level after the compression has been released. Furthermore, the increase in the peak flow is linearly related to the rate of pressure application up to a value of 4 mm. Hg per second. Thereafter the effect tails off as the resistance to the ejected blood builds up to reach a maximum when the pressure is applied at about 10 mm. Hg per second.

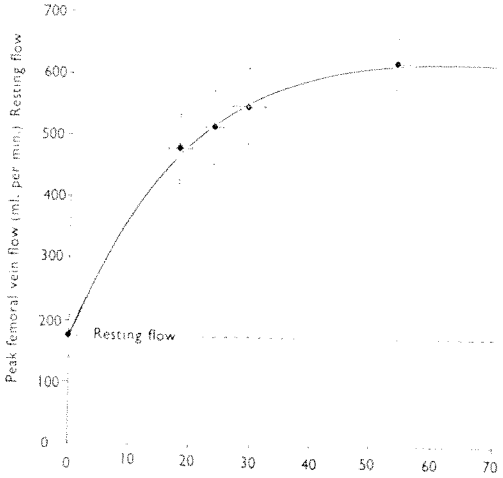

FIG. 4.—Graph showing the peak femoral vein flow achieved by intermittent compression as a function of the interval between the pressure impulses. The level of the resting flow is also shown. (The vertical and horizontal bars represent ±1 S.D. about the mean value.)

The mean level of the femoral vein flow is, however, largely unaltered, a small but haphazard increase being produced which is relatively insignificant. Similar findings have been obtained in the field of pressure-assisted circulations where the mean flow is rarely, if ever, increased by the effects of intermittent compression (Hahnloser, Gallo, and Schenk, 1966; Mullens, Sugg, Kennelly, Jones, and Mitchell, 1971).

A technique has been developed by which the relatively steady venous flow in the leg may be made pulsatile without at the same time producing any overall increase in the limb perfusion. A clinical trial has been initiated to investigate the efficacy of this technique as a prophylactic measure against post-operative deep-vein thrombosis, and it is hoped that the results obtained will lead to a greater understanding of the role of haemodynamics in the initiation of deep-vein thrombosis.

Acknowledgements.—The authors are indebted to the Wates' and British Heart Foundations, without whose generous support this work would not have been possible. We would also thank Epac Ltd. for kindly loaning the Therepac controller used in this investigation.

A NEW NON-INVASIVE TECHNIQUE FOR ASSESSMENT OF SUPERFICIAL FEMORAL ARTERY OBSTRUCTION

BY J. P. WOODCOCK,

R. G. GOSLING,*

SENIOR LECTURER, DEPARTMENT OF PHYSICS, GUY'S HOSPITAL MEDICAL SCHOOL

AND D. E. FITZGERALD

READER, DEPARTMENT OF EXPERIMENTAL MEDICINE, ROYAL COLLEGE OF SURGEONS IN IRELAND

SUMMARY

A transcutaneous technique is described utilizing two ultrasonic Doppler-shift flow-velocity meters simultaneously at sites down the arterial system of the leg in patients with superficial femoral disease. The change in shape of the blood-velocity/time wave-form over the cardiac cycle and the pulse propagation time between the two sites are measured. The transit time and change in pulse shape are used to assess limb viability. This method is compared with two other non-invasive techniques: whole-limb flow measured by a strain-gauge plethysmograph and with the systolic pressure difference between the arm and the calf. It is shown that as the pulse propagation time and the degree of damping of the blood-velocity/time wave-form increase, then limb perfusion decreases, and a nomogram is presented relating these parameters.

IN assessing patients for reconstructive vascular surgery to circumvent a femoral artery block, it is important to have some estimate of the dynamic capability of the collateral around the block and of the distal circulation in the whole limb. Current pre-operative techniques rest mainly on angiography, plethysmography, and brachial/calf pressure differences. Whilst angiography outlines the vessels and is probably essential if surgery is decided upon, it does involve some risk and discomfort as well as hospitalization. These factors mitigate against the procedure as a routine *initial* screening test. Plethysmography is essentially a whole-limb measurement and lacks vessel-specific information. Pressure-gradients down a particular vessel, as inferred from measurements with a thigh or calf cuff, can be misleading (Allen and Terry, 1969).

The transcutaneous Doppler-shift blood-velocity meter has made it possible to measure the velocity of blood-flow in almost any particular vessel atraumatically (Rushmer, Baker, and Stegall, 1966; Strandness, Schultz, Sumner, and Rushmer, 1967). The instrument and associated tape-recorder are portable and easily used, if necessary in the ward or office. The signals may be processed elsewhere to obtain a record of the arterial blood-velocity variation with time through each cardiac cycle (Gosling, King, Newman, and Woodcock, 1969). We have shown (Woodcock, 1970; FitzGerald, Gosling, and Woodcock, 1971a, b; Gosling, Dunbar, King, Newman, Side, Woodcock, FitzGerald, Keates, and MacMillan, 1971) that by measuring the damping of such an arterial velocity/time wave-form, together with the time of pulse propagation, along any section of an artery it is possible to produce a system of grading the dynamic capability of any collateral circulation present, and also to give a description of the vessel capability in cases of arterial disease in which there are no complete blocks.

The purpose of this paper is to present, in cases of superficial femoral artery obstruction, a comparison of the use of regional arterial blood-velocity/time wave-forms obtained transcutaneously by the ultrasound Doppler-shift technique with the assessment of limb viability given by occlusive strain-gauge plethysmography (hyperaemic flow) and that obtained by measuring the systolic pressure difference between the calf and the right arm. These techniques are all non-invasive. However, the information from the ultrasonic technique also compares favourably with that obtained from arteriograms (Woodcock, 1970).

MATERIALS AND METHODS

Two Doppler-shift flow-velocity meters[*] are used simultaneously and successively at the following sites down the leg: the common femoral and popliteal arteries; the common femoral and posterior tibial arteries. Each instrument generates ultrasound at 5 MHz in a hand-held probe consisting essentially of two small $2{\cdot}5 \times 6{\cdot}0$-mm. piezo-electric crystals (PZT 5H), mounted coplanarly, acting as a transmitter and a receiver. The probe is placed lightly on the skin and the ultrasonic beam is coupled into the tissue via a suitable jelly. Ultrasound is then scattered by the moving blood-cells in any underlying vessel that the beam traverses. The radiation that is back-scattered towards the probe emerges through the skin and is detected by the receiver crystal. This back-scattered ultrasound is shifted in frequency by the velocity of the blood-cells according to the Doppler effect.[†] The frequency shift is in the audio-range for physiological blood velocities, e.g., 0–6 kHz for a velocity from 0 to 100 cm. per sec. with a beam inclined at about 30° to the vessel axis. Thus, an audio-frequency signal is generated which is proportional to the velocity of each scattering blood-cell within the incident beam.

Signals from any two arterial sites, generated as described above, are continuously recorded on a two-channel Revox 77K stereo tape-recorder and the frequency spectrum—corresponding to all the velocities present in the vessel—is displayed as a sonogram (*Fig.* 1) using a Kay Sonagraph.[‡] We have shown (Gosling and others, 1969) that the maximum frequency envelope of such a sonogram is closely similar in shape to the instantaneous average velocity/time wave-form as generated by an electromagnetic flowmeter, over a wide range of conditions, whereas this is not true of the output of any electronic averaging device, e.g., a zero-crossing frequency meter. Therefore, in all that follows we have used the maximum frequency envelope of the sonogram to represent the blood-velocity wave-form over the cardiac cycle. The transit time of the pulse wave between any two sites is simply measured by displaying the two signals simultaneously on a single sonogram. *Fig.* 1 shows such a sonogram obtained from the Doppler-shift signals from the common femoral and posterior tibial arteries in a normal healthy subject. This figure also illustrates the construction of the blood-velocity wave-form shape and the measurement of pulse propagation time.

[†] $\Delta f = 2fv\cos\phi/c$, where Δf is the Doppler shift, f the frequency of the ultrasonic beam at angle ϕ to the axis of the vessel, v the velocity of the blood-cell (assumed parallel to the axis), and c the velocity of ultrasound propagation in tissue.

[‡] Model 6061B Kay Electric Co., Pine Brooks, New Jersey, U.S.A.

In order to compare the blood-velocity wave-forms obtained at different sites on the same patient, or from different patients, it is necessary to eliminate the unknown calibration factor—converting Doppler-shift frequency to blood-velocity—operating on the ordinate of each sonogram, i.e., some form of normalization is required. We have suggested (Gosling and others, 1971) that the shape of the blood-velocity/time wave-form over the whole of one cardiac cycle may be characterized by the pulsatility index (P.I.), which we have defined as the sum of the maximum oscillatory energy of the Fourier harmonics of the wave-form divided by the energy of mean forward flow (*see* Appendix). To obtain the Fourier harmonics the blood-velocity/time wave-form recorded at each site is digitized (in x and y) using a d-Mac electromagnetic pencil follower interfaced to an IBM 029 card punch which automatically assembles the data in a convenient format for computation. These data are then Fourier analysed

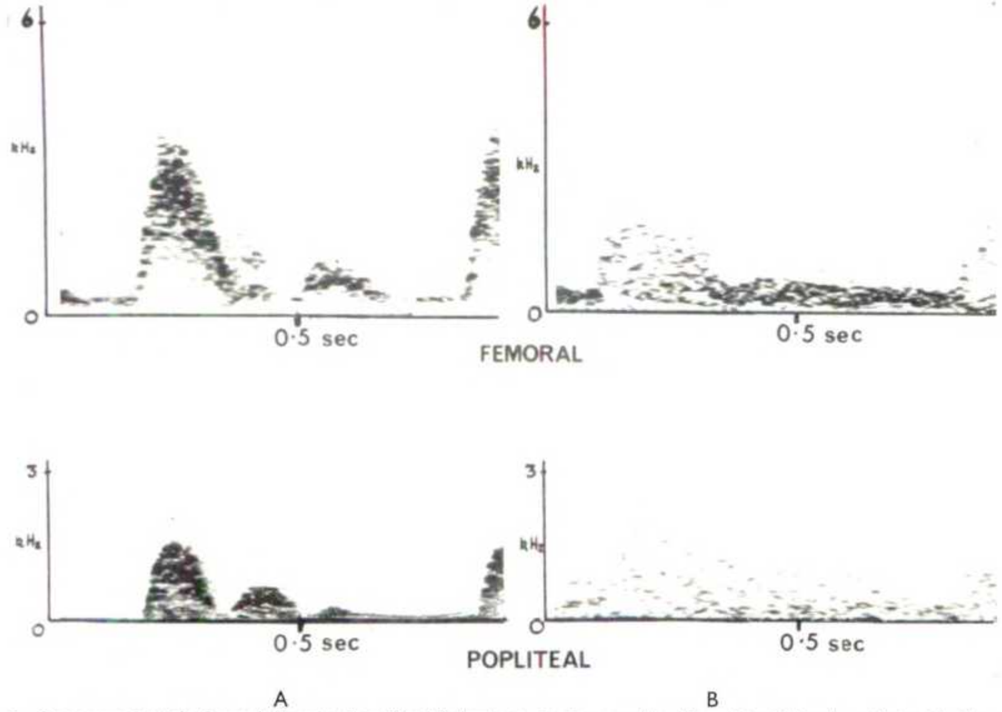

FIG. 2.—Sonograms from the femoral (above) and popliteal (below) arteries of a normal healthy subject (A) and a patient with atheromatous involvement of the iliac artery and a superficial femoral block (B). The P.I. values of these waveforms are: Normal: femoral P.I. = 7·0; popliteal P.I. = 7·5; hence Δ = 0·9. Abnormal: femoral P.I. = 1·6; popliteal P.I. = 0·6; hence Δ = 2·7.

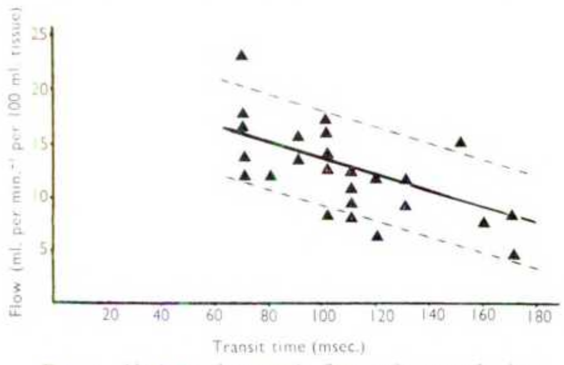

FIG. 3.—Maximum hyperaemic flow against transit time. The regression line is shown with dashed lines representing ± 1 standard deviations of the mean. The correlation coefficient, $r_s = 0·57$ and the level of probability $P_s \leqslant 0·01$.

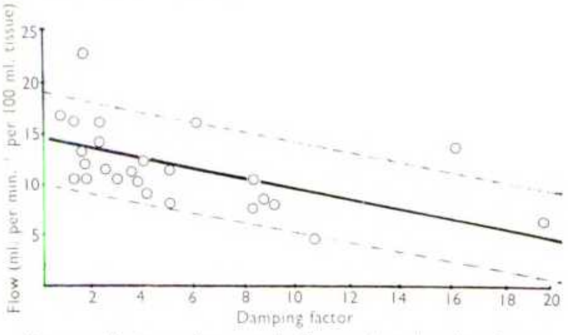

FIG. 4.—Maximum hyperaemic flow against damping factor, $r = 0·76$ and $P \leqslant 0·01$.

by an IBM 360 computer using a program written by Gosling and Goldring (1967–8).

Damping of the blood-velocity/time wave-form is quantified by the damping factor (Δ), which is defined as the P.I. value of the proximal velocity/time wave-form divided by the P.I. value of that at the distal site. In this way a single number specifies the degree of damping introduced by a section of the arterial system. The extent of the damping in an obstructed leg (abnormal) may be compared with the wave-forms from a normal, healthy subject in *Fig.* 2. In the diseased leg the input wave-form at the femoral artery is less pulsatile, i.e., more damped, than in the normal leg. This indicates atheromatous involvement proximal to the measuring site, i.e., in the aorto-iliac segment. The wave-form at the popliteal artery is hardly pulsatile at all in the diseased leg, i.e., it is considerably more damped than the femoral pulse in this leg. This damping, in addition to the longer than normal transit time between the two sites, indicates a complete block of the superficial femoral artery. This was confirmed by arteriography.

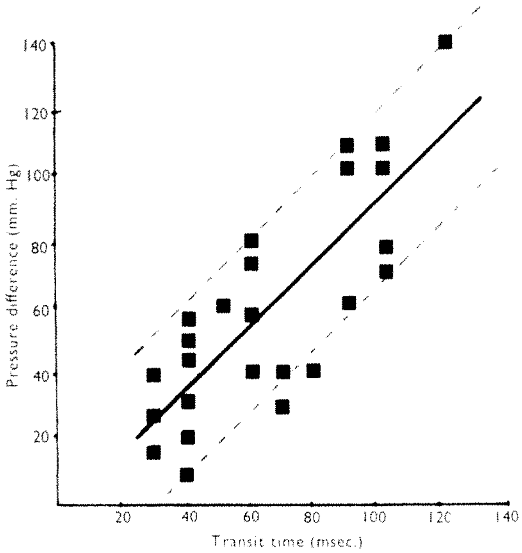

FIG. 5.—Pressure difference against transit time; $r = 0{\cdot}76$ and $P \leqslant 0{\cdot}01$.

Whole-limb perfusion was measured directly with a strain-gauge plethysmograph placed in the mid-calf position and a thigh occlusion cuff. Maximum flow was recorded under conditions of reactive hyperaemia produced by 200 mm. Hg occlusion pressure in the thigh cuff for 5 minutes while the patient exercised. As an indirect method of assessing limb perfusion the systolic pressures in both the calf and the right arm were also measured. The sphygmomanometer cuff was placed just below the knee and the posterior tibial pulse was detected by means of the Doppler-shift velocity meter. The cuff was inflated until the signal disappeared and deflated until the first flow signal was heard. This pressure is then taken as the systolic pressure in the calf. Similarly, for the arm pressure the flow signal is detected at the brachial artery. It is interesting to note that this method gives values consistently higher by about 10 mm. Hg than those obtained by listening for Korotkoff sounds.

RESULTS

Measurements were made on 25 subjects with occlusive disease of the superficial femoral artery. *Fig.* 3 shows the maximum flow in reactive hyperaemia plotted against the pulse transit time measured in conditions of normal resting flow with a supine patient. The regression line and correlation coefficient were calculated and it was found that the flow (F) in ml. per min. per 100 ml. tissue is related to the transit time (T) by the following relationship:—

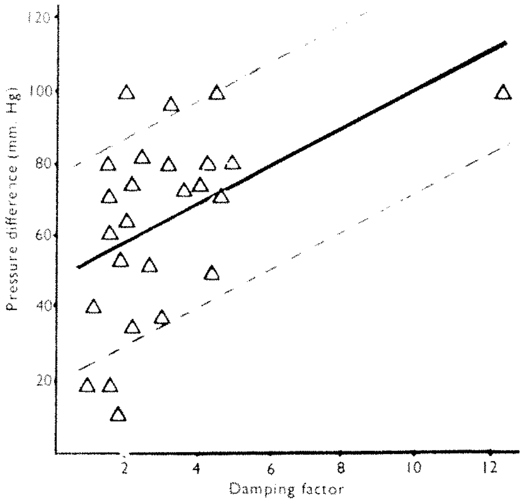

FIG. 6.—Pressure difference against damping factor; $r = 0{\cdot}4$ and $P \leqslant 0{\cdot}01$.

$$F = -0{\cdot}08T + 20{\cdot}4.$$

The results are significant to a level of probability of $P \leqslant 0{\cdot}01$.

Fig. 4 shows the maximum flow plotted against the damping factor. The regression line and the correlation coefficient were calculated and the flow is related to the damping factor by

$$F = -0{\cdot}4\Delta + 14,$$

with a level of probability of $P \leqslant 0{\cdot}01$.

In *Figs.* 3 and 4 the transit times and damping factors were measured between the common femoral and posterior tibial arteries, whilst the 'maximum flow' was measured with a strain-gauge in the mid-calf position. If the limb has additional occlusions distal to the gauge, then a longer transit time and a greater damping factor will be introduced and may therefore account for the spread of the data.

The difference, P_s, between the systolic blood-pressure measured in the arm and the systolic blood-pressure measured in the calf distal to the arterial occlusion is related to the transit time and damping in *Figs.* 5 and 6. The regression lines and correlation coefficients were calculated in both cases, giving

$$P_s = 0{\cdot}96T - 4 \quad \text{and} \quad P_s = 5{\cdot}4\Delta + 48.$$

Both sets of results are significant to a level of probability of $P \leqslant 0{\cdot}01$. These results show that as the pressure drop across the collateral increases the transit time and damping factor also increase.

DISCUSSION

The results shown here indicate a good correlation between the ultrasonic technique and the two other non-invasive methods which are frequently used to estimate the extent of peripheral arterial disease. In addition, the linear relationship found between Δ and *T* derived from the ultrasound measurements and the flow indicated by plethysmography demonstrates that it is possible to use Δ and *T* to grade limbs to levels of hyperaemic flow between 10 and 15 ml. per min. per 100 ml. tissue and to below 10 ml. per min. per 100 ml. tissue. FitzGerald, Keates, and MacMillan (1971) have shown that the maximum blood-flows in conditions of reactive hyperaemia can be divided arbitrarily into two categories which separate the more severely affected limbs, namely, flows above and below 10 ml. per min. per 100 ml. tissue. Flows above 10 ml. per min. per 100 ml. tissue are indicative of an exercise tolerance of about 250 m. or more, and flow rates below this level indicate exercising tolerance of about 50 m.

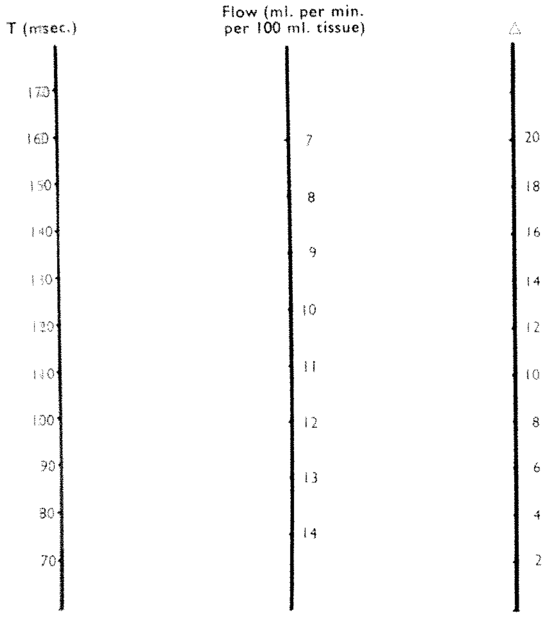

FIG. 7.—Nomogram relating the transit time and damping factor between the common femoral and posterior tibial arteries with the maximum hyperaemic flow measured in the mid-calf.

A nomogram has been constructed using the regression lines obtained for flow *F* plotted against *T*, and *F* against Δ. Thus, if the damping factor and transit time over the common femoral and posterior tibial section are measured in a patient with disease of the superficial femoral artery the flow-rate in the mid-calf region can be inferred (*Fig.* 7).

The use of the nomogram is illustrated by the following example. The transit time over the femoral and posterior tibial segment was 130 msec. for a patient with a superficial femoral block, and the damping factor over the segment was 2·5. A straight line drawn from the 130-msec. point on the *T*-axis to the 2·5 point on the Δ-axis intersects the flow-rate axis at 12·0 ml. per min. per 100 ml. tissue. The hyperaemic flow-rate actually measured with the strain-gauge was 11·5 ml. per min. per 100 ml. tissue. The standard deviation of the regression lines in *Figs.* 3 and 4 is ± 4·0 ml. per min. per 100 ml. tissue. Therefore, about 70 per cent of any flow values derived from the nomogram may be expected to lie within these limits.

COMMENT

From the foregoing we would suggest that values of Δ and *T* derived from the ultrasonic measurements can be used not only to grade the collateral arteries and to infer their elastic state, as reported elsewhere (Woodcock, 1970; FitzGerald and others, 1971a; Gosling and others, 1971), but also to indicate indirectly the actual limb perfusion. This combination of vessel-specific and whole-limb information obtained atraumatically and non-invasively from a supine resting patient makes the ultrasonic technique an attractive one for initial screening and repeated examination of patients with peripheral arterial disease.

APPENDIX

The instantaneous blood-velocity, $\bar{v}$, averaged across the cross-section of any vessel, is a function of time, and may be written $\bar{v}(t)$. One of the most simple and elegant ways of mathematically describing such a complex wave-form was first pointed out by Fourier in 1892. Thus $\bar{v}(t)$ may be regarded as a steady forward flow-velocity on which is superimposed a purely sinusoidal oscillatory flow consisting of a number of harmonic components, the first having the same period as the cardiac cycle, the second, half of this period, the third harmonic, one-third of the period, and so on. It should be noted that the net flow over one cardiac cycle owing to these oscillatory harmonics is zero. They are, however, directly related to the elasticity of the system, hence their importance.

Therefore we may write

$$\bar{v}(t) = V_0 + \sum_{r=1}^{r=n} V_r \cos(rwt - \theta_r), \tag{1}$$

where V_0 is the mean forward flow over one cardiac cycle, $V_r \cos(rwt - \theta_r)$ is the *r*th harmonic of flow-velocity and varies with time, *t*, over the cardiac cycle of period $2\pi/w$ seconds, V_r is the amplitude and θ_r the phase angle of this harmonic, and n is the number of harmonics required to give a true representation of $\bar{v}(t)$. In most experimental determinations of $\bar{v}$ the noise level of the apparatus is reached by $n \sim 10$.

In the work presented here the maximum Doppler-shift signal $\Delta \wedge f$ at any instant is taken as being proportional to $\bar{v}$, and we examine the maximum frequency envelope over one cardiac cycle, $\Delta \wedge f(t)$. Thus, we may write $\bar{v}(t) = \Delta \wedge f(t) . C$, where C is some constant of the apparatus/patient arrangement. Fourier analysis of the $\Delta \wedge f(t)$ wave-form then allows us to write

$$\begin{aligned} \bar{v}(t) &= \Delta \wedge f(t) . C \\ &= C . \Delta \wedge f_0 + \sum_{r=1}^{r=n} \mathrm{C} . \Delta \wedge f_r \cos(rwt - \theta_r). \end{aligned} \tag{2}$$

Thus, if we define P.I. as the sum of the maximum oscillatory energy of the Fourier harmonics of the flow-velocity wave-form divided by the energy of mean forward flow we have

$$\text{P.I.} \equiv \sum_{r=1}^{r=n} V_r^2 \Big/ V_0^2,$$

and on equating (1) and (2),

$$\text{P.I.} = \sum_{r=1}^{r=n} \Delta \wedge f^2 r \Big/ \Delta \wedge f_0^2,$$

the calibration constant C having cancelled out, making P.I. a function of the maximum frequency envelope which is independent of the calibration constant.

THE FATE OF AORTIC VALVE HOMOGRAFTS

AN EXPERIMENTAL STUDY

SUMMARY

Segments of homograft aortic valve cusp and aortic sinus wall have been inserted as patches in the abdominal aortic wall of sheep. The donor valves were prepared in one of three ways: (1) fresh valves, (2) freeze-dried valves sterilized with antibiotics and ethylene oxide, and (3) valves which had been cooled at a controlled rate to −70° C. in a medium containing the cryoprotective agent, dimethyl sulphoxide. Histological examination of the implanted tissue obtained at intervals up to 2 years failed to show survival of any donor cells, whichever method of preparation had been used. The elastic tissue in the freeze-dried series had become calcified by 2 years, and although valves prepared in this way appeared to elicit no immunological response, both the fresh and frozen tissue were infiltrated by lymphocytes and plasma cells by 2 weeks. This round-cell infiltration reached a peak at 4 weeks and then subsided again. The response to fresh valves was more marked and more prolonged than that to frozen valves.

WHETHER it is better to replace a diseased aortic valve with a prosthesis or a homograft remains undecided (Duvoisin and McGoon, 1969). Homografts have the advantage of a central flow path and a negligible incidence of thrombo-embolism, but problems of procurement, sterilization, and storage have restricted their popularity. Many methods of sterilizing and storing homografts destroy the cells of the valve, leaving a dead biological prosthesis (Hudson, 1966; Smith, 1967). Moreover, the elastic and collagen structures of the valve are often weakened by these same methods (Harris, Kowalik, Marks, and Malm, 1968). Dimethyl sulphoxide (DMSO) is a cryoprotective agent which has been used successfully to preserve cells and tissues at low

temperatures (Smith, 1961, 1965; Farrant, 1965a, b). This paper compares the long-term fate of aortic valve homografts in sheep; the valves which were used were either fresh, freeze-dried, or frozen in a medium containing DMSO.

MATERIALS AND METHODS

Segments of aortic valve of sheep consisting of a separate cusp and the adjacent ascending aortic wall were prepared in one of three ways:—

1. Fresh valves were obtained aseptically from sacrificed animals and were placed in normal saline at room temperature for approximately 45 minutes before being transplanted.

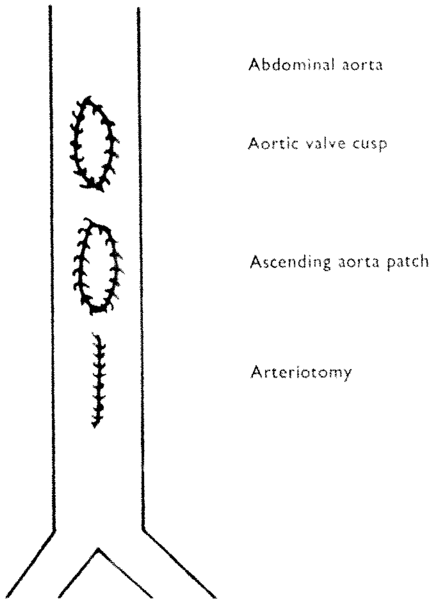

FIG. 1.—Diagram showing the types of patches which were inserted in the abdominal aorta.

2. Valves obtained from freshly sacrificed animals were either processed immediately or stored at −12° C. After trimming, the valve segments were soaked in normal saline containing penicillin, streptomycin, and nystatin for 24 hours at 4° C. before being rinsed with saline and placed in freeze-drying tubes. The tubes were filled with a mixture of ethylene oxide, 5 per cent, and carbon dioxide, 95 per cent, and the segments were left in the gas at 4° C. for a further 24 hours. After this, the tissue was flash-frozen and connected to a freeze-drying machine for 24 hours. The sealed tubes were stored at room temperature until required, when the material was reconstituted by adding sterile water at room temperature (Longmore, Lockey, Ross, and Pickering, 1966).

3. Fresh hearts were obtained aseptically immediately after death and valve segments were incubated for 30 minutes at 20° C. in a Pyrex tube containing a tissue-culture medium (Parker 199) with penicillin and streptomycin, 25 per cent calf serum, and 10 per cent DMSO. The tubes were heat-sealed and cooled at a rate of 1° C. per minute to −15° C., then at 5° C. per minute to −40° C., and then as rapidly as possible to −70° C., at which temperature the tissue was stored until required. The valve was reconstituted by warming it rapidly in a water-bath at 40° C. until all the ice had melted. The ampoule was opened aseptically and the concentration of DMSO was reduced in stages.

Young Clun Forest Cross sheep were used as the recipient animal. Under general anaesthesia an extraperitoneal approach to the abdominal aorta was made. Using a shunt within the aortic lumen to maintain distal arterial blood-flow, segments of the donor cusp and the adjacent aortic wall were inserted as patches to close holes cut in the aortic wall (*Fig.* 1). Each animal received one patch of aortic cusp and one patch of aortic wall from the same donor prepared in one of the three ways already described. No anticoagulants, steroids, or cytotoxic drugs were used.

Animals were sacrificed at 2, 4, and 8 weeks, 6 months, and 1 and 2 years after operation. On recovery of the patches, special note was made of the degree of periarterial reaction, the presence of aneurysms of the patches, the state of the intima, and whether any thrombus was present. The patches were examined histologically for general structural appearance and degree of cellular infiltration, the presence of calcification, and pyroninophilic cells. Bacterial infection was excluded with Gram's stain.

RESULTS

Eighty-eight sheep were operated on over a period of 16 months. Nine animals died either at operation or within 12 hours of operation, and 6 animals were found to be paraplegic. The combined operative mortality and morbidity in the first 20 operations was 55 per cent, and in the next 68 operations 5·8 per cent.

Gross Appearance.—*Table I* shows the incidence of gross aneurysm and abnormal dilatation of the cusp and aorta patches in the three groups at different time intervals. The freeze-dried patches show an increasing tendency to fail the longer they have been in place, while some of the fresh and frozen patches failed early. Flecks of fibrin and some areas of platelet thrombi were seen on the intimal surfaces of a few patches in the early weeks after transplantation. Thrombosis of the aorta occurred in only 3 animals, 2 of which had received freeze-dried patches, all of which had become aneurysmal. In those animals free of aneurysm formation, peri-adventitial reaction in the form of a thick layer of fibrous tissue was present in some specimens from all groups in the early weeks. The reaction was most marked in the fresh series.

Histological Appearance.—It was difficult to identify the cusp patches microscopically in many specimens even at 2 weeks, and attention was concentrated on changes in the aorta patches. Very few donor cells were seen in the freeze-dried patches at 4 weeks and those that remained were often pyknotic. Loss of cellularity was also noted in the fresh and frozen patches, but although the process continued at a slower rate than in the freeze-dried series all the patches were completely acellular by 6 months. Careful examination of the aorta patches for evidence of fibroblast proliferation failed to show convincing evidence that active tissue repair was being carried out in any of the three series of patches. Areas of collagen deposition, however, were seen in all specimens as part of the reparative process, becoming organized at the host–graft junction and on both the adventitial and intimal surfaces of the patches. New elastic fibrils were also seen in these areas, but no definite elastic lamina was ever formed. The surface of the graft in contact with the blood-stream rapidly became covered with a layer of fibroblast-like cells, and, later, collagen fibres were laid down in this pseudo-intima. Elastic tissue degeneration steadily progressed in all three groups of patches, and no particular method of preparation appeared to be advantageous. Calcification occurred almost exclusively in the freeze-dried series, all the specimens showing calcium deposits in the elastica of the aorta patches at 2 years (*Fig.* 2). In both the fresh and the frozen series the patches were surrounded by pyroninophilic lymphocytes and plasma cells by 2 weeks. This round-cell accumulation reached a peak of activity by 4 weeks and then subsided again (*Fig.* 3). The response to fresh valves was both more marked and more prolonged than that to frozen valves, but very little activity was present in either the fresh or frozen group after 6 months. Valves in the freeze-dried series did not stimulate round-cell reaction.

DISCUSSION

By placing segments of aortic valve cusp and ascending aortic wall as patches in the abdominal aorta of sheep we have used a simple model in order to obtain material for histological examination over a 2-year period. For all three methods of preparation, fresh, freeze-dried, and frozen, there is no definite histological evidence that any donor cells survive homotransplantation. Previous work has established that sterilizing with ethylene oxide and then freeze-drying arterial segments destroys the cells (Creech, DeBakey, Cooley, and Self, 1954). It has also been reported that single-leaflet aortic valve replacements in dogs retained their cellularity over a period of 2½ years (Cleveland, Madge, and Lower, 1967), and that at 12 months, female (donor) cells were present on culture from the free edge of the grafted tissue (Barnes, Mohri, and Merendino, 1968). The reason that we have been unable to confirm this is probably due to the positioning of our material as patches in the aortic wall, and also due to the difficulty in identifying the site of the cusp patch after a period of time. We have also been unable to show histologically the persistence of viable cells in fresh-tissue patches which were grafted into the recipient animal within 45 minutes of sacrifice. The aorta patches were acellular by 6 months, and although an infiltration of a few elongated cells between the elastic fibres was apparent at 1 and 2 years there was little evidence of any new elastic or collagen fibres being laid down actually in the patches, and the elongated cells were almost certainly host cells which had migrated from the edge of the patch.

The calcification of freeze-dried arterial homografts led to this method of preparation being abandoned in the late 1950's (Creech, Debakey, Cooley, and Halpert, 1956; Szilagyi, McDonald, Smith, and Whitcomb, 1957; DeWeese, Woods, and Dale, 1959), and the calcification of human aortic valve homografts prepared in a similar way was forecast by Lord Brock (1968) and has since been confirmed (Missen and Roberts, 1970). In our series, calcification occurred almost exclusively in the freeze-dried series, and all the specimens showed deposits of calcium in the aorta patches at 2 years. None of the cusp patches became calcified. Elastic tissue degeneration was steadily progressive with time in all three groups of aorta patch, and no particular method of preparation was advantageous.

Patches in the freeze-dried series elicited very little in the way of immunological activity, whereas there was a brisk immunological response, which was well developed at 2 weeks, reaching a peak at 4 weeks, and then subsiding again, in both the fresh and frozen series. The response to fresh valves was more marked and more prolonged than that to frozen valves, but very little activity was present in either the fresh or frozen group after 6 months. Complete rejection, however, does not appear to have taken place, as many patches survived the period at which immunological activity would have been at its height.

Although no direct evidence of the viability of the frozen patches is presented, the immunological response to homografts of aortic valves preserved in this way is so similar to that stimulated by fresh homografts that it is possible that the frozen grafts may have been viable at the time of transplantation. However, as it is unlikely that freshly transplanted cells survive, there seems little to be gained from transplanting living valves until tissue-matching techniques are used in the selection of donor valves or unless the immunological response is suppressed with immunosuppressive drugs. More emphasis needs to be placed on finding ways of sterilizing and preserving these biological prostheses which do not seriously reduce the durability and functional behaviour of homograft valves.

SHORT NOTES OF RARE OR OBSCURE CASES

CROSSED RENAL ECTOPIA WITHOUT FUSION ASSOCIATED WITH CARCINOMA OF THE RENAL PELVIS

A CASE REPORT

BY J. E. CASTRO AND M. HANDLEY ASHKEN
THE UROLOGICAL UNIT, UNITED NORWICH HOSPITALS, NORWICH

SUMMARY

A case of crossed renal ectopia complicated by hydronephrosis, calculus, pyelonephritis, and tumour is described. The aetiology of the complications is discussed and the incidence of tumours in non-fused, crossed renal ectopia is described.

CROSSED renal ectopia is characterized by the kidney being on the opposite side to normal and its ureter crossing the midline to enter the bladder on the correct side. In 57 reported cases the ectopic and normal kidney had not fused and in 3 of these cases the ectopic kidney contained a malignant tumour. The case presented here is the fourth case of malignant tumour in a non-fused, crossed ectopic kidney.

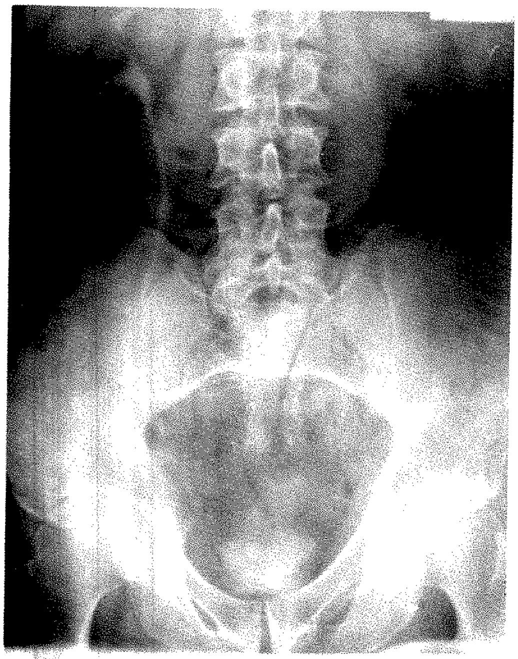

FIG. 1.—Excretion urogram to show a normal right kidney but no concentration in the left kidney.

CASE REPORT

Mr. A. E. Y., a 61-year-old builder and undertaker, was admitted in July, 1969, for investigation of 2 months' persistent haematuria in which blood was mixed with the urine. There was associated discomfort in the left iliac fossa, but no colic, loin pain, dysuria, or pyrexia. His general health was good but 6 months previously he had passed a small calculus per urethra. On physical examination the patient was obese and no organs or masses were felt; the blood-pressure was 170/110 mm. Hg.

INVESTIGATIONS.—Microscopic examination of the urine showed 1 white and 250 red blood-cells per high-power field but the urine was bacteriologically sterile. Blood-urea was 29 mg. per 100 ml. and serum electrolytes were normal. Serum uric acid was 6·6 mg. per 100 ml., corrected serum calcium 9·5 mg. per 100 ml., inorganic phosphate 3·1 mg. per 100 ml., and skeletal radiology

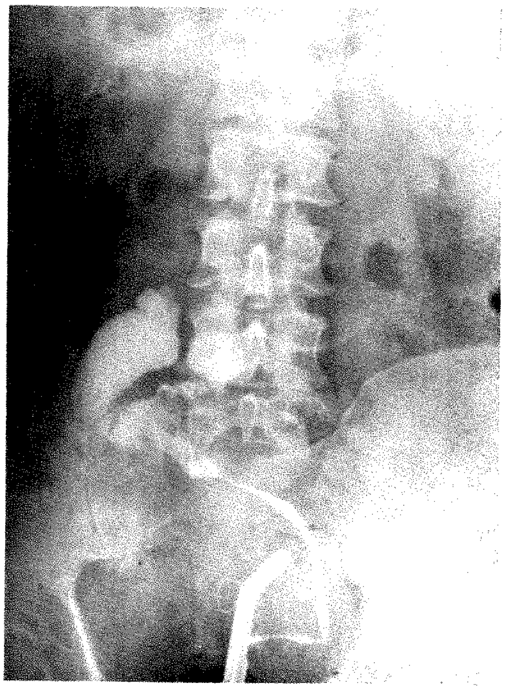

FIG. 2.—Left bulb ureterogram showing crossed ectopia of the left kidney. The ectopic kidney is pyelonephritic and hydronephrotic with a filling defect in the pelvi-ureteric junction.

showed no evidence of hyperparathyroidism. Haemoglobin was 99 per cent, the white-cell count 11,500 (with a normal differential), and the E.S.R. was 3 mm. per hour. Chest radiography was normal and excretion urography (*Fig.* 1) showed a normal right kidney but no concentration in the left kidney. Cystoscopy under general anaesthesia revealed a normal bladder and ureteric orifices. A left bulb ureterogram (*Fig.* 2) unexpectedly demonstrated crossed renal ectopia with the ectopic kidney lying in front of the right sacro-iliac joint. The kidney was small and pyelonephritic and there was a filling defect in the pelvi-ureteric junction, suggestive of a tumour or a blood-clot. A right transfemoral aortogram was carried out but failed to demonstrate the blood-supply to the abnormal kidney.

The ectopic kidney was explored through an oblique muscle-cutting incision in the right iliac fossa. An extraperitoneal approach was used and the kidney was found lying over the pelvic brim but not fused to the normal right kidney. It was small, but hydronephrotic, with a solid mass palpable at the pelvi-ureteric junction. The vascular pedicle descended from above but the origin was not clearly defined. The blood-vessels were ligated, the kidney removed, and the ureter was traced across the midline behind the mesorectum and was excised. Because of the patient's obesity a Pfannenstiel incision was necessary to remove the remaining 6 cm. of extravesical ureter, the intramural part of the ureter, and a cuff of bladder. His postoperative convalescence was unremarkable except for some infection of the nephrectomy wound. His subsequent follow-up will include urine cytology and cystoscopy.

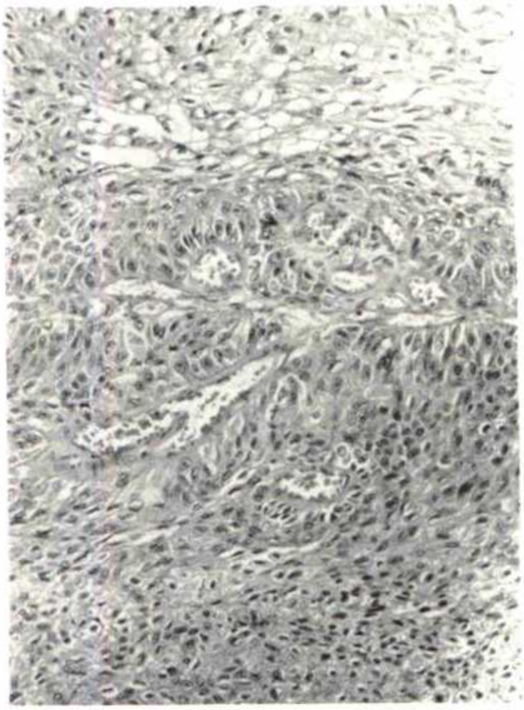

FIG. 4.—Histological section showing tumour of the renal pelvis. H. and E. (× 240).

PATHOLOGY.—The kidney was small, 9·5 × 5 × 3·5 cm. (*Fig.* 3), with reduction of renal substance and corresponding caliceal dilatation. The dilated renal pelvis contained soft grey tumour which also covered part of the caliceal mucosa and there were also tiny papillary nodules on the mucosa of the upper ureter. Histological examination (*Fig.* 4) showed a part solid and part papillary, transitional-cell carcinoma with foci of squamous differentiation. Mitoses were not very numerous but there was superficial invasion. There was no macroscopical or histological evidence of tumour in the lower ureter and microscopic examination of the kidney showed the changes of pyelonephritis.

DISCUSSION

Crossed renal ectopia was reported once in 7000 autopsies by Kretschmer (1925) and once in 5300 pyelographic examinations by Takahashi and Iwashita (Abeshouse, 1947). In most instances the normal and ectopic kidneys fuse to form one of the anatomical abnormalities described by Amesur and Singh (1963). Abeshouse (1947) reviewed the literature and found 337 such cases and later McDonald and McClellan (1957) found another 41.

Crossed renal ectopia without fusion accounts for only 10 per cent of cases (Malament and Majnarich, 1960). McDonald and McClellan (1957) found 40 cases and Pathak (1965) added a further 7. Since these reports 9 further cases have been described including the present one (*Table I*). Crossed renal ectopia of a solitary kidney has been reported in only 11 cases (Dworin, 1969).

Crossed ectopic kidneys are subject to more disease than normal kidneys (McDonald and McClellan, 1957), and the complications include infection, calculus formation, volvulus (Ranshoff, 1920), hydronephrosis (Diaz, 1953), giant hydronephrosis (Hurley and Kelley, 1969), and tumour (Lee, 1949). The present case possibly demonstrates four complications, namely, pyelonephritis, calculus formation, hydronephrosis, and tumour (it is, of course, not possible to be certain that the calculus came from the ectopic kidney).

Table II.—INCIDENCE OF TUMOUR IN CROSSED RENAL ECTOPIA WITHOUT FUSION

SEX	ECTOPIC SIDE	HISTOLOGY	AUTHOR	NO. OF CASES
M.	Left	Adenocarcinoma	Patch (1937)	1
M.	Right	Adenocarcinoma	Langworthy and Drexler (1942)	1
F.	Right	Squamous carcinoma of the pelvis	Lee (1949)	1
M.	Left	Squamous and transitional carcinoma of the pelvis	Castro and Ashken (1972)	1

Only 3 previous cases of malignant tumour in a non-fused, crossed ectopic kidney have been described (*Table II*); 2 of these were adenocarcinomas and 1 a squamous carcinoma of the renal pelvis. In the present case the tumour was in the renal pelvis and the histology was a mixture of squamous and transitional epithelia. The association of the latter with renal calculi is well established (Oberkircher, Straubitz, and Blick, 1951).

Hydronephrosis is the commonest complication of ectopic kidneys (Diaz, 1953), owing possibly to adherent blood-vessels or extrinsic pressure on abnormally placed ureters. This predisposes to infection and calculus formation, and the latter may cause squamous metaplasia and tumour of the renal pelvis. It is submitted that such a sequence occurred in the present case.

Crossed renal ectopia may be associated with spina bifida occulta (King and Holland, 1964) and solitary crossed ectopic kidney was associated with other congenital abnormalities in 9 of the 11 cases described by Dworin (1969). No congenital abnormality was found in the present case.

ADDENDUM

On follow-up Mr. A. E. Y. has had no urinary symptoms but in July, 1970, cytological examination of his urine showed neoplastic cells. Cystoscopy confirmed multiple foci of papillary tumour on the left bladder wall extending down to the bladder neck, and they were treated by transurethral resection and cystodiathermy, histology showing low-grade transitional-cell carcinoma.

A further check cystoscopy in October, 1970, showed further papillary tumour on the left bladder wall which responded well to cystodiathermy, but histology now showed evidence of superficial invasion in places so a course of cobalt-60 teletherapy was given (tumour dose 2200 rad). Further check cystoscopies have not revealed any further tumour, the last cystoscopy being in September, 1971.

AORTIC ANEURYSM FOLLOWING EXTERNAL CARDIAC MASSAGE

By C. P. MAYERS

DEPARTMENT OF PATHOLOGY, UNIVERSITY OF EDINBURGH

SUMMARY

Various hazards of external cardiac massage, such as rib fracture and bone-marrow emboli, are well known. This paper describes an unusual hazard, aortic aneurysm. The mechanism of production of this lesion differs in several respects from that of most closed-chest aortic lesions.

EXTERNAL cardiac massage must be vigorous to be successful, and this implies a high risk of complications, a risk which is usually acceptable under the circumstances. The complications have been reported by Barringer, Salzman, Jones, and Friedlich (1961), Jude, Kouwenhoven, and Knickerbocker (1961), Himmelhoch, Dekker, Gazzaniga, and Like (1964), Silberberg and Rachmanninoff (1964), Smith and Anthonisen (1965), Linko, Koskinen, Siitonen, and Ruosteenoja (1967), Roser (1967), Poulsen (1968), Fletcher (1969), and Jeresaty, Godar, and Liss (1969). Rib fractures and bone-marrow emboli have commonly been found. Other complications which have been less frequently reported have included traumatic lesions variously involving the pericardium, the pleural cavities, the peritoneum, and the abdominal viscera. Four cases of transient oliguria, 1 case of laceration of the diaphragm, and 3 cases of permanent severe brain damage have also been recorded as complications. Aortic aneurysm formation as a hazard of external cardiac massage has not been reported before.

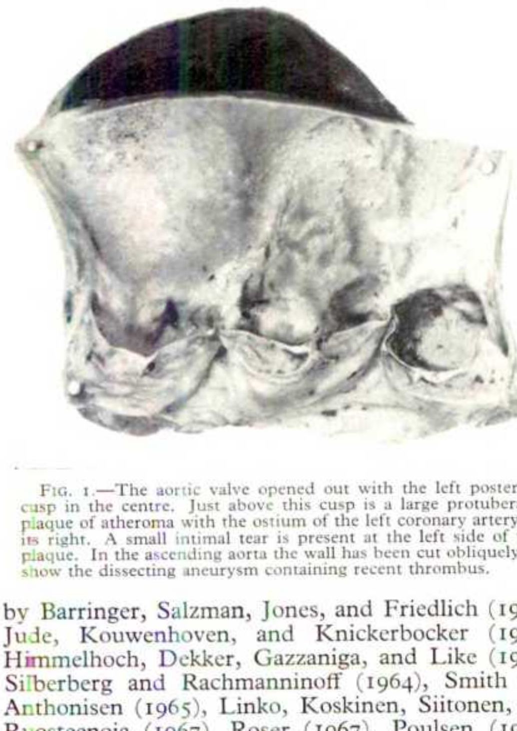

FIG. 1.—The aortic valve opened out with the left posterior cusp in the centre. Just above this cusp is a large protuberant plaque of atheroma with the ostium of the left coronary artery to its right. A small intimal tear is present at the left side of the plaque. In the ascending aorta the wall has been cut obliquely to show the dissecting aneurysm containing recent thrombus.

CASE REPORT

A hypertensive woman, aged 55 years, was admitted with a subarachnoid haemorrhage. After right brachial and left carotid angiography a bilateral frontal craniotomy was performed and clips were applied to two congenital aneurysms, each about 5 mm. in diameter, on the right anterior and on the left posterior communicating arteries.

The patient did not fully regain consciousness after the operation, and later became unconscious. Severe brain oedema developed. External cardiac massage was required, and cardiopulmonary resuscitation was initiated. She was subsequently maintained on a ventilator for 24 hours, after which time an iso-electric electro-encephalographic pattern was found. There was no spontaneous breathing when the ventilator was switched off.

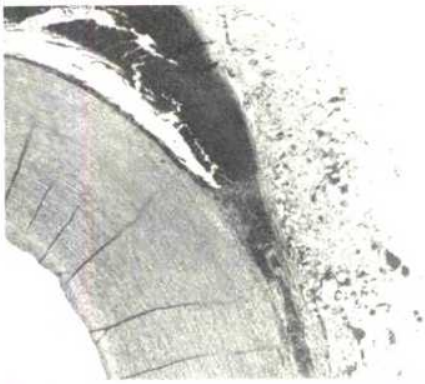

FIG. 2.—A section through the wall of the ascending aorta at the margin of the dissecting aneurysm. The aorta shows degeneration of the medial lamina, particularly in the outer third where the aneurysm has separated it into two layers. H and E. (× 17.)

NECROPSY SUMMARY.—

1. The presence of two clipped aneurysms was confirmed. There was gross herniation of the frontal lobes at the craniotomy site. The cerebral hemispheres, brainstem, and cerebellum were soft and swollen, and serial coronal sectioning showed recent, widespread, patchy, ischaemic damage in all areas and in all arterial territories.

2. Superficial bruising of the anterior chest wall was present, without fracture of the ribs or costochondral separation. There was also some bruising in the adventitia of the pulmonary trunk just above the pulmonary valve ring.

3. A recent dissecting aneurysm was present in the medial lamina of the wall of the ascending aorta (*Fig.* 1). It extended from just above the anterior aortic valve sinus upwards and posteriorly to involve the whole of the posterior wall of the aortic arch, and extended between 1 and 3 cm. along each of the three major branches of the aortic arch. It was also noted that the medial lamina was weak, and that further separation of the layers of the medial lamina could readily be produced by blunt dissection.

A small 4 × 1-mm. triangular intimal tear which communicated with the aneurysm was present on the left side of the anterior aortic valve sinus just above the level of the valve cusp and at the edge of a 1-cm. calcified and protuberant plaque of atheroma.

4. Widespread and severe patchy atheromatous degeneration was present in all the major arteries.

5. There was moderate hypertrophy of the myocardium of the left ventricle.

There were no macroscopic or microscopic features to other conditions that may be associated with aneurysm formation, such as Marfan's syndrome, coarctation of the aorta, syphilitic aortitis, or pregnancy.

HISTOLOGICAL FINDINGS.—The sections of the aorta showed atheromatous thickening of the intima, together with degeneration of the medial lamina (*Fig.* 2). The aneurysm was between the inner and outer layers of the medial lamina and contained recent unlaminated thrombus, with only slight reactive changes at the margins.

None of the sections showed any evidence of bone-marrow emboli.

DISCUSSION

The site of the intimal tear at the edge of a large, unbendable, atheromatous plaque and the presence of bruising in the anterior chest wall and around the root of the pulmonary trunk suggest that the precipitating cause of this lesion was compression of the inflexible great vessel against the vertebral column. The presence of necrosis in the medial lamina of the aorta presumably facilitated subsequent dissection from the intimal breach. The mechanism of production in this case differs in several respects from that of most closed-chest aortic lesions, which are mainly found in young atheroma-free adults who have been injured in road-traffic accidents. In such cases the lesions appear to be due to fixation and stretching of the thoracic aorta (Parmley, Mattingly, Marion, and Jahnke, 1958; Sevitt, 1968).

The possibility that the lesion in the present case had been produced by arteriography was investigated. Discussion with the radiologist revealed that the catheters which had been inserted for arteriography had extended only as far centrally as the right brachial artery and the bifurcation of the left common carotid artery. At no time had the catheters reached as far as the right subclavian artery or the main part of the left common carotid artery, and this possibility was therefore discounted.

The histological appearance of recent thrombus with only early reactive changes at the edges suggested that the haemorrhage must have occurred at about the time that external cardiac massage was applied. It would be an improbable coincidence of events if the lesion was to be regarded as having arisen spontaneously.

Acknowledgement.—I am grateful to Mr. E. R. Hitchcock, Department of Surgical Neurology, Western General Hospital, Edinburgh, for permission to publish this case.

LEIOMYOMA OF THE OESOPHAGUS WITH CALCIFICATION

BY PHILLIP HUDDY AND GORDON GRIFFITHS
PRINCESS MARGARET HOSPITAL, SWINDON

SUMMARY

The successful removal of a leiomyoma of the oesophagus in a man aged 64 years is described. The exceptional feature was the presence of calcification within the tumour which is almost unknown. The differential diagnosis from extrinsic causes which produce a similar appearance is discussed in view of this misleading feature. A brief general description of the clinical, radiological, and surgical aspects of leiomyomata of the oesophagus is given.

LEIOMYOMA of the oesophagus is a rare tumour and up to 1968 only about 200 cases had been recorded. Flavell (1953) records that Sussins in 1559 was the first to describe a case. Deverall (1968) reports that 876 carcinomata of the oesophagus and only 12 leiomyomata occurred in his department in a 23-year period, an incidence of 1·5 per cent. The tumours may rarely be multiple and Storey and Adams (1956) report their occurrence in about 7 per cent of cases while Allison (1967) mentions multiplicity in association with Schatzki's ring. The tumour may appear in any part of the oesophagus, but the lower third is the commonest site. Johnston, Clagett, and McDonald (1953) report 53 per cent in the lower third, 35 per cent in the middle third, and 12 per cent in the upper third. This latter figure is of interest because of the muscular layers of the upper third. *Gray's Anatomy* recalls 'in the upper quarter, both layers consist of striped muscle, in the second quarter bundles of smooth muscle appear and these gradually replace the striped muscle more caudally'.

The unusual and misleading feature of this case was the presence of stippled calcification; this is almost unknown.

CASE REPORT

A male patient aged 64 was admitted to the Princess Margaret Hospital, Swindon, on 5 Nov., 1968, with a history of intermittent hoarseness and indigestion for 2 years, and central retrosternal pain for 3 months with a sensation of food sticking at the back of the throat. On examination he had minimal clubbing of the fingers but no other abnormal physical signs. The blood-pressure was 140/90, haemoglobin, 106 per cent, and W.B.C., 9300.

On 30 and 31 Oct., barium swallows were carried out followed by tomography.

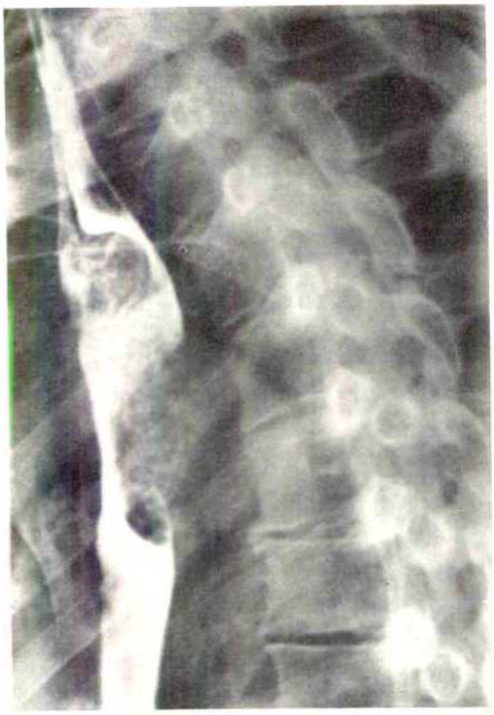

FIG. 1.—Barium swallow showing a filling defect but no obstruction caused by a mass which showed marked stippled calcification.

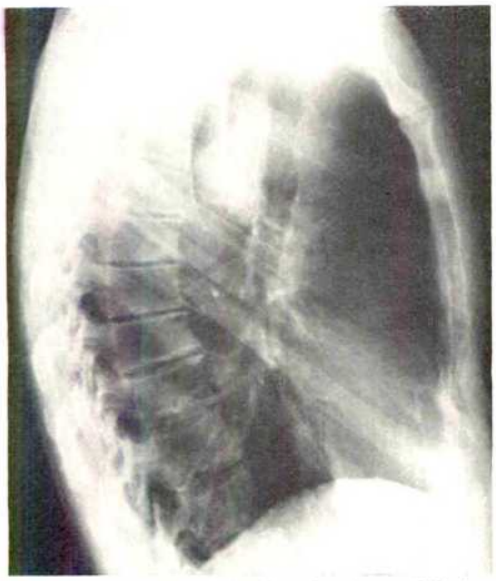

FIG. 3.—Lateral view of the chest showing a calcified mass lying immediately posterior to the trachea above the bifurcation. The dorsal spine appears normal apart from slight lipping. The lung fields appear clear.

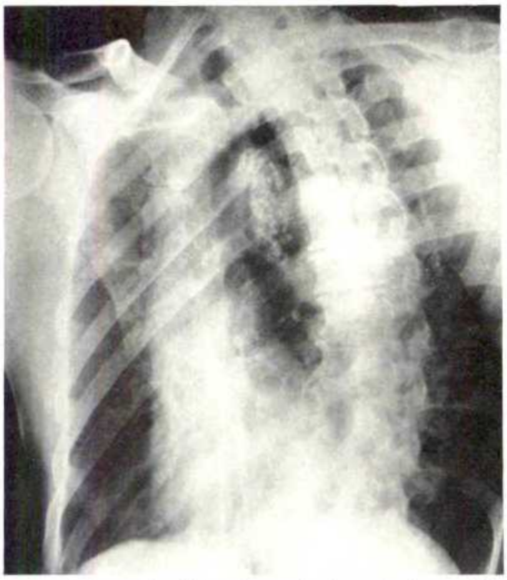

FIG. 2.—Left anterior oblique view of the chest showing a calcified mass lying in the upper mediastinum.

These investigations showed that there was a filling defect approximately 7 cm. in length (*Fig.* 1) on the antero-lateral aspect of the oesophagus close to the aortic knuckle. In this area the oesophagus was dilated and the filling defect exhibited marked stippled calcification (*Figs.* 2, 3). The defect did not move on swallowing and it did not show pulsation. It was thought that the mass was somewhat nodular superiorly. The upper and lower extremities of the filling defect were clearly defined, and a general impression was gained that the filling defect was probably either within the lumen or in the wall of the oesophagus, rather than outside. The tomographs showed that the calcification apparently fused with the oesophageal shadow, suggesting that the tumour might actually be within the oesophageal wall. The first reaction to this filling defect was that it was a neoplasm, but the presence of calcification was unknown and other causes outside the oesophagus were considered. It was thought not to be vascular as there was no pulsation and the type of calcification did not suggest a dermoid. A neurofibroma was considered in view of a lump on the left forearm but, on 13 Nov., it was excised and shown to be a lipoma. Other possibilities considered were a hamartoma or a calcified abscess, but there was no abnormality seen in the adjacent spine or lung fields.

On 6 Nov., oesophagoscopy was carried out and 25 cm. from the top of the oesophagus there was a lesion consisting of two lumps both bulging into the left wall of the oesophagus with a slightly yellow appearance and thought to be covered with normal oesophageal mucosa. They were non-pulsating and they were not hard. The oesophagus below was quite normal. A biopsy of the mucosa was taken which was shown to be normal. Bronchoscopy was carried out on 13 Nov., by Dr. J. Waddell, which showed a normal trachea with slight bulging of the posterior wall with possibly slightly anticlockwise rotation of the carina. The bronchi looked normal; no biopsy was taken.

On 27 Dec. the patient was admitted to the London Hospital under Mr. Geoffrey Flavell, and was operated on on 1 Jan., 1969. He had been of the opinion that, although the filling defect looked exactly as one sees in a leiomyoma, calcification of oesophageal leiomyomata appears to be unrecorded, although it does occur in uterine fibroids. He considered the most likely diagnosis was a mass of calcified glands or possibly a bronchogenic cyst or true ectopic thyroid. He did not think it was vascular.

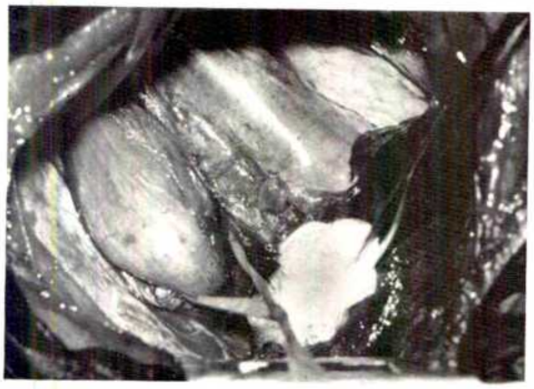

FIG. 4.—Fusiform swelling demonstrated at operation distending the upper oesophagus.

At operation the patient was explored through the right chest and a fusiform swelling of the upper oesophagus, which was crepitant to the touch and clearly calcified, was found (*Figs.* 4, 5). It was thought that this might have been a haemangioma, but when the muscle coat was incised, a white fusiform tumour partly encircling the mucosal tube shelled out with great ease and had all the macroscopic characters of a leiomyoma.

On section of the material, calcified areas up to 3–4 mm. in diameter were demonstrated, situated in an oedematous ground substance which contained scanty cells, singly or in bundles, some of which had nuclear characteristics of smooth muscle, together with other cells which appeared to be fibroblasts (*Fig.* 6).

The patient was discharged on 11 Jan., having completely lost his dysphagia, and is well at the present date.

DISCUSSION

The sex distribution of these rare tumours has been reported as a 2 : 1 ratio of males to females by Gilfillan (1966), but in the pooled reported cases of Barrett (1964), Glanville (1965), Deverall (1968), Engelmann and Scialla (1968), and ourselves, there were 15 males to 16 females.

The diagnosis may be puzzling and treatment may be difficult (Glanville, 1965). The presenting symptom is variable, the majority presenting with dysphagia, retrosternal pain, or reflux, although Barrett (1964) states that 50 per cent are symptomless. More unusual is the presence of bleeding. Respiratory symptoms occur occasionally presumably due to the 'spill over' phenomenon. Weight-loss may be marked, as occurred in 2 of Glanville's cases. Its presence does not necessarily signify malignancy as it may be due to starvation. Cases have been recorded of leiomyomata being on long pedicles appearing in the mouth and then disappearing again. They may also present in the fundus of the stomach. At the lower end of the oesophagus they may be associated with hiatus herniation, oesophagitis, and subsequent ulceration and haemorrhage, and the presence of such associated conditions make the diagnosis in the lower third more difficult than in the middle third (Deverall, 1968). A leiomyoma may be discovered incidentally at thoracotomy carried out for another lesion.

Radiologically, leiomyomata usually present as mediastinal shadows or as well-defined filling defects of the oesophagus. The findings may be bizarre as some tumours become very large and the mediastinal shadow is due to a combination of the tumour itself and the dilated oesophagus above. The mediastinal shadow, however, may be only very small and barely perceptible (Deverall, 1968).

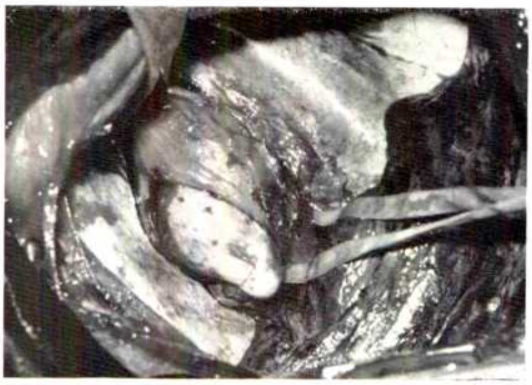

FIG. 5.—Calcified leiomyoma, crepitant to the touch, protruding through the incised oesophagus.

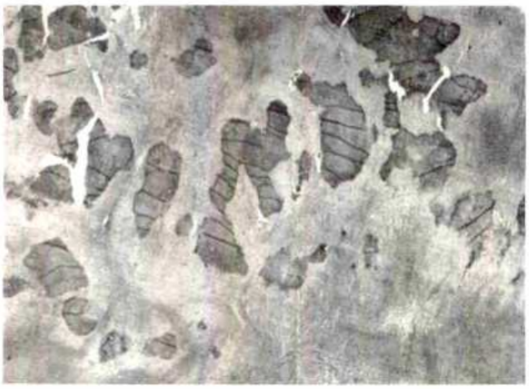

FIG. 6.—Section of the leiomyoma showing calcified areas up to 3–4 mm. in diameter lying in an oedematous ground substance together with cells having nuclear characteristics of smooth muscle with fibroblasts. (× 4.)

Leiomyomata may be either pedunculated or intramural. A pedunculated tumour may move up and down. Hence it may be difficult to diagnose and radiographic examination in the head-down position may be helpful (Barrett, 1964; Glanville, 1965; Deverall, 1968). The intramural tumours may become large and encroach on the lumen of the oesophagus, stretching the oesophagus over the tumour and producing dilatation. Dysphagia is not produced by this, but certain intramural tumours encircle the oesophagus and as soon as this occurs dysphagia supervenes. These cases are often mistaken for a carcinoma (Barrett, 1964). At the lower end of the oesophagus the condition may be mistaken for achalasia, owing to the dilatation (Shanks and Kerley, 1959). Conversely, the presence of a leiomyoma may be related to the failure of hiatal function (Deverall, 1968).

The case recorded here presented with almost all the radiological features of an intraluminal leiomyoma, the exceptional feature being the presence of calcification. On screening one had the impression that there was a lobulated mass within the oesophagus, the extent of the calcified mass corresponding with the filling defect. The dilatation of the oesophagus and the clearly defined diverging and converging folds of mucous membrane above and below the tumour were typical. It did not, however, move on swallowing which one usually finds in a leiomyoma of the upper oesophagus. There was no pulsation which made a vascular cause and an aberrant vessel unlikely.

It may be extremely difficult to distinguish between an intrinsic and an extrinsic tumour especially if the latter is fixed to the oesophagus by adhesions (Harper and Tiscenco, 1945). Shanks and Kerley (1959) illustrate an example of an abscess due to tuberculous glands, the pressure of which produced a filling defect on the oesophagus, exactly similar to that of a leiomyoma.

The two essential investigations are barium swallow and oesophagoscopy. Oesophagoscopy must complement the barium swallow to confirm or correct the diagnosis as differentiation from carcinoma may be very difficult and it is essential that the correct diagnosis is established to enable the correct surgical approach to be made (Gilfillan, 1966). A leiomyoma may also occur in association with other conditions, including a carcinoma (Barrett, 1964). Storey and Adams (1956) report that 7 cases out of 63 leiomyomata were diagnosed as carcinoma, and presumably they were treated accordingly. Carcinoma may present as an apparent leiomyoma as in 2 cases of Engelmann and Scialla (1968). Oesophagoscopy and biopsy corrected the impression of a leiomyoma demonstrated at barium swallow. The converse may also occur and Gilfillan (1966) reports a case which was thought to be a carcinoma radiologically but which subsequently proved to be a leiomyoma. Ulceration in a carcinoma may be minute. Enlarged mediastinal glands caused by malignant infiltration from a carcinoma may produce smooth filling defects on the oesophagus which simulate primary carcinoma and, conversely, large glandular masses may arise owing to associated non-malignant hyperplasia, simulating malignant glands macroscopically. Microscopic calcification may occur (Gilfillan, 1966; Pawlowski, 1966; Deverall, 1968). This is not surprising histologically as leiomyomata are very much like uterine fibroids which calcify fairly commonly. Unlike fibroids, however, the degree of calcification does not assume macroscopic proportions. Barrett (1964), however, describes a case in a woman of 60 years with a calcified leiomyoma at the lower end of the oesophagus which produced dysphagia and vomiting after meals owing to obstruction. This was clearly demonstrated radiologically on plain films.

Bronchoscopy is usually carried out to exclude bronchial lesions producing pressure.

At oesophagoscopy, in this particular case, the instrument passed easily down the lumen, the mucosa was seen to be intact, and a yellowish swelling was seen bulging into the left wall.

We can foresee difficulty in making a diagnosis in obstructive cases, where the submucosal spread of a carcinoma often holds up the instrument and makes visualization at biopsy difficult or impossible. The question of biopsy of a leiomyoma is of doubtful value, when a carcinoma can be excluded, because it may destroy the plane of enucleation of a tumour and make perforation at operation more likely.

Treatment of these tumours should usually be by their removal, presuming the patient to be fit. Three principal methods are available. Enucleation with repair of the muscle wall is the ideal method for most cases because it involves little local trauma and the mortality is low. For pedunculated lesions the best method of removal is probably by oesophagotomy with excision of the tumour at the base of its stalk. Thirdly, if there is a likelihood of the tumour having undergone malignant change (which is a rare complication) or if there is doubt about the diagnosis, resection and reconstruction is the method of choice.

Acknowledgements.—We wish to thank Mr. Geoffrey Flavell for access to, and inclusion of, his operative notes and comments on this case, and for his help in the preparation of this paper.

We would also like to thank Dr. Robert Martlew for his comments on the section, Mrs. Sheila Huddy and Miss B. Griffiths for their secretarial help, and the Photographic Departments of the London Hospital, and the Princess Margaret Hospital, Swindon, for their help with the illustrations.

A CASE OF TRAUMATIC RUPTURE OF THE THORACIC AORTA ASSOCIATED WITH HYPOTHERMIA

By M. R. THOMPSON
THE ROYAL INFIRMARY, SHEFFIELD

SUMMARY

This communication reports a case of traumatic rupture of the thoracic aorta. The literature on this subject is reviewed, the problem of diagnosis is discussed, and the importance of acute hypertension as a diagnostic sign is stressed. In view of the fact that the hypertension in the case reported here occurred in the presence of good femoral pulses and persisted after operation, the cause of the hypertension may not be simply an acute coarctation syndrome but may be due to damage to the cardiac plexuses around the site of rupture. It also emphasizes the importance of not rewarming severely traumatized hypothermic patients until facilities are available to replace blood-loss.

TRAUMATIC rupture of the thoracic aorta usually occurs adjacent to the ligamentum arteriosum in young males, and is associated with accidents involving rapid deceleration. It is surprising that many survive this injury. Strassmann (1947) reported 18 per cent surviving 1–18 hours, and Parmley, Mattingly, Marion, and Jahnke (1958) reported 19 per cent surviving from 24 hours to 10 weeks. It is probable that the incidence of this condition will increase with the development of high-speed travel.

As aortic rupture is often associated with other severe injuries the diagnosis may not be made immediately. However, as it is particularly amenable to surgical repair (Gerbode, Braimbridge, Osborn, Hood, and French, 1957; Eiseman and Rainer, 1958; Spencer, Guerin, Blake, and Bahnson, 1961; Dobell, MacNaughton, and Crutchlow, 1964; Jahnke, Fisher, and Jones, 1964; McKnight, Meyer, and Neville, 1964; Schonholtz and Jahnke, 1964; Bromley, Hobbs, and Robinson, 1965; McClenathan and Brettschneider, 1965; Rey Balter, 1965; Alley, 1966; Beall, Arbregast, Hallman, and Cooley, 1967; Clarke, Brandt, Cole, and Barratt-Boyes, 1967; Kiser, 1968; Keen, Brabrook, and McGinn, 1969; Malloy, 1970) there should be a high index of suspicion of aortic rupture in high-velocity accidents so that an early diagnosis can be made.

CASE REPORT

A 19-year-old university student was buried under a pile of rocks after falling about 9 m. while pot-holing in Derbyshire.

During his rescue from the caves the general practitioner in charge of the operation decided against using a rubber protection suit, being in favour of getting the patient out of the cave as quickly as possible.

On admission to the Sheffield Royal Infirmary Casualty Department 8 hours after the fall the patient was chilled, shivering, and had peripheral cyanosis. He was covered with minor lacerations and abrasions, but there was no external evidence of severe injury. On examination his pulse was 120 per minute, his blood-pressure was 90/40, and his rectal temperature was 32·2° C. He was tender on compression of the chest and had minimal physical signs in the left chest. He was tender in both hypochondria, and bowel-sounds were absent. Radiographs showed a crack fracture of the ilium on both sides and avulsion of the transverse process of the third lumbar vertebra.

The patient was transferred to the ward and was slowly warmed with blankets. Six hours after admission his temperature was 38·4° C., his blood-pressure had fallen to 80/50, and his pulse was 120 per minute. At this time he was becoming dyspnoeic and was developing physical signs of a left haemopneumothorax, which a chest radiograph confirmed. After transfusion with 400 ml. of plasma, his blood-pressure rose to 110/60 and he was transferred to the operating theatre.

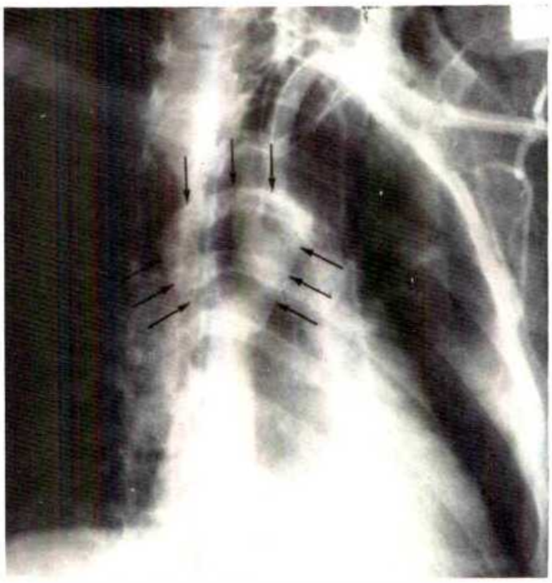

FIG. 1.—Aortogram showing an aneurysm just distal to the left subclavian artery.

A left-sided anterolateral chest drain was inserted and a left paramedian abdominal incision was made. A ruptured spleen was removed and a ruptured liver was repaired.

Postoperatively the patient was at first greatly improved. However, 3 days after the operation he had developed a collapsing pulse with a blood-pressure of 200–190/60. He had also developed a systolic murmur over the left scapula region, and a chest radiograph showed widening of the mediastinum and cardiomegaly. There were good femoral pulses on both sides.

Four days after admission the heart continued to increase in size, the systolic murmur was louder and could be heard in the lumbar region, and the left hypochondrium and the blood-pressure continued to be raised. The blood-pressure varied from recording to recording, involving mainly the systolic reading with a correspondingly high pulse-pressure. An aortogram was then performed (*Fig.* 1) and this showed an aneurysm of the aorta, distal to the left subclavian artery. At thoracotomy there was a complete tear of the aorta at the usual site just below the left subclavian artery. The aneurysm was resected and a Teflon graft was inserted.

Postoperatively the patient made a good recovery but his blood-pressure remained raised and varied between 200/60 and 140/80. At the time of his discharge, 5 weeks after admission, his blood-pressure was fairly stable at 140/80.

Present case	200/60	180/60	Femoral pulses at first normal, becoming weaker

* This case was complicated as the patient was pregnant and had a previous history of mild hypertension.

DISCUSSION

The patient arrived at the hospital 8 hours after sustaining a ruptured spleen, liver, lung, and aorta. His initial shocked state was due to trauma, blood-loss, and hypothermia. The peripheral vasoconstriction secondary to hypothermia probably helped to maintain his blood-pressure.

Slow rewarming may result in cutaneous vasodilatation and a fall in arterial blood-pressure, because of the shunting of a considerable proportion of the cardiac output into the periphery (Cooper and Ross, 1960). This would have been particularly dangerous in this case and the decision not to stop the journey to dress the patient in a rubber exposure suit may have saved his life.

McClenathan and Brettschneider (1965), in a discussion of traumatic aortic rupture, list the following points which should make one wary of this condition. The first four were present in the case described here.

1. A history of horizontal deceleration and chest pain even without external injury to the chest.
2. Widening of the mediastinum on chest radiographs.
3. The development of a soft systolic murmur heard over the lower thoracic or lumbar vertebrae.
4. Unexplained haemopneumothorax.
5. Development of an acute coarctation syndrome.

All these points suggest the advisability of carrying out angiograms. McClenathan and Brettschneider (1965) also stress that the key to the treatment of this condition is a high index of suspicion, early diagnosis, and surgical repair in all cases.

Eiseman and Rainer (1958), Malm and Deterling (1960), and Jahnke and others (1964) have described cases associated with hypertension, and Laforet (1965) has suggested that acute hypertension with a coarctation syndrome is probably caused by aortic obstruction at the site of rupture. However, as the case described here had hypertension both before and after operation and associated with normal femoral pulses it would suggest that raised labile systolic hypertension, not necessarily associated with an acute coarctation syndrome, should be added to the points of McClenathan and Brettschneider (1965) in helping to make a diagnosis. *Table I* lists other reports of cases of acute hypertension associated with traumatic rupture of the thoracic aorta.

The aetiology of the hypertension may be, as suggested by Rice and Wittstruck (1951), due to local segmental spasm of the aorta and/or reflex irritation of the cardiac plexuses which are related to the site of rupture. The latter would explain the persistence of hypertension for some time after the repair.

Acknowledgements.—I would like to thank Mr. Clifford Jones and Mr. A. G. Norman for permission to publish details of this case, Professor M. A. Epstein for his helpful criticism, and Miss R. E. Menheneott for secretarial services.

THE NON-ABSORBABLE CYSTIC DUCT LIGATURE

BY A. GUNN

SENIOR REGISTRAR, MANCHESTER ROYAL INFIRMARY

SUMMARY

A case is reported of a common bile-duct calculus which had formed around a non-absorbable cystic duct ligature used during cholecystectomy 6 years previously. Although there are advantages in the use of the non-absorbable cystic duct ligature, the risk of migration to the common duct and consequent stone formation is probably greater than is recognized.

POST-CHOLECYSTECTOMY choledocholithiasis is usually due to stones which were present at the original operation. However, stones may form around non-absorbable sutures used to close a choledochotomy and for this reason absorbable sutures are generally used for this purpose. The occurrence of common-duct stones around non-absorbable cystic duct ligatures which have migrated into the common duct is less widely appreciated, and random personal inquiries amongst registrars revealed that non-absorbable cystic duct ligatures are still used by many surgeons throughout Britain, in some centres more so than in others. In Scandinavia, however, Milbourn (1949) reported 2 cases of common-duct stones which had formed around silk ligatures used during cholecystectomy, and further cases have been reported in Scandinavia by Silvennoinen and Asp (1956) and Ahleberg (1959). Recently, Sigler and Sahler (1969) reported a case in America of a common bile-duct calculus with a silk cystic duct ligature as a nidus.

A case is reported of a common bile-duct calculus in association with a thread cystic duct ligature used during cholecystectomy 6 years previously, and attention is drawn to this complication of non-absorbable cystic duct ligatures.

CASE REPORT

A 49-year-old multiparous woman had a cholecystectomy in September, 1964, the cystic duct and artery being ligated with thread. There was no history of jaundice and the common bile-duct looked and felt normal although an operative cholangiogram was not performed. Postoperatively she developed clinical and radiological evidence of a right subphrenic abscess which settled on conservative treatment and she was discharged home 1 month after the operation.

The patient was readmitted to Manchester Royal Infirmary in May, 1970, with an 18-month history of intermittent severe pain in the right hypochondrium, radiating to the right scapular region. On closer questioning she said that she had suffered an occasional mild ache in the right hypochondrium ever since the previous operation. She had passed dark urine during attacks of the pain. The serum alkaline phosphatase was raised at 21 K.A. units per 100 ml. and a drip-infusion cholangiogram showed a dilated common bile-duct.

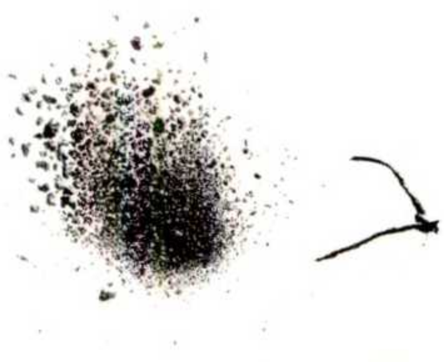

FIG. 1.—The fragmented stone removed from the lower end of the common bile-duct together with a thread ligature.

At laparotomy on 13 May a dilated common bile-duct of 1·5 cm. was confirmed by an operative cholangiogram with a filling defect in the lower duct. The common bile-duct was opened and a fragmented stone was removed from its lower end together with a thread ligature (*Fig.* 1). A transduodenal sphincteroplasty was performed and the duct was flushed with normal saline. The patient made a smooth postoperative recovery and the T-tube was removed on the eleventh day after a cholangiogram had shown no residual stones. She was well and symptom-free 5 months after the operation.

DISCUSSION

Sigmoidoscopic examination often reveals the extrusion of non-absorbable serosal ligatures into the lumen of the rectum after an anterior resection (Goligher, 1967), and presumably cystic duct ligatures may similarly migrate into the common bile-duct. This may be helped by necrosis of the cystic duct stump, and Sigler and Sahler (1969) postulate that local infection predisposes to this event. Certainly in the case reported here there was evidence of a subphrenic abscess.

Many surgeons prefer a non-absorbable ligature for the cystic duct because of its superior knot-holding qualities and the sometimes serious consequences of a leaking cystic duct stump. The occurrence of common-duct stones in association with non-absorbable cystic duct ligatures, however, is probably more common than is recognized, and Ahleberg (1959) gives an incidence of at least 0·6 per cent. The recent introduction of an absorbable material with improved handling and knot-holding properties (polyglycolic acid) may prove an effective compromise.

Acknowledgement.—I am indebted to Mr. W. F. Nicholson for permission to report this case admitted under his care.

REVIEWS AND NOTICES OF BOOKS

Transplantation Today. Edited by Hans Balner, D. W. van Bekkum, The Netherlands, and Felix T. Rapaport, New York. 10 × 6¾ in. Pp. 978. Illustrated. 1971. New York: Grune & Stratton Inc. $25.

This large volume contains the Proceedings of the Third International Congress of the Transplantation Society, which was held at The Hague, The Netherlands, in September, 1970.

The volume is dedicated to Sir Peter Medawar, and there is a pleasing photograph of Sir Peter at the commencement of the book.

The volume is a truly international production and papers from all the important centres are included in this book.

Professor R. Y. Calne, of Cambridge, contributes an interesting paper on Antigen-induced Immunosuppression for Organ Grafting, in which he gives a selective review on this subject.

As one would expect in a work such as this, the various chapters are equally divided between animal experimentation and human material.

The preservation of organs and tissues is discussed at length. The mode of action of antilymphocyte sera (ALS) is considered in some detail.

This book is most comprehensive in its outlook and every facet of this important subject has been covered.

There is an extended author index at the end of the book.

This book will have a wide appeal and will remain the reference volume *par excellence* for some years to come.

Ischemic Forms of Venous Thrombosis. By Henry Haimovici, M.D., New York. 9 × 6 in. Pp. 230 + x. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $23.

This is a useful monograph on a rather neglected subject, for venous gangrene or gangrene due to venous occlusion is not well documented in world medical literature.

From the surgical point of view, postoperative ischaemic thrombophlebitis includes phlegmasia caerulea dolens and venous gangrene. The former is likely to occur after operations on the gastro-intestinal tract and the latter after operations within the pelvis.

Professor Haimovici has put the medical profession in his debt by publishing a comprehensive and detailed review of the well-documented published cases. This book will be of great assistance to anyone who wishes to do some further research work on this subject.

There seems to be very little consensus of opinion as to the best method of treatment for these forms of venous thrombosis. Sympathetic blocks and anticoagulants are advocated, and so is thrombectomy, local excision, and skin-grafting. Whatever treatment is advocated, a considerable proportion of patients will require amputation, and this is not without risk.

This is an excellent reference volume on this not too well-known condition.

Fortschritte der Kiefer- und Gesichts-Chirurgie. Edited by K. Schuchardt, Hamburg. 10½ × 7⅝ in. Pp. 290. Illustrated. 1970. Stuttgart: Georg Thieme Verlag. DM.156.

This volume on faciomaxillary surgery is one of a series of annual productions. This particular volume deals with the diagnosis and treatment of mesenchymal tumours and hyperplastic lesions of the mouth, jaw, and face. The volume contains no less than forty-four separate papers presented by different authors, many of which are case reports or reports of a small series. However, malignant lesions such as sarcoma are dealt with in detail. Each chapter has an extensive list of references and there is a full summary not only in English but also in French and Spanish. Although there is no statement to the effect, the final section dealing with discussion suggests that this volume is in fact the report of a meeting. Unfortunately, all the discussions had been collected at the end of the book and it might have been more helpful to have the relevant discussion at the end of each chapter. The volume is beautifully produced with a large number of high-quality photographs, and although expensive it should be available to all those specializing in faciomaxillary surgery.

Surgery for Nurses. Twelfth edition. By JAMES MORONEY, M.B., Ch.B., F.R.C.S., L.R.C.P., Consultant Surgeon, Broadgreen Hospital, Liverpool. 8½ × 5½ in. Pp. 632 + x. Illustrated. 1971. Edinburgh: E. & S. Livingstone. £2·75.

THE popularity of this book speaks for itself—twelve editions in 20 years is a great achievement for any author. This new twelfth edition has been extensively revised and rewritten and many new illustrations have been added.

The book provides an excellent, well-illustrated up-to-date text for student nurses. This book will help nurses pass their Final State Examination, and will prove as popular as former editions.

Pathogenese und Klinik des akuten Nierenversagens. Edited by ULRICH GESSLER, KARL SCHRÖDER, and HORST WEIDINGER, Nürnberg. 9 × 6 in. Pp. 261 + x, with 138 illustrations. 1971. Stuttgart: Georg Thieme Verlag. DM.42.

THIS is a report of a symposium held in December, 1969, and deals with the aetiology and clinical picture of renal failure. Twenty-eight separate papers dealing with pharmacology, animal experiments, and various forms of treatment are discussed and each paper has an appended discussion reported in full. A large number of the papers are published in English, and those published in German have a long English summary. The book is extremely well produced and illustrated and should find its place on the shelves of everyone interested in nephrology.

Methods in Mammalian Embryology. Edited by JOSEPH C. DANIEL, jun., University of Colorado. 10 × 6½ in. Pp. 532 + xv, with 186 illustrations. 1971. Reading: W. H. Freeman & Co. Ltd. £10·70.

THIS important book will make a strong appeal to a great variety of scientific research workers, for it contains a wealth of material.

Since the Second World War the field of experimental mammalian embryology has expanded to an enormous extent. This book is very practical in its outlook and contains some excellent chapters on practical subjects such as the collection and preservation of spermatozoa, obtaining eggs and embryos from sheep and pigs, and egg storage and transfer.

Tissue culture of various parts of the genital system receives considerable attention.

Today research workers can observe the inside of the living uterus, and study the exposed guinea-pig foetus.

This book, which gives extensive coverage to this important subject, will interest not only embryologists, zoologists, and cancer research workers, but also a wide variety of scientists who are interested in associated subjects.

Atlas röntgenologischer Befunde am operierten Magen. By E. BAUDISCH, Friedrich-Schiller-Universität, Jena. 11⅜ × 8½ in. Pp. 344. Illustrated. 1970. Jena: Veb. Gustav Fischer Verlag. DM.134.

THIS book offers a large quantity of radiographs of patients who were operated upon for oesophageal and gastric diseases, mostly resections. The principal goal of the author is to give an impression to the radiologist of the surgical techniques that were applied by offering him a series of postoperative X-rays. Nevertheless surgeons can profit as well, obtaining information about the aftermath of their operations.

Though one would be happier if, besides the pictures after Billroth-II gastrectomies, the situation after Billroth-I gastrectomies and vagotomies had been demonstrated, nevertheless, the numerous reproductions of radiographs are impressive.

Some conclusions might be drawn: after oesophageal resections many fistulae appear; in cases of total gastrectomy interposition of a piece of small intestine (more than 15 cm. long) appears satisfactory; when an antecolonic Billroth-II resection is performed, an anastomosis of the Braun type might be useful.

Proceedings of the Fourth Annual Leucocyte Culture Conference. Edited by O. ROSS MCINTYRE, Hanover, New Hampshire. 9¼ × 6½ in. Pp. 580 + xxiii. Illustrated. 1971. New York: Appleton-Century-Crofts. $19.50.

THIS large volume contains the forty-two original papers presented at the Fourth Annual Leucocyte Culture Conference, which was held at Dartmouth Medical School, Hanover, New Hampshire, in June, 1969.

It may be said after reading these numerous papers that they provide an excellent detailed survey of the current knowledge and recent advances in the field of lymph culture and cellular immunity.

The field of lymphocyte culture is a large and expanding one, and much more research work still remains to be done. The cell membrane has come in for much extended work, and the role of pinocytotic vacuoles is discussed at some length. One of the features of this book is the discussion at the end of each paper. The illustrations, especially the electron micrographs of various cultures of cells fixed in situ, are of a high order.

Doctor Barbara Brain is to be congratulated on her verses on the lymphocyte, two of which we record:—

> The Lymphocyte is small and round,
> And innocent of face,
> Which is extremely handy
> For a cell that circulates.
>
> Its size and shape allow our friend
> The Lymphocyte to squeeze
> Through tissue spaces, nodes, and spleen,
> And small capillaries.

Colposcopy. A Scientific and Practical Approach to the Cervix in Health and Disease. By MALCOLM COPPLESON, M.D. (Syd.), F.R.C.O.G., Sydney; ELLIS PIXLEY, M.B., B.S. (Qld), M.R.C.O.G., Perth; and BEVAN REID, M.D. (Syd.), B.V.Sc., D.T.M. and H., Sydney. 9¾ × 6¾ in. Pp. 346 + xi. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $21.50.

THIS is an important monograph on an important subject. Anything which will help in the early diagnosis of cancer of the cervix is very worth while.

In this book the colposcopic appearances of the cervix uteri in health and in disease are interestingly and practically described in detail. In addition, the unique value of colposcopy in defining the precise sites of preclinical carcinoma and other epithelial conditions is graphically illustrated. Although there are two forms of instrument, the Zeiss one is probably the better. It is a modified operating microscope mounted on a heavy mobile base and is positioned upon a system of arms allowing universal movement and easy manipulation. The optical head provides high-intensity illumination along the optical pathway and a variable magnification, ranging from × 6 to × 40, which may be changed without refocusing. To the head may be attached a photographic unit with a separate optical pathway which can be focused with the plane of the viewing optics. An electronic flash is fitted for photography.

The atlas portion of the monograph includes many colpophotographs illustrating the variations in appearance in native, physiological, and atypical epithelia, carcinoma, and miscellaneous conditions. All the colpophotographs are of a very high order and are most instructive.

This is a book which all gynaecologists and research workers should read.

The Plain X-ray in the Diagnosis of the Acute Abdomen. By M. H. GOUGH, M.S. (Lond.), F.R.C.S., and MICHAEL W. L. GEAR, D.M., M.Ch. (Oxon.), F.R.C.S., Gloucester. 9 × 6 in. Pp. 188 + xi. Illustrated. 1971. Oxford: Blackwell Scientific Publications. £3·50.

THIS is a surgical handbook with notes on Clinical Presentation and Differential Diagnosis. It is a useful book not only for the student but also for house-surgeons and casualty officers, for it presents practical ways in helping to make a diagnosis in abdominal conditions. The book is divided into six chapters, each of which is illustrated with good X-ray pictures. Besides the diseases of the alimentary system, diseases of the genito-urinary system and trauma are all covered in a good practical way.

Diseases occurring in infancy and childhood are dealt with in a very sound manner.

The matured clinical acumen of the authors is clearly manifested in this book.

Autologous Transfusions. By GEORGE MILLES, M.S., M.D., HIRAM T. LANGSTON, M.S., M.D., and WILLIAM DALESSANDRO, B.S., M.D., F.A.C.P., Chicago. 9¾ × 6¾ in. Pp. 127 + viii, with 11 illustrations. 1971. Springfield, Ill.: Charles C. Thomas. $11.75.

THIS book certainly convinces the reader of the value of autologous transfusions during or after operations, especially in the aged. Venesection of the patient prior to all types of elective surgery make up the bulk of this book. The authors record the details of more than 500 thoracic surgical cases as well as many other patients subjected to presurgical venesection of one or more units of blood for later transfusion. They conclude that all patients selected for elective surgery whose haematological reserve is adequate can serve as the source of more than 50 per cent of the blood that they may need, thereby reducing the drain on the blood banks.

This book stimulates the modern surgeon to a new approach in the pre- and postoperative treatment of his patients.

Biochemical Consequences of Chronic Renal Failure. By M. R. WILLS, M.D., M.R.C. Path., London. 9 × 6 in. Pp. 218, with 9 illustrations. 1971. Aylesbury: Harvey Miller & Metcalf Ltd. £3.

THIS is a most useful book and it appears at an opportune time when surgeons in particular are interested in their patients who are likely to develop uraemia.

It is true that today chronic renal failure is treated by long-term intermittent dialysis, yet the clinician wants to know how his patient is progressing, and this book will be his constant guide, and as a reference volume it could not be bettered.

This monograph gives a lucid and excellent survey of the state of our knowledge of the function of the kidney in controlling the various biochemical systems in the body, and of the consequences to those systems of renal failure.

There can be no doubt that this book will appeal not only to postgraduate students but also to physicians, surgeons, and pathologists.

A most complete list of references is given at the end of this book, comprising 39 pages.

The Hand. By LEE MILFORD, M.D., Memphis, Tennessee. 10½ × 7 in. Pp. 282 + viii, with 308 illustrations. 1971. London: Henry Kimpton. £8·75.

THIS large monograph on the hand is an expanded edition of the author's chapter on the hand in the fifth edition of Campbell's *Operative Orthopaedics*

The importance of the hand from a surgical point of view is manifested in the fact that so many 'hand clinics' have emerged in hospitals up and down the land.

This volume considers the hand from every point of view, including congenital deformities, injuries, nerve palsies, and tumours—in fact every facet of the surgery of the hand has been adequately covered.

The illustrations, over 300 of them, have been well chosen and are a feature of the book. The line drawings are particularly good and so are the X-ray pictures. The various and numerous operative techniques are illustrated in a very clear and practical way.

The list of references at the end of the book is extensive and covers some 14 pages.

This book should be in every medical library, for it is an excellent reference volume. Casualty officers and residents will find the book of real value to them.

Immunobiology. Edited by ROBERT A. GOOD, M.D., and DAVID W. FISHER, Minnesota. 11 × 8½ in. Pp. 305 + xii. Illustrated. 1971. Reading: W. H. Freeman & Co. Ltd. £5·20.

THIS large volume is concerned with common knowledge of basic concepts in immunology and their clinical applications.

There are some thirty contributors to this volume, two of whom come from England, namely Sir Peter Medawar and James L. Gowans, both of whom have made considerable advances in our knowledge of immunology.

The book is divided into five large sections: Section 1 is devoted to the development of the immune systems: cellular mechanisms of immune response. Section 2 deals with humoral antibodies. Section 3 is concerned with mediators and effectors of immunity. Section 4 is devoted to the pathogenetic mechanisms involving immunologic factors, while Section 5 deals with clinical applications of immunology in prophylaxis and in therapy. It is in this last section that Sir Peter Medawar writes on antilymphocytic serum, its properties and potential.

Today immunobiology presents both sides of the scientific coin: such basic concepts and achievements as the synthesis of functional DNA and the molecular nature of antibodies are represented, as are the important clinical applications, such as organ transplantation, the control of Rh disease, and current techniques of vaccination.

This book will make a popular appeal to many branches of the medical profession.

Disadine

POVIDONE IODINE TRADE MARK

surgical scrub

EFFECTIVE AGAINST

Gram+VE and Gram-VE Pathogens, Spores, Viruses, Fungi.

ADVANTAGES

Non toxic, Non irritant, Non sensitising, Rapid Action, Cannot be contaminated.

Now widely accepted in theatres by surgical and nursing staff as the effective surgical scrub for hand disinfection.

Supplied in 5 litre & 500 ml.packs.
Elbow operated wall dispensers & foot operated dispensers available.

Other products available in the DISADINE range:-

**Disadine Tincture, Disadine Solution,
Disadine Dry Powder Aerosol.**

Samples & literature available on request from:-
Avlex Ltd., Leigh Street, Wigan, Lancs.
A subsidiary company of Imperial Chemical Industries Limited.

CLEAR THE FLOOR!

HANAULUX SATELLITE ceiling mounted auxiliary lamp

Specially designed for mounting on the ceiling fitting of Sierex Boston or Stockholm operating theatre lamps, the Satellite auxiliary lamp leaves the floor clear of fittings and trailing cables. It can be adjusted independent of the main lamp to provide complete and efficient lighting for every type of surgery.

Two models are available:

The Universal gives a single spot of high intensity light for augmenting the main lighting.

The Hamburg provides a completely separate area of lighting where two teams are operating simultaneously, as in heart surgery.

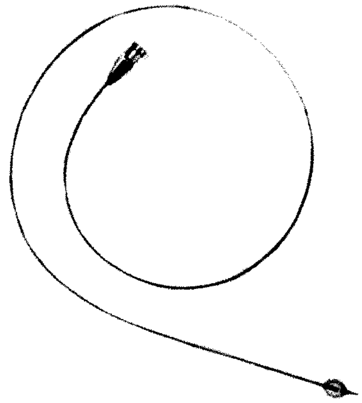
FOGARTY CATHETERS FOR ACUTE VASCULAR OCCLUSION



FOR: Venous Thrombectomy

Occlusion/Emergency Tamponade

Arterial Embolectomy

Dilation/Creation of Atrial Septal Defects in Infants

Double Lumen Balloon Catheter/Creation of Atrial Septal Defects in Infants

Biliary Balloon Probe/Exploration and Removal of Debris and Stones

Irrigation

Rugged Universal Hub Fits All Luer-Lok Type Syringes

BALLOON CATHETER CONCEPT

Each catheter has a specially constructed balloon at the distal tip (except Irrigation Catheter). In thrombectomy and embolectomy, when the catheter is introduced into a vein or artery, the instrument follows the path of least resistance and the tip threads itself past the thrombus or plaque. The balloon is then inflated with sterile fluid and the catheter withdrawn, bringing the clot with it. As an emergency tamponade, for dilation, or as a biliary probe, the balloon is similarly inflated.

GENERAL DESIGN FEATURES

1. Tips on the various types are specially designed for the particular procedure; all are soft and atraumatic.
2. Controlled symmetrical balloon geometry.
3. Secure balloon attachment by epoxied suture.
4. Length marked catheter bodies.

Explanation of Model Numbers in the following table: i.e.: 32-6F

1971 *360 pages* *98 illustrations* **£6·00**

SEPTIC SHOCK IN MAN

Edited by S. G. HERSHEY, LOUIS R. M. DEL GUERCIO and RITA McCONN

1972 *320 pages* *68 illustrations* **£4·75**

By compiling the collective experience of a diverse group of physician-investigators in shock units, the editors stimulate further inquiry into this highly lethal disorder.

AN AID TO CLINICAL SURGERY

PETER R. SCOTT

1971 *336 pages* *60 illustrations* **£4·00**

The purpose of this book is to offer a concise aid to the study of clinical surgery rather than such comprehensive cover of the subject as is already available in the many standard texts. To this end every effort has been made at impartiality and clarity, with deliberate restriction of the subject matter to common clinical fields.

SURGICAL DISORDERS OF THE PERIPHERAL NERVES

Sir HERBERT SEDDON

1971 *352 pages* *325 illustrations* **£8·00**

The author gives a thorough and detailed account of surgical disorders of the peripheral nerves. No attempt has been made to describe the many reconstructive operations that may be required, though they are mentioned.

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·10	£2·80	£3·20	£3·80	£4·30	£4·80	£5·90	£6·90
4	2·70	3·90	4·60	5·40	6·16	6·90	8·40	9·90
6/8	4·50	5·80	7·10	8·30	9·60	10·80	13·40	15·90
10/12	7·20	9·80	11·70	13·70	15·70	17·70	21·80	25·40
14/16	8·70	11·10	13·50	15·90	18·30	20·70	25·50	30·30
18/20	11·40	15·10	18·20	21·30	24·50	27·70	33·90	39·00
COVERS	1·50	2·10	2·70	3·30	3·90	4·50	5·70	6·90

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 58. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St. Martin's House,* 159 *Clapham High Street, London, S.W.*4.

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

KEEP AHEAD IN PATIENT PROTECTION...

...AND KEEP AHEAD IN COMFORT

with SURGINE* Theatre Caps

Protection for Your Patient

- the unique fabric design prevents the passage and fall-out of hair debris.
- complete disposability prevents introduction of potentially infectious organisms into the laundry system.

Comfort for You

- the specially contoured crown and adjustable tie bands fit all but those with long hair.
- the soft non-woven fabric is light and cool to wear.

Convenience for Others

- saves valuable time by eliminating sorting, repairing and packing in service departments.
- saves cost and reliance on the laundry service.

PROGRESS IN THE PREVENTION OF
POST-OPERATIVE DEEP VEIN THROMBOSIS

New British double-blind study
confirms the prophylactic value of

LOMODEX® 70

"...is more effective, safer, and more readily applicable than the use of oral anti-coagulant therapy for the prevention of thromboembolic complications following major pelvic surgery."

Lancet, 7751, i, 1972.

LOMODEX 70 (formerly Dextraven 70) has been shown to produce a highly significant reduction in the incidence of thrombosis when administered during surgery. The properties of LOMODEX 70 are such that, apart from its ability to maintain blood volume, it has been shown to have a significant effect on the changes of factors V, VIII & fibrinogen during the operative procedure.

Thus, the routine use of LOMODEX 70 during surgery represents a real step forward in the prevention of this all too common hazard with none of the problems associated with anti-coagulant therapy.

LOMODEX® 70

a Fisons clinical dextran

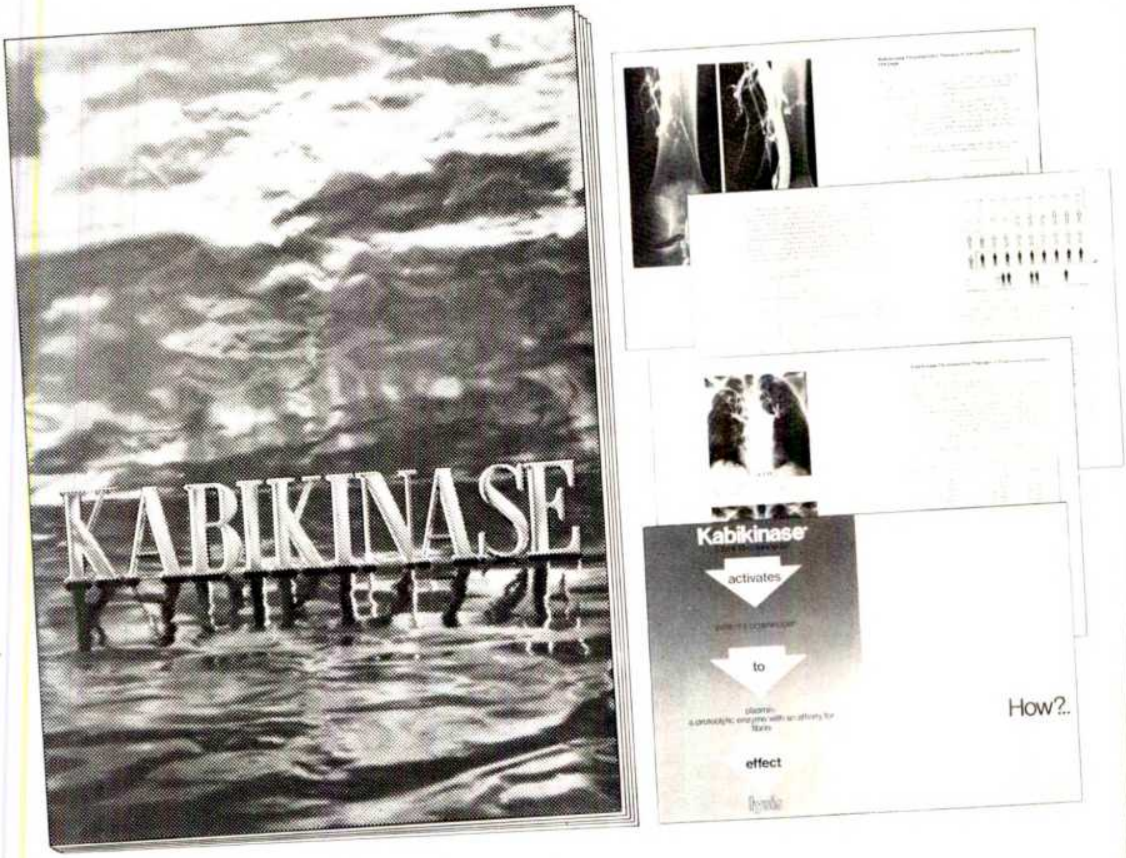
PORTEX **Britain's life line to the world**



Immediately available on request
the up-to-date manual on **Thrombolytic Therapy**

This manual describes how highly purified streptokinase (Kabikinase), potentiates the body's natural ability to dissolve thrombi.

It discusses the respective roles of thrombolysis and anticoagulation, and defines the place for Kabikinase Thrombolytic Therapy in:

venous thrombosis "... 30 per cent of ill medical and surgical patients develop thrombi. ..." There are comments on clinical detection, diagnostic procedures and sequelae;

pulmonary embolism "... the cause of death of 1 in 200 hospital admissions." The "at risk" patient is identified;

acute arterial thromboembolism – the results of thrombolysis are discussed;

chronic arterial occlusive disease – recent work is described.

Reference is made also to:

Thrombolysis for coronary thrombosis, clotted haemodialysis shunts, occlusion of retinal vessels, meningitis and ventriculitis.

Early treatment of deep vein thrombosis preserves valvular function and should avert the post-phlebitic leg.

Medical embolectomy for pulmonary embolism is now the first line of attack.

Thrombolytic therapy is facilitated by the Kabikinase Standard Dosage Scheme.

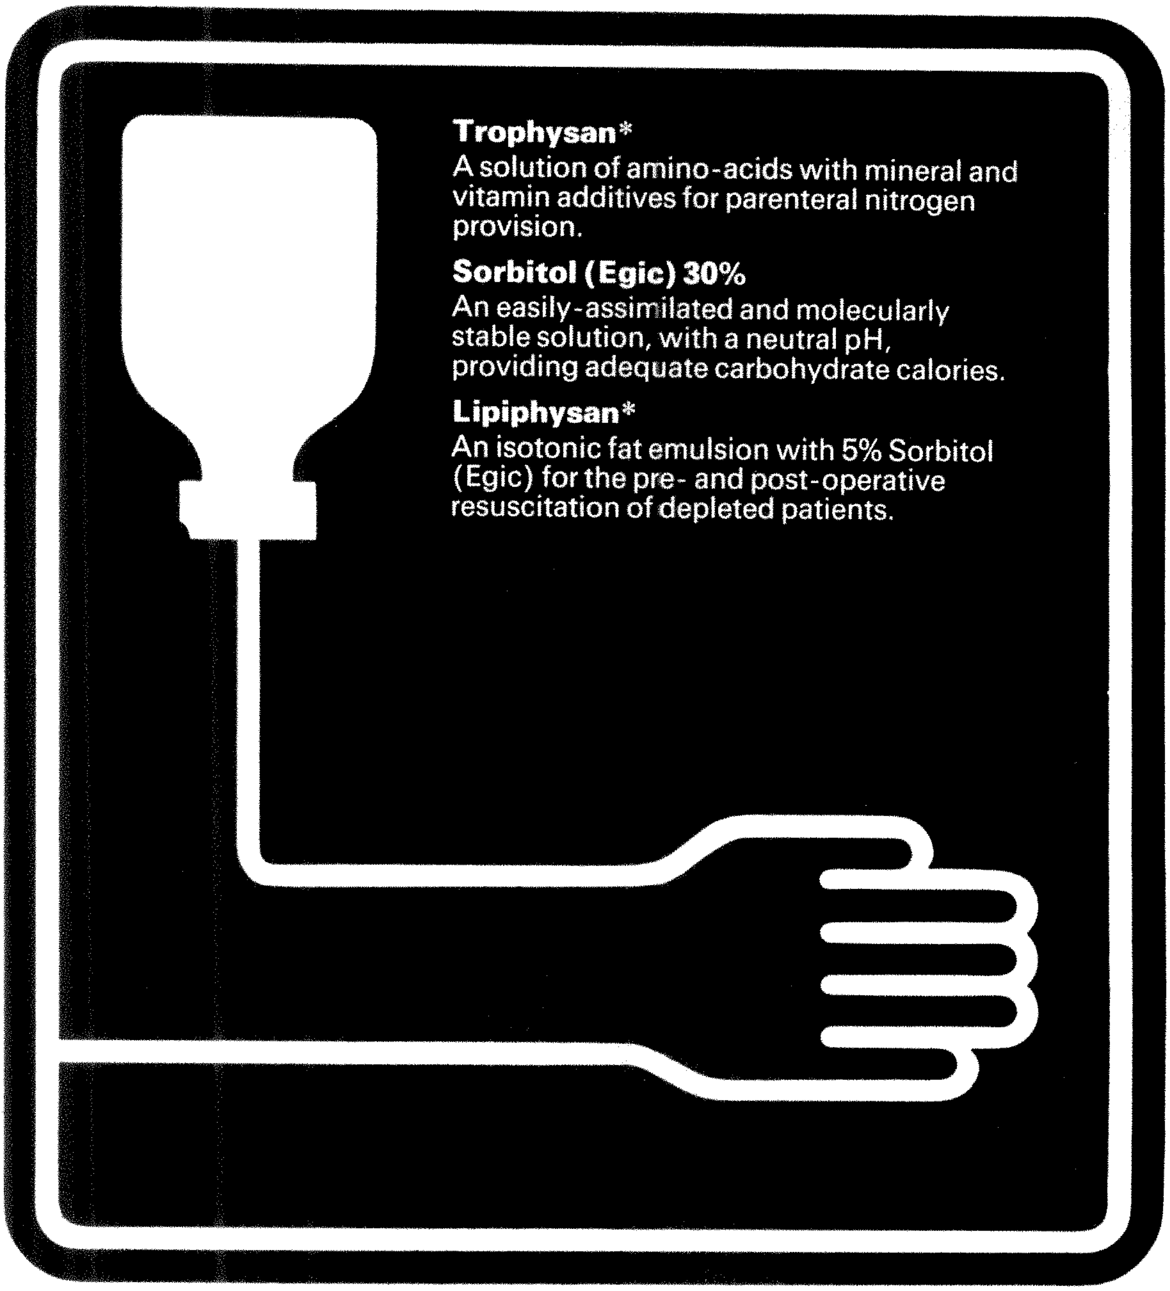
The problem of nutritional deficiency in surgery

In surgery of the GI tract the malnourished patient is a poor surgical risk. Pre-operative parenteral nutrition ensures adequate provision of nitrogen and calories and the correction of any electrolytic imbalance. This is best achieved by the use of SERVIER intravenous nutritional solutions.



Trophysan*
A solution of amino-acids with mineral and vitamin additives for parenteral nitrogen provision.

Sorbitol (Egic) 30%
An easily-assimilated and molecularly stable solution, with a neutral pH, providing adequate carbohydrate calories.

Lipiphysan*
An isotonic fat emulsion with 5% Sorbitol (Egic) for the pre- and post-operative resuscitation of depleted patients.

When nutritional deficiency is a problem, Servier has the solution.

ORIGINAL PAPERS

ULCERATION OF THE MOUTH, PHARYNX, AND LARYNX IN CROHN'S DISEASE OF THE INTESTINE

By C. B. CROFT and A. R. WILKINSON
THE GENERAL INFIRMARY, LEEDS

SUMMARY

Three hundred and thirty-two cases of Crohn's enteritis were reviewed retrospectively and 20 or 6·1 per cent were found to have suffered from oral ulceration at some stage during their illness. One of these patients with histological evidence of Crohn's disease in the mouth, pharynx, and larynx is described in detail.

WITHIN the past decade Crohn's disease has been diagnosed with increasing frequency, and it has been recognized, moreover, that the distribution of the condition is much more protean than Crohn, Ginzburg, and Oppenheimer (1932) had imagined when they described their first cases affecting the terminal ileum. The same disease is now known to occur anywhere in the small bowel, in the colon and rectum (Lockhart-Mummery and Morson, 1960), in the stomach or duodenum (Comfort, Weber, Bagenstoss, and Keely, 1950; Pryse-Davies, 1964; Wise, Kyriakos, McCown, and Ballinger, 1971), and in the oesophagus (Gelford and Krone, 1968). Recently, 2 cases have been reported of alleged Crohn's disease invading the mouth (Dudeney and Todd, 1969; Issa, 1971), which has stimulated us to review the records of the series of 332 cases of Crohn's disease treated at Leeds Infirmary between 1939 and 1968 inclusive to see how many had suffered from oral ulceration. Twenty patients with this complication were discovered.

CLINICAL MATERIAL AND FINDINGS

Of the 20 patients with Crohn's disease and concomitant oral ulceration, 14 were interviewed and re-examined. Four patients who now live a considerable distance from the hospital were contacted by postal questionnaire. The remaining 2 patients had died and were not considered further in this study. Details of the 18 cases reviewed are listed in *Table I.*

Sex Incidence.—It will be seen that there were 9 males and 9 females, a ratio of 1 : 1, which is the same sex ratio as for the parent series of 332 cases of Crohn's disease.

Relation to Bowel Symptoms.—In 3 patients oral ulceration occurred as a presenting feature of the illness, and in 1 patient the onset of oral ulceration actually preceded bowel symptoms by 1 month. In 10 patients oral ulceration appeared from 2 weeks to 3 years after the onset of bowel symptoms (within 6 months in half of them). Four patients developed oral ulceration in the postoperative period, 2 of these occurring within 1 month of operation. It could be argued that oral lesions encountered postoperatively may be due to other specific causes such as candidiasis or vitamin deficiencies, but it is much less likely that the commoner oral ulceration occurring preoperatively could be so caused.

Severity of Ulceration.—Oral ulceration was described as severe in 10 patients, meaning that the lesions were bad enough to cause dysphagia. The majority of these cases exhibited recognizable oedema of the lips and bleeding from the mouth. The remaining 8 patients gave histories of recurring attacks of oral ulceration but these were deemed to be mild.

Site of Intestinal Lesions.—In 8 patients—7 with severe mouth ulcers—Crohn's lesion in the intestine was confined to the large bowel. As there were 70 cases in the original series with colonic or rectal lesions, the incidence of oral ulceration in association with Crohn's disease of the large bowel was 11·4 per cent. Five patients with oral ulceration had involvement of the terminal ileum alone, out of 136 patients with this distribution of intestinal disease, an incidence of 3·6 per cent. The remaining 5 cases with oral ulceration had Crohn's lesions involving both the colon and the terminal ileum and were derived from the group of 115 cases with mixed lesions of the bowel, an incidence of 4·3 per cent.

Physical Findings at Review.—On examination of the 14 patients who attended for review at hospital only 4 showed signs of previous oral ulceration. Three of them had diffuse scarring of the soft palate (*Fig.* 1). One patient still has florid changes in his mouth and laryngopharynx (*see* Case Report).

Treatment.—Four patients were ill enough to require treatment for their oral condition with

P. H.	40 M.	Ileum	Right hemicolectomy	Mild	2 months	1 month post-operatively	Nil	2 months	No specific treatment

systemic steroids, and all responded well to this therapy. One patient who developed oral ulceration postoperatively was treated with parenteral vitamin supplements with good effect, which suggests that the cause of the oral ulceration in this case may have been a deficiency state rather than Crohn's disease. The remaining 13 patients received no specific treatment for their oral lesions. However, 9 patients stated that after undergoing surgery for their intestinal lesion the oral ulceration disappeared and did not recur.

Histological Examination of Mouth Lesions.—Unfortunately, biopsy of the oral ulcers was performed in only 1 of the 18 cases where the oral lesions were active, the resulting histological examination producing clear evidence of a granulomatous lesion that could be diagnosed as Crohn's disease. This case is recorded in detail below.

CASE REPORT

P. C., a 27-year-old male, was referred to the Professorial Surgical Unit at Leeds General Infirmary in April, 1970. He gave a 15-year history of recurrent diarrhoea with the intermittent passage of blood and mucus and recurrent oral ulceration. This condition had been serious enough to warrant hospital admission on three occasions. Over the years his general condition had steadily deteriorated, with weight-loss, recurrent chest infections, and increasingly frequent bouts of diarrhoea.

On examination the patient was emaciated and clinically anaemic. Abdominal examination was unremarkable. No abnormality was evident in the anal region. Sigmoidoscopy to 14 cm. revealed relatively normal mucosa, with normal vessel pattern and no contact bleeding. There was a good deal of mucus visible in the bowel lumen. A barium-enema study showed loss of haustral pattern throughout the large bowel, with appearances of colitis polyposa. Examination of the mouth revealed widespread 'aphthous' ulceration of the buccal mucosa and palate.

In view of the patient's long-standing history and steady deterioration it was decided to proceed to total proctocolectomy with ileostomy.

At laparotomy on 4 May the terminal 30 cm. of the ileum and the large bowel from the caecum to the upper descending colon were found to be contracted and thickened, but the sigmoid colon and rectum appeared normal. A proctocolectomy was performed and an ileostomy was established. Postoperative progress was uneventful, apart from a chest infection which responded to physiotherapy and antibiotics (ampicillin), and the patient was discharged home on 20 May with his wounds healing satisfactorily.

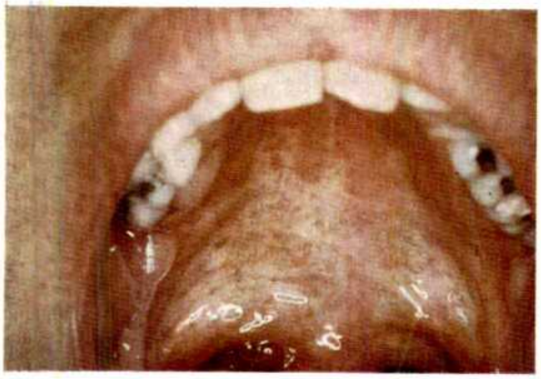

FIG. 1.—D. A. Scarring of the soft palate.

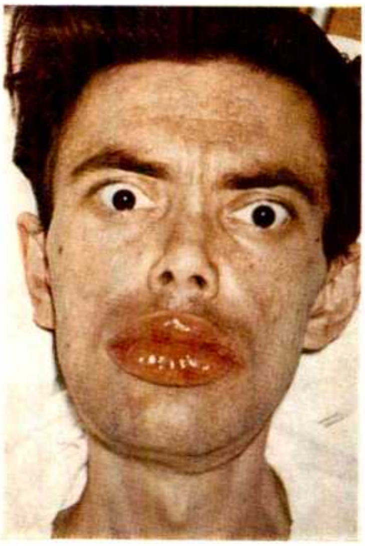

FIG. 2.—P. C. Facial features.

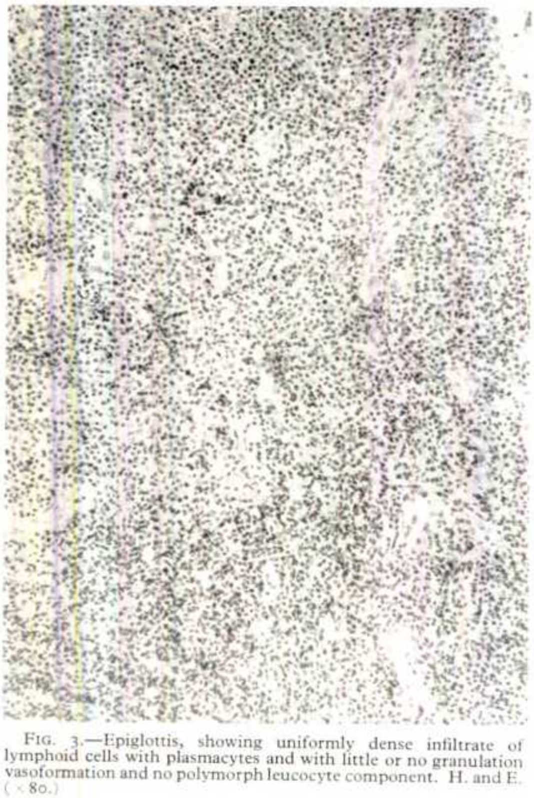

FIG. 3.—Epiglottis, showing uniformly dense infiltrate of lymphoid cells with plasmacytes and with little or no granulation vasoformation and no polymorph leucocyte component. H. and E. (×80.)

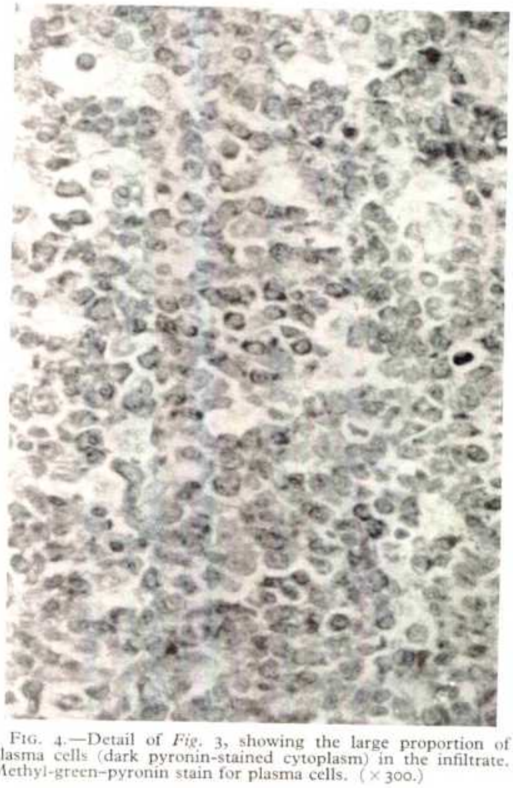

FIG. 4.—Detail of *Fig.* 3, showing the large proportion of plasma cells (dark pyronin-stained cytoplasm) in the infiltrate. Methyl-green–pyronin stain for plasma cells. (×300.)

Pathological examination of the operative specimen showed characteristic changes of Crohn's disease of the large intestine.

SUBSEQUENT PROGRESS.—On 13 June the patient was seen in the out-patients' clinic complaining of severe ulceration of the mouth with dysphagia. On examination he had grossly oedematous swollen lips and tongue (*Fig.* 2), and also inflammation and ulceration of the oral and pharyngeal mucosa. A tentative diagnosis of oral candidiasis was made and treatment with nystatin lozenges was instituted. During this period the patient was also using a local steroid application prescribed by his general practitioner. On 17 June he was readmitted because of the failure of his oral ulceration to respond to treatment. Medication with nystatin lozenges was continued and was augmented by the application of gentian violet to the lips. On this régime his oral condition improved and he was discharged home again on 24 June.

On review 3 weeks later he reported increasing ulceration of the lips and throat with expectoration of blood and mucus. He was experiencing considerable pain and dysphagia and had lost 1 stone in weight since discharge from hospital. His symptoms were so severe that he was immediately readmitted. Under general anaesthesia direct pharyngolaryngoscopy (Mr. Oliver Lord) showed generalized ulceration and oedema of the mucosa of the oral cavity, pharynx, and larynx. The epiglottis was surrounded by a mass of granulation tissue, the arytenoids and false cords were oedematous, but the vocal cords appeared normal. Several biopsies were taken from affected areas, but they were reported to show merely lymphoblastic and plasma-cell infiltration of the tissues, which did not admit of a firm histological diagnosis.

In view of the patient's deteriorating clinical state he was started on prednisone, 10 mg. three times a day, on a tentative clinical diagnosis of Crohn's disease of the mouth, with subsequent reduction of the oedema and of the other changes in the appearance of the oral and pharyngolaryngeal mucosa. This improvement was maintained for several months, but at repeat laryngoscopy on 17 Feb., 1971, the alveolar and palatal mucosae were observed to be thickened and granular and similar changes were noted on the epiglottis and false vocal cords. Further biopsies were taken from each of these areas.

HISTOLOGICAL REPORT ON THE SECOND BIOPSIES.—Professor C. E. Lumsden reported that all biopsies on light microscopy (*Fig.* 3) showed an intensely packed infiltrate, predominantly of plasma cells and large lymphocytes, lying beneath an intact mucosa which did not show evidence of 'aphthous' ulceration. Although the infiltration of cells was intense there was no evidence of follicle formation. Histochemical studies showed the plasma cells to be pyroninophilic (*Fig.* 4). Immunofluorescence studies failed to reveal the presence of immunoglobulin A in any of the cells, but immunoglobulin G and M reactions were given by a proportion of the plasma cells in the infiltrate. The conclusion reached was that these histological findings indicated a variant of Crohn's disease affecting the mouth and laryngopharynx.

Currently, the patient still demonstrates the changes described above and also has developed bilateral sensorineural deafness following a viral illness in March, 1971. The deafness may be attributed to the damage caused by infection in a patient on systemic steroids, and it is of such degree as to require a hearing aid for perception of normal conversation.

DISCUSSION

Of the 2 cases of alleged Crohn's disease of the mouth previously reported by Dudeney and Todd (1969) and Issa (1971), the former exhibited suggestive but not diagnostic features of Crohn's disease in the oral lesion, and in the latter there was no definite evidence of an associated intestinal lesion. Of the 18 cases with oral ulceration discovered in our review of 332 patients with established Crohn's disease of the intestinal tract, only 1 had had a biopsy of the oral lesion taken; the histological report on this biopsy showed changes compatible with Crohn's disease of the mouth and laryngopharynx. As far as we are aware, involvement of the laryngopharynx in a patient with Crohn's disease of the intestine has not previously been reported.

In view of the lack of histological material from the mouth ulcers in our 17 other patients, the precise nature of their oral lesions and the relationship of these lesions to their intestinal conditions are matters for conjecture. It is of interest, and perhaps significant, however, that the lesions in the mouth were presenting features in 3 of these cases, as they were in the patient with a positive biopsy, whilst in 5 of the remaining 14 cases these lesions developed within 6 months of the onset of bowel symptoms. In 14 patients the oral ulceration appeared before operation was performed. The occurrence of the ulcers in the mouth early in the course of the disease in 9 of our cases certainly renders it much less likely that the ulceration was due to candidiasis or vitamin deficiency in these patients.

Against the theory that some of these oral lesions were manifestations of Crohn's disease involving the oropharynx is the fact that most of them healed on conservative management. This is a more satisfactory response than is usually obtained by conservative management of Crohn's lesions at other sites. However, it may be significant that in 17 of our 18 cases the associated intestinal lesion was ultimately excised and many patients noted an improvement in their oral condition following operation.

Acknowledgements.—We are deeply indebted to Professor J. C. Goligher for allowing us to report his cases and for helpful criticism during the preparation of the paper, to Mr. O. C. Lord for his help with the otolaryngological aspects of this paper, to Mr. F. T. de Dombal for advice on statistics concerning the present series of patients with Crohn's disease, to Professor C. E. Lumsden for advice concerning the histological report and for supplying the photomicrograph in *Fig.* 3, and finally to Miss E. Bartholomew for typing the paper.

ILEAL RECURRENCE AFTER ILEOSTOMY AND EXCISION OF THE LARGE BOWEL FOR CROHN'S DISEASE

By J. C. GOLIGHER
UNIVERSITY DEPARTMENT OF SURGERY, GENERAL INFIRMARY, LEEDS

SUMMARY

Seven cases are recorded of 'recurrent' Crohn's disease in the terminal ileum following ileostomy and colectomy or proctocolectomy for Crohn's disease of the large intestine or alleged ulcerative colitis. The clinical, radiological, and pathological features are described and the management is discussed.

WHEN it was first recognized (Wells, 1952; Brooke, 1959; Lockhart-Mummery and Morson, 1960) that Crohn's enteritis could on occasions be mainly or entirely localized to the large intestine, the impression was quickly formed that this large-bowel version of the condition might carry a much more favourable prognosis after surgical treatment than did the more usual small-bowel lesion (Cornes and Stecher, 1961; Jones, Lennard-Jones, and Lockhart-Mummery, 1966). In this matter, however, a cynic might have felt that the wish could have been to some extent father to the thought, for recurrent Crohn's disease after large-bowel surgery involving creation of an ileostomy might be expected to present serious difficulties in management. A recent follow-up of our own sizeable series of patients at the Leeds General Infirmary treated surgically for Crohn's lesions in various parts of the intestinal tract (de Dombal, Burton, and Goligher, 1971a, b; Goligher, de Dombal, and Burton, 1971, 1972) has confirmed that the recurrence rate of disease mainly or exclusively restricted to the colon and rectum has indeed been significantly less than that of disease mainly or entirely confined to the small bowel. It has shown, further, that of the various forms of colectomy practised for Crohn's disease of the large intestine, the one that seemed to afford the greatest protection against recurrence was an ileostomy and proctocolectomy (combined with excision of more or less of the lower ileum, if diseased). However, the fact remains that

patients may develop recurrence after excision of Crohn's disease of the large bowel, *even when the initial lesion was contained entirely within the colon and rectum and did not encroach at all on the small bowel, and even when it was removed by a complete proctocolectomy with ileostomy.*

During the past 2 years 7 patients have been seen with Crohn's disease in the distal small bowel following previous excisional surgery and ileostomy for inflammatory disease of the large bowel. Four of them were included, as regards both their primary lesions and the recurrence, in the series of cases of Crohn's disease that formed the basis of our recent reports on the long-term outcome of this condition (de Dombal and others, 1971a, b; Goligher and others, 1971, 1972). One patient was included in that series for the primary lesion, but the recurrence arose since the data were analysed. The remaining 2 patients are entirely outside our comprehensive survey, for they both presented after it had been completed, 1 of them, incidentally, having had her primary operation elsewhere. It seemed worth while to publish these cases because they illustrate well some of the problems involved in the diagnosis and treatment of this form of recurrence.

CASE REPORTS

Case 1.—J. D. M., a male, born on 10 Aug., 1943.

In April, 1967, this patient underwent complete proctocolectomy with excision of 28 cm. of terminal ileum and establishment of an ileostomy for Crohn's disease of the rectum, colon, and distal ileum. Examination of the operative specimen showed gross disease in the upper rectum and colon as far proximally as the distal ascending colon. The proximal ascending colon and caecum were apparently normal, but there was a patch of enteritis in the last 6 cm. of ileum immediately adjacent to the ileocaecal junction. The more proximal ileum was normal.

The patient made a good recovery from this operation and remained well until September, 1969, when he reported that for 3 weeks he had been experiencing colicky abdominal pains and borborygmi with some abdominal distension and looseness of the ileal discharge. On one occasion he had noticed some blood with the faeces. Abdominal examination revealed no obvious abnormality. The ileostomy appeared satisfactory and digital examination excluded any significant narrowing at skin level, though the finger was not advanced into the abdomen because of discomfort. A barium-meal and follow-through examination showed a normal small bowel except for the last 10 cm. of ileum leading up to the ileostomy, which were narrowed and rigid (*Fig.* 1 A).

Treatment was by reoperation, at which the terminal 40 cm. of ileum were resected and a new ileostomy was established at the old site. Pathological examination of the resected bowel showed gross and microscopic changes of Crohn's disease in its distal 15 cm., the remainder being normal (*Fig.* 1 B). The general condition of the patient on review in September, 1971 (2 years later), was excellent and his ileostomy was functioning normally.

Case 2.—S. M., a male, born on 10 March, 1932.

In July, 1958, this patient was treated by ileostomy and complete proctocolectomy for what was thought clinically to be ulcerative colitis. Examination of the operative specimen, however, showed features more suggestive of Crohn's disease—multiple small areas of ulceration up to 1 cm. in diameter, a localized stenosis at the hepatic flexure, and, on histological section, occasional giant-cell follicles. The 8 cm. of lower ileum attached to the colon had a granular mucosa throughout and a few inflammatory polyps were noted, but no frank ulceration was present.

The patient enjoyed excellent health for 11 years following this operation. Then, in June, 1969, he began to have occasional colicky abdominal pains and looseness of the ileostomy discharge. Quite frequently he observed blood in the faeces. These symptoms gradually became more severe till he reported to hospital in January, 1970. Examination showed a normal-looking ileostomy. Digital examination and passage of the sigmoidoscope through the stoma revealed a thick, granular, partly ulcerated mucosa in the ileum for 8 cm. within the abdomen. A biopsy was taken and showed the histological picture of Crohn's disease. A barium-meal and follow-through study demonstrated characteristic changes of Crohn's enteritis in the terminal ileum (*Fig.* 2 A). Operation was advised and consisted of excision of the terminal 60 cm. of ileum including the ileostomy, a new ileostomy being fashioned at the old site. The postoperative course was marred by the development of an abdominal abscess, which had to be drained. Subsequent recovery was uneventful, and when seen in September, 1971, the patient was in excellent general health and was back at his old job; his ileostomy was acting normally. Pathological examination of the resected small bowel (*Fig.* 2 B) showed thickening of the wall with oedema and ulceration of the mucosa in the distal two-thirds; the proximal 25 cm. appeared grossly normal. Histological sections revealed typical changes of Crohn's disease, especially in the distal extremity of the loop, and also in two related lymph-nodes.

Case 3.—J. R., a male, born on 16 Sept., 1917.

In January, 1959, this patient had a typical segment of Crohn's enteritis in the terminal ileum removed by a right hemicolectomy and terminal ile-ectomy. He remained well till late 1961, when he developed a recurrence of his diarrhoea, and in the next 10 weeks he lost 15·8 kg. in weight. Barium-enema examinations revealed appearances of ulcerative colitis. Sigmoidoscopy to 12 cm. showed a normal mucosa throughout but mucopus was noted coming down from a higher level. In February, 1962, the patient underwent a further laparotomy and had the remaining colon removed and an ileorectal anastomosis established. On pathological examination of the specimen gross appearances compatible with a diagnosis of Crohn's disease of the colon were observed, with a 'skip' lesion in the caecum and two in the ileum.

Convalescence from this operation was slow owing to a wound infection, eventuating in a persistent fistula from the anastomotic site to the abdominal wall. Sometimes flatus escaped from the fistula. The patient's general condition remained indifferent, and after 6 months he had an abdominoperineal excision of the rectum with the establishment of a permanent ileostomy. Thereafter he made a rapid and complete recovery and quickly became reconciled to his ileostomy.

The patient led a normal active existence up to January, 1970, when he reported to hospital again, complaining of recurrent attacks of abdominal pain and loss of 6·3 kg. in weight in the preceding 3 or 4 months. Though no abnormality could be detected on clinical examination of the ileostomy and the abdomen, a recurrence of Crohn's disease was suspected and a barium-meal and follow-through examination was ordered. This confirmed the diagnosis by showing a narrowed segment of the lower ileum. In February, 1970, the patient proceeded to a further laparotomy and had the diseased portion of the bowel excised and a new ileostomy established. The operative specimen (*Fig.* 3) showed typical changes of Crohn's disease in its distal half. Since this operation, up to the latest review in September, 1971, the patient has been well and his ileostomy has functioned normally.

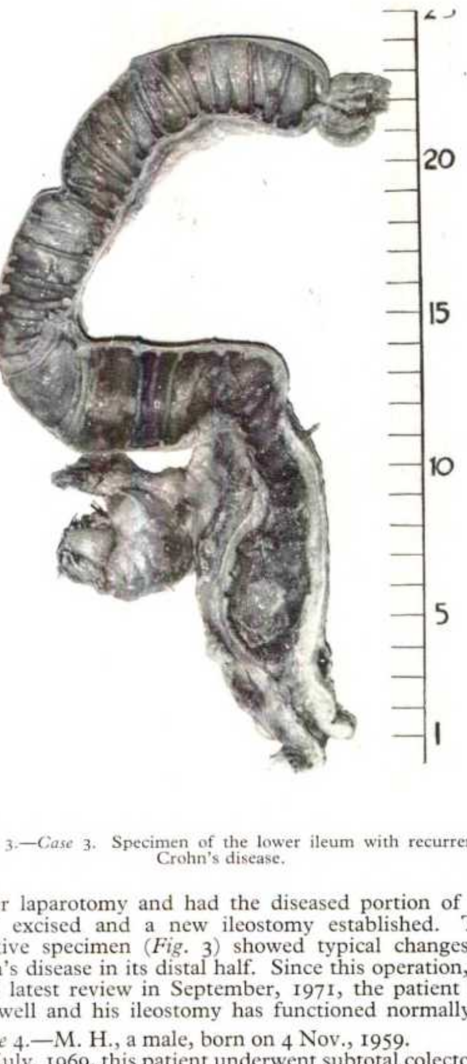

FIG. 3.—*Case* 3. Specimen of the lower ileum with recurrent Crohn's disease.

Case 4.—M. H., a male, born on 4 Nov., 1959.

In July, 1969, this patient underwent subtotal colectomy and ileostomy for a colitis, which it was suspected might be of Crohn's type because of the relatively slight involvement of the rectum compared with the rest of the large bowel. Pathological examination of the operative specimen (*Fig.* 4 A), however, showed gross and microscopical features that were considered to be diagnostic of ordinary ulcerative colitis. The short stump of ileum attached to the colon in the specimen was absolutely normal.

Following operation the patient made a reasonable recovery so far as the healing of his wound and the action of his ileostomy were concerned, but improvement in his general health seemed slow. Then in April, 1970, on attending for a periodic review, he was found to have a fistula through the inferior part of the ileostomy spout just beyond skin level. No other abnormality could be demonstrated in relation to the stoma on clinical examination, and it was thought that the fistula might be due to chafing by the flange of the ileostomy appliance. However, the patient also complained of occasional colicky abdominal pains and very loose faeces, and therefore a barium-meal and follow-through examination was ordered and showed clear evidence of Crohn's disease in the distal ileum (*Fig.* 4 B). In May, 1970, a further laparotomy was performed at which the terminal 40 cm. or so of small bowel, including the ileostomy, were excised and a new ileostomy was established at the same site. Pathological examination (*Fig.* 4 C) showed that the distal third of removed bowel was the seat of Crohn's disease. Since this second operation the patient has regained normal general health, and his ileostomy was working well at review in September, 1971.

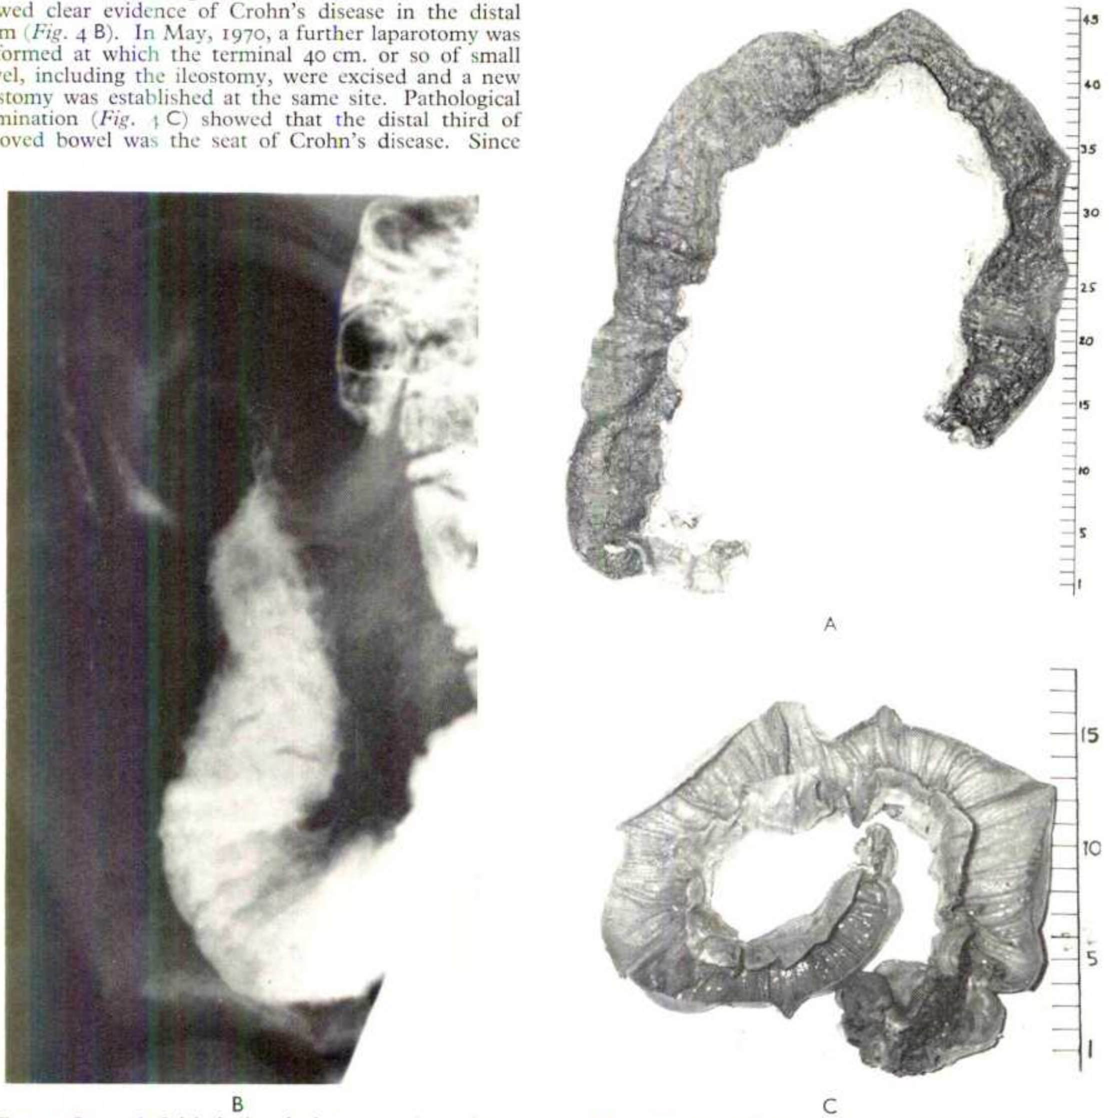

FIG. 4.—*Case* 4. A, Original subtotal colectomy specimen of apparent ulcerative colitis. B, Radiograph from the barium-meal and follow-through examination showing Crohn's lesion in the terminal ileum immediately proximal to the ileostomy. C, Specimen of the lower ileum containing Crohn's lesion.

Case 5.—H. A., a male, born on 10 April, 1940.

The illness of this patient commenced with rectal bleeding in 1961, and on sigmoidoscopy this was found to be due to a diffuse granular proctitis extending as far proximally as 12 cm. from the anal verge. Despite conservative management with salazopyrine and topical steroid enemas, under which there were occasional phases of improvement when the rectal mucosa reverted virtually to normal on sigmoidoscopic examination, the condition became complicated by the development of perianal and submucous abscesses, and the mucosal inflammatory changes gradually extended proximally beyond the reach of the sigmoidoscope. A barium-enema study in October, 1965, showed colitis confined to the rectum and sigmoid, but in January, 1966, the changes were found to have progressed as far proximally as the splenic flexure. At this stage the patient was treated by ileostomy and complete proctocolectomy, the appearances of the operative specimen being found to be those of Crohn's disease of the large bowel rather than of ulcerative colitis.

After this operation the patient remained well till February, 1970, when he began to have colicky abdominal pains and he noticed that the ileostomy discharge had become liquid. He was also anorexic. When he reported to hospital a month later he had lost about 6 kg. in weight. The ileostomy appeared normal on clinical examination, but on barium-meal and follow-through examination, changes of Crohn's disease were observed in the distal ileum. At a further laparotomy in March, 1970, the last 44 cm. of ileum were excised together with the ileostomy, and a new ileostomy was created at the former ileostomy site. Pathological examination of the resected specimen (*Fig.* 5) showed Crohn's disease in the terminal half. Following the operation the patient has remained in excellent health and has had no further trouble with his ileostomy up to the time of review in September, 1971.

FIG. 6.—*Case* 6. A, Radiograph from the barium-meal and follow-through examination showing the diseased terminal ileum. B, Operative specimens of the terminal ileum and rectal stump, showing Crohn's enteritis in the distal half of the former and throughout the length of the latter.

Case 6.—D. B., a female, born on 14 Nov., 1926.

In 1958 this patient had an ileostomy and subtotal colectomy in another hospital for what was alleged to be ulcerative colitis. She was well thereafter till 1968, when she developed an abscess in the vicinity of the umbilicus. This was incised but continued discharging pus, flatus, and a slight amount of faecal-looking material intermittently. When seen in October, 1970, the patient had a very inadequate, contracted and deformed ileostomy, the skin around the stoma was reddened and digested from frequent leakage of faeces, and there was a fistulous opening at the umbilicus. A sinogram demonstrated that the fistula connected with the terminal ileum, which was diseased. On barium-meal and follow-through examination (*Fig.* 6 A) a narrowed segment of bowel was shown leading up to the ileostomy. Rectal examination with the sigmoidoscope revealed a thickened granular bleeding mucosa.

The patient was advised to have both the small-bowel recurrence and the rectal stump removed, and this was done in November, 1970, by an abdominoperineal operation, a new ileostomy being established on the opposite side of the abdomen. Pathological examination of the operative specimens (*Fig.* 6 B) showed that the rectal stump was inflamed and ulcerated throughout its length, and the ileal stump was similarly affected in its distal half. The histological appearances in both the specimens were those of Crohn's disease. Recovery from this operation was quite protracted because of severe sepsis in the perineal wound, which took 4 months to deal. The patient's ileostomy was entirely satisfactory when she was reviewed in September, 1971.

Case 7.—M. T., a female, born on 6 Sept., 1928.

In 1959 this patient had a complete proctocolectomy and excision of 2·5 m. of terminal ileum together with the establishment of an ileostomy for Crohn's disease of the large and small bowel. The postoperative course after the operation was complicated by very profuse ileostomy diarrhoea, with loss of up to 5–6 litres of fluid from the stoma in the 24 hours. With the aid of codeine phosphate in large doses this state of affairs was controlled to some extent, and it was possible to wean the patient off intravenous infusions of fluid and electrolytes. However, at the time of discharge from hospital 7 weeks after operation the ileostomy discharge still amounted to $2\frac{1}{2}$ litres, and the patient required oral supplements of sodium, potassium, calcium, and magnesium, as well as injections of cytamen.

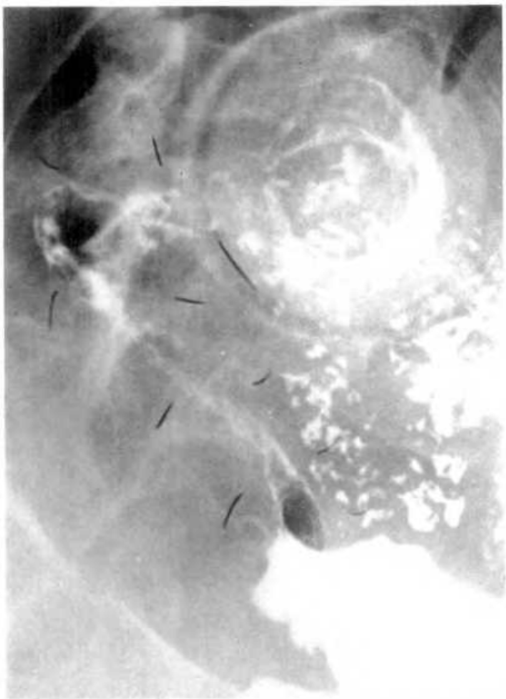

FIG. 7.—*Case* 7. Radiological appearances of the recurrence in the last 10 cm. of the small bowel proximal to the ileostomy.

During the succeeding years the patient led a somewhat precarious existence owing to impaired nutrition and lack of energy, and periodically she needed to come into hospital for short spells for correction of metabolic deficiencies. During one of these readmissions in 1964 a barium-meal and follow-through study was equivocally reported as showing possible recurrence in the small bowel. This was noted in our records, but no further surgical intervention was advised. In January, 1971, the patient was readmitted in a state of dehydration and depletion, which was corrected by suitable infusions. It appeared on interrogation that she had recently been having a good deal of colicky pain. Examination of the ileostomy with the finger detected some thickening and induration of the mucosa just within the abdomen, and, on passing a sigmoidoscope into the terminal ileum through the stoma, the mucosa was seen to be thickened and nodular. A mucosal biopsy revealed appearances of Crohn's disease. A barium-meal and follow-through study showed narrowing of the terminal 7·5 cm. or so of the ileum extending up to the stoma (*Fig.* 7). Elsewhere the small intestine seemed normal.

Although further operation was advised on this occasion to excise the recurrence, the patient and her physician felt that they would prefer to continue with medical management for the time being.

DISCUSSION

The early years of ileostomy surgery for ulcerative colitis were marred by the frequent occurrence of a special form of ileostomy obstruction or dysfunction (Warren and McKittrick, 1951; Counsell and Goligher, 1952) which was due in the early postoperative period to the oedematous state of that part of the ileum of which the serosa was exposed in the projecting ileal spout, and at a later stage to subsequent fibrous stenosis at skin level. With the introduction of the method of eversion of the end of the ileum and its primary suture to the cut edge of the skin (Brooke, 1952; Crile and Turnbull, 1954), this particular type of ileostomy dysfunction has largely been eliminated (Watts, de Dombal, and Goligher, 1966a, b; Goligher, 1967). However, patients with ileostomies are still rather prone to have episodes of partial or complete intestinal obstruction at a higher level owing to kinking or compression of the small bowel by an intraperitoneal adhesion or other mechanical cause. Another cause of obstruction to be considered in patients whose original large-bowel lesion was due to Crohn's disease is the development of a recurrence of this condition in the small bowel. With the steeply rising incidence of Crohn's disease of the large intestine in recent years and the greater number of patients with this condition being submitted to ileostomy, ileal recurrence is becoming an increasingly important cause of obstructive episodes in ileostomy patients. Because of the fact that until recent years not a few cases of Crohn's disease of the large bowel were wrongly diagnosed clinically and pathologically as ordinary ulcerative colitis—as in *Cases* 4 and 5 in the present group of patients—recurrent Crohn's disease of the small bowel should also be thought of as a cause of obstruction in patients whose ileostomies were said to have been performed for ulcerative colitis.

All but 1 of our 7 patients (*Case* 6) with Crohn's lesions in the ileum proximal to their ileostomies had had their original operation performed in the Department of Surgery at the General Infirmary, Leeds, and were known to have had an eversion technique used for construction of their stomas. It was thus unlikely that their recent bowel symptoms would be found to be due to stenosis at the ileostomy, and this tentative conclusion was confirmed by visual and digital examination of the ileostomy in each of the 6 cases, which showed that there was no significant narrowing at the stoma itself in any of them. In 2 patients (*Cases* 4 and 6) fistulas were found to be present in relation to the ileostomy. One fistula (*Case* 4) was in the actual ileostomy spout and could well have been due to repeated friction from a badly applied ileostomy bag. The other fistula (*Case* 6) was connected with the bowel at a somewhat higher level and opened at the umbilicus, which was highly suspicious of an ileal Crohn's lesion proximal to the stoma. This patient, who had had her original operation for 'colitis' performed elsewhere, also exhibited a very contracted and somewhat deformed ileostomy, which in itself suggested the possibility of recurrent Crohn's disease. In 2 patients (*Cases* 2 and 7) it was possible with deep digital palpation of the ileostomy under a short general anaesthetic to reach a zone of narrowing and induration in the ileum inside the abdomen, and in both of these cases the passage of a sigmoidoscope through the stoma for a short distance revealed 'cobblestoning' of the ileal mucosa and allowed biopsies to be taken showing histological appearances of Crohn's disease.

Two patients (*Cases* 1 and 2) complained not only of obstructive episodes with colicky pains and change of the faeces to a liquid consistency but also of *occasionally passing blood in the faeces*. This symptom seemed to establish beyond all doubt that there was some lesion in the bowel wall itself as the source of the bleeding, and made the diagnosis of recurrent Crohn's disease much more likely than that of obstruction due to adhesions.

What clinched the diagnosis in most cases, however, was the radiological appearance after a barium-meal and follow-through examination (*Figs.* 1 A, 2 A, 4 B, 6 A, 7). Not only did the barium study show clearly the narrowed irregular segment representing the site of the recurrence—usually in the last 7·5–10 cm. of ileum, just inside the abdominal cavity and leading up to the stoma—but it also demonstrated that most of the small bowel proximal to this segment was normal, which was a very important consideration in planning further therapy.

Elsewhere (de Dombal and others, 1971a, b; Goligher and others, 1971, 1972) we have emphasized the principle followed by us in the management of Crohn's disease, namely to operate and reoperate as required, the criterion of success being the relief of symptoms. In accordance with this policy all of the present 7 patients were offered further surgical treatment to excise the diseased portion of small bowel and to establish a fresh ileostomy. *Case* 7 declined, while the other 6 accepted. The operation performed was very similar in all instances. The abdomen was reopened through the old left paramedian incision. After a thorough exploration to determine the extent of the recurrence and to exclude any 'skip' lesions or other intra-abdominal abnormality, the diseased segment of ileum and the related mesentery were excised, together with the old ileostomy distally and 25 or 30 cm. of apparently normal small bowel proximally. The cut end of the remaining small gut was then brought out as a new ileostomy at the old site in 5 patients and at a new site in the left abdomen in *Case* 6, the stoma being fashioned by the usual eversion technique (Goligher, 1967).

The 6 surgically treated patients all made good recoveries from their operations and were out of hospital within 2 weeks, except for *Case* 6 who had a rectal stump removed by abdominoperineal excision at the same time and developed a very septic perineal wound which took 4 months to heal. All the patients were reviewed in September, 1971, and all appeared to be in excellent general health and to be enjoying normal ileostomy function. Admittedly the interval since operation, which ranges from 11 months to 2 years, is in no case very long, and further recurrence in the fullness of time in some of these patients is certainly a possibility, but they may well go for several years before this happens, or it may never occur, for it is difficult to prognosticate with any accuracy in Crohn's disease. *Case* 3 is particularly interesting in this respect, for this patient originally had a terminal ile-ectomy and limited right hemicolectomy for Crohn's disease of the terminal ileum in January, 1959. He developed a recurrence in the rest of the colon in 1961, and he had a subtotal colectomy with ileorectal anastomosis in February, 1962, followed a few months later by an abdominoperineal excision of the rectal stump and a permanent ileostomy. He then remained in perfect health, doing his ordinary work as a storeman for nearly 8 years till February, 1970, when he developed an ileal recurrence. After his latest ile-ectomy and new ileostomy for this condition he has been able to return to his former job again. In all, therefore, this patient has had 4 operations in over 12½ years, and at present, 18 months after his last operation, he rates himself as 100 per cent fit.

In view of the recent report by Knill-Jones, Morson, and Williams (1970) of a form of prestomal ileitis, distinct from recurrent Crohn's ileitis, arising proximal to the ileostomy for ulcerative colitis, it should be pointed out that in all our 7 cases, including the 2 whose original colectomy specimens were thought to show ulcerative colitis (*Cases* 4 and 6), the subsequent ileal lesion revealed clear histological evidence of Crohn's disease.

Acknowledgements.—I should like to record my sincere thanks to Drs. K. Simpkins and R. S. Harris for performing the majority of the radiological examinations on these patients, and to Drs. M. Cook, C. Abbot, F. G. Shiel, and H. Thompson for conducting the histopathological studies.

THROUGH-KNEE AMPUTATION

By J. F. NEWCOMBE
CENTRAL MIDDLESEX HOSPITAL, LONDON

and R. W. MARCUSON
THE MIDDLESEX HOSPITAL, LONDON

SUMMARY

Forty-three through-knee disarticulation amputations in 41 patients are reviewed. In 11 patients the procedure was entirely palliative, and 8 of these died within 1 month of operation. Of the 30 patients for whom a prosthesis was planned, only 2 died within this period. Ten patients were measured for a walking pylon preoperatively. The value of premeasurement is demonstrated by the speed of rehabilitation which was achieved by this group. The time scale of rehabilitation was much longer in those patients who were measured for their prostheses postoperatively. However, other adverse factors were present in this group, and their importance is discussed. Despite these factors, a very high rate of ultimate rehabilitation was obtained. Healing was obtained in 83 per cent of the entire series. The results indicate that the through-knee amputation is excellent for the elderly patient with atherosclerotic gangrene of the foot. The importance of an active programme of walking training in this advanced age-group is particularly stressed.

THE concept of amputation through the knee-joint is a very old one, but only relatively recently has there been a revival of this technique as applied to the problem of atherosclerotic gangrene (Early, 1968).

There appear to be two main reasons for the unpopularity of the through-knee procedure: first, the difficulty of designing an acceptable prosthesis, and, secondly, the poor reputation that this operation has acquired for primary healing (Taylor, 1967). It is this latter reason that has led many workers to advocate the Stokes-Gritti procedure in preference to simple disarticulation.

It is evident that any amputation in the ischaemic lower limb must be a compromise. The longer the stump, the greater is the control of any subsequent prosthesis, but unfortunately the smaller is the chance of primary healing. Thus, the standard below-knee amputation, although an excellent procedure when successful, has a failure rate of approximately 30 per cent (Dale and Capps, 1959; Tolstedt and Bell, 1961) when performed for atherosclerotic gangrene.

The above-knee amputation, on the other hand, has a good reputation for primary healing, but successful rehabilitation with a satisfactory prosthesis presents great problems in elderly patients. Furthermore, it carries an appreciable mortality, ranging from 18 to 30 per cent in published series (Gilchrist, 1961; Ham, MacKenzie, and Loewenthal, 1964; Otteman and Stahlgren, 1965).

It might be expected, therefore, that some form of through-knee procedure would prove a satisfactory compromise. Experience with the Stokes-Gritti operation indicates that this is indeed so. Martin, Stuart, and Maelor-Thomas (1967) found that this operation combines the advantage of a high rate of primary healing with the provision of good leverage for controlling the prosthesis. It is, however, not an easy amputation stump on which to fit a satisfactory prosthesis, although this has been denied by some workers (Middleton and Webster, 1962; Nayman, 1964; Lishman, 1965). The long conical shape of the stump provides a relatively small area for end-bearing, and the tendency of the prosthesis to rotate usually necessitates the added security of a pelvic band.

A through-knee disarticulation, besides being a technically simpler operation, does not have these disadvantages (Gillis, 1961). Its broad bulbous stump (*Fig.* 1) permits total end-bearing without discomfort, and its shape is such that with a close-fitting thigh corset the prosthesis cannot rotate (Vitali, Harris, and Redhead, 1967). This enables the final limb to be of light construction with no provision for ischial weight-bearing and without a pelvic band (*Fig.* 2).

An additional advantage of the through-knee procedure is that the length and shape of the stump are accurately known before the amputation is performed. Hence, in suitable cases, preoperative measurement can be made and the first walking pylon is therefore under construction while the stump is healing (Harding, 1967). This considerably shortens the duration of hospital care.

With these considerations in mind it seemed that the place of the through-knee operation in the management of atherosclerotic gangrene should be reassessed.

The present report analyses the results of 43 consecutive through-knee disarticulation amputations carried out on 41 patients in a district general hospital over a period of 4 years.

OPERATIVE TECHNIQUE

The technique used was essentially the same as that described by Batch, Spittler, and McFaddin (1954), but it was modified in several important respects.

With the patient supine and the knee flexed to a right-angle, *equal* flaps were marked out on the skin. The midpoint of the anterior flap was 3 cm. below the tibial tubercle, and the upsweep at the lateral and medial ends of the incision only reached a point at the same level as the tubercle (*Fig.* 3). We believe the construction of unequal flaps with the anterior flap longer than the posterior one to be a major cause of failure to heal in this operation.

With the incision we describe the extra length of the posterior flap ensures that the skin in the region of the stitch-line is completely slack. During the

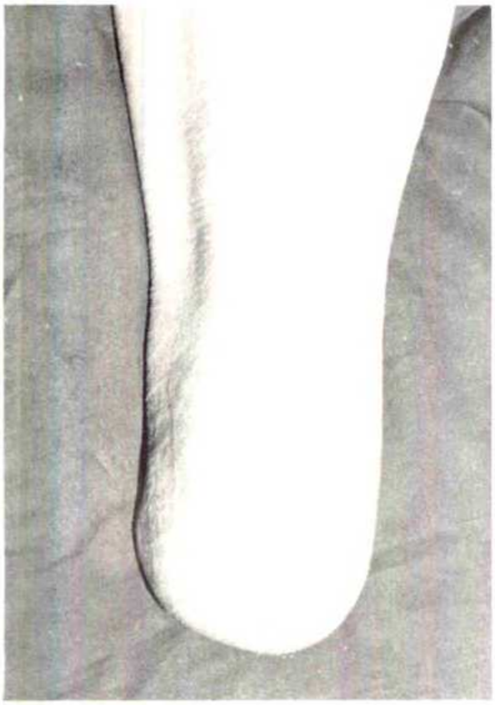

FIG. 1.—Anterior view of a through-knee disarticulation.

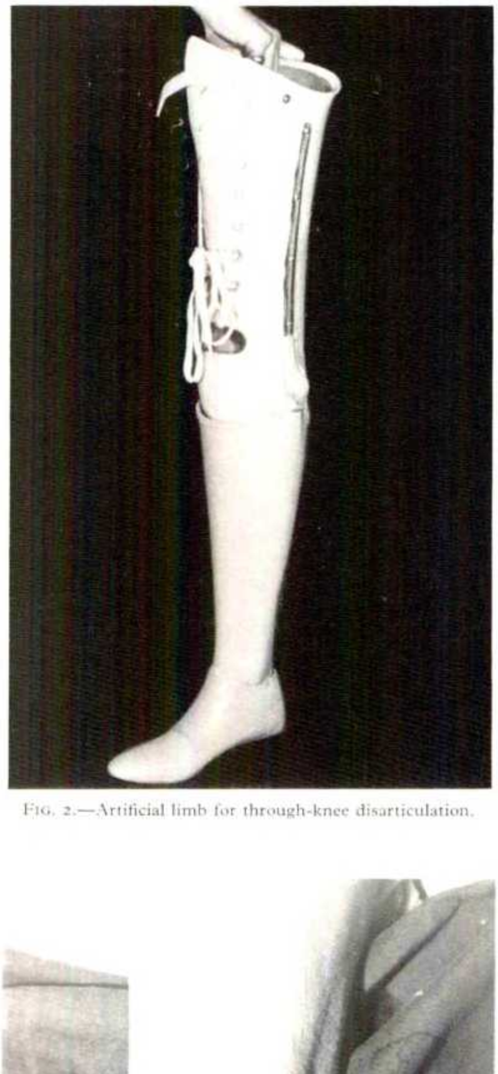

FIG. 2.—Artificial limb for through-knee disarticulation.

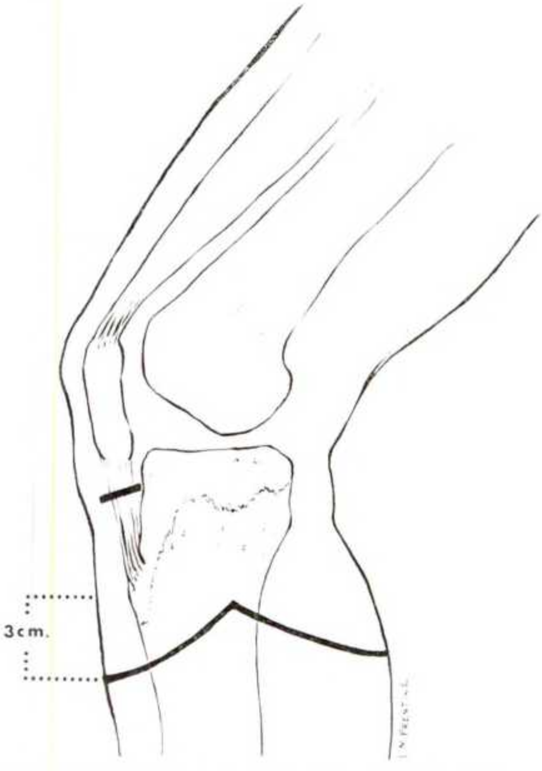

FIG. 3.—Showing the line of incision to give a suture-line without tension.

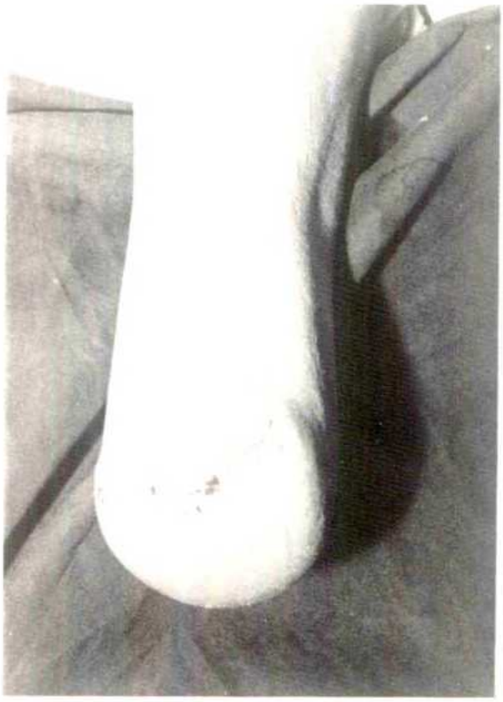

FIG. 4.—Posterior view of a through-knee disarticulation.

succeeding days this slackness is progressively taken up, and by the time the sutures are removed on the fourteenth day a perfect stump will be found (*Fig.* 4). A suture-line which is under the slightest tension when it is constructed will tend to be pulled apart during the postoperative period before the sutures are removed.

When the capsule of the knee-joint is reached it is reflected off the upper end of the tibia. The ligamentum patellae is divided and the joint is entered. The cruciate ligaments are divided and the tibia is displaced forwards to enable the posterior capsule to be divided as low down as possible. In some early cases the menisci were left behind, but we now routinely remove them.

With the division of the posterior capsule, the popliteal nerve and vessels are seen. The vessels are divided between clamps and are ligated individually. The popliteal nerve is cleanly transected and allowed to retract. The two bellies of the gastrocnemius are now divided as close to the femur as possible and the leg is now completely free.

With the assistant guiding the patella downwards the ligamentum patellae is sutured to the posterior capsule with interrupted No. 1 chromic catgut mattress sutures. Using the same suture technique, the cut edges of the capsule are then closed over the condyles of the femur. It has not been our practice to stitch the hamstring tendons to the cruciate ligaments, as described by Harding (1967), and no demonstrable weakness of hip extension has been apparent.

Table I.—DETAILS OF THE THREE GROUPS OF PATIENTS STUDIED

GROUP	NO. OF PATIENTS			AGE		NO. OF AMPUTATIONS
	Male	Female	Total	Mean	Range	
1	7	3	10	67	52–81	10
2	15	5	20	68	55–81	22
3	6	5	11	76	65–88	11

The skin is closed with interrupted sutures of 00 monofilament nylon, a Redivac suction drain being placed in the subcutaneous space for 24 hours.

Ampicillin and cloxacillin in a dosage of 250 mg. 6-hourly are given for 5 days postoperatively.

The stump is padded with cotton-wool and a firm 6-inch crêpe bandage is applied to prevent postoperative oedema. Normally the dressing is kept in place for 14 days, i.e., until the skin sutures are removed. After this a firm Rayelast bandage is applied and renewed daily.

ANALYSIS OF RESULTS

The patients have been divided into three groups:—

Group 1. Patients who were suitable for preoperative measurements and early postoperative fitting of a walking pylon.

Group 2. Patients for whom a prosthesis was planned but who were unsuitable for preoperative measurement and early postoperative fitting. There were four main reasons for allocation to this group:—

a. Poor general condition, making survival of the patient uncertain.

b. Severe rest pain leading to urgent amputation.

c. Failure of recent vascular reconstruction.

d. Doubt that the amputation stump would survive because of a high level of demarcation.

Group 3. Patients for whom the operation was entirely palliative.

The constitution of these groups is shown in *Table I.* It will be seen that the age structure of groups 1 and 2 is practically identical but that of group 3 is considerably higher.

Table II.—THE INCIDENCE OF POTENTIALLY ADVERSE FACTORS IN THE THREE GROUPS OF PATIENTS STUDIED

OTHER CONDITIONS	GROUP 1 (10 patients)	GROUP 2 (20 patients)	GROUP 3 (11 patients)
Diabetes	0	6	1
Cardiac failure	0	3	1
Recent coronary thrombosis	0	1	0
Hemiparesis	1	3	1
Senile mental changes	0	0	6
Recent failed arterial surgery	1	2	0
Previous contralateral amputation	0	3	0
Chronic bronchitis	1	0	1
Severe hypertension	1	3	0
Malignant disease	0	0	2

Table III.—NUMBER OF PATIENTS SURVIVING IN THE GROUPS STUDIED

GROUP	NO. OF PATIENTS	NO. OF PATIENTS SURVIVING			
		At 1 Week	At 1 Month	At 6 Months	At 12 Months
1	10	10	10	9	9
2	20	19	18	15	14
3	11	10	3	1	0

Table II shows the incidence of potentially adverse factors in the patients in the three groups. As would be expected, these were considerably more numerous in group 2 than in group 1. In group 3 the most common factor was senile mental deterioration of such a degree as to make rehabilitation with a prosthesis quite impossible.

It must be emphasized that advanced age alone was not considered a contra-indication to fitting a patient with a walking pylon. Both groups 1 and 2 contain patients in their ninth decade who were successfully taught to walk with a prosthesis.

Mortality.—*Table III* shows the survival pattern of the patients in the three groups, all of whom have now been followed up for a minimum of 1 year. In the series as a whole the mortality at the end of the fourth postoperative week was 10 out of 41 patients (23 per cent), which at first sight would appear to be unacceptably high. Howard, Chamberlain, and Macpherson (1969) reported a mortality of 14 per cent in their series of through-knee amputations. Martin and others (1967) had a mortality of only 6 per cent in their series of 237 Stokes-Gritti amputations. However, it will be seen that in the present series no fewer than 8 of the 10 deaths were in the palliative operation group (group 3). The mortality within 1 month of operation in those patients for whom there was a real prospect of rehabilitation was only 2 out of 30 patients (6 per cent).

After 6 months 5 of the original 20 patients in group 2 had died. In group 1 only 1 patient had died by this time, whereas, by contrast, in group 3 only 1 patient was still alive.

This analysis emphasizes the importance of separating out the purely palliative amputations when discussing mortality. Clearly, in any series of cases the overall figures will depend on the proportion of patients who fall into this category.

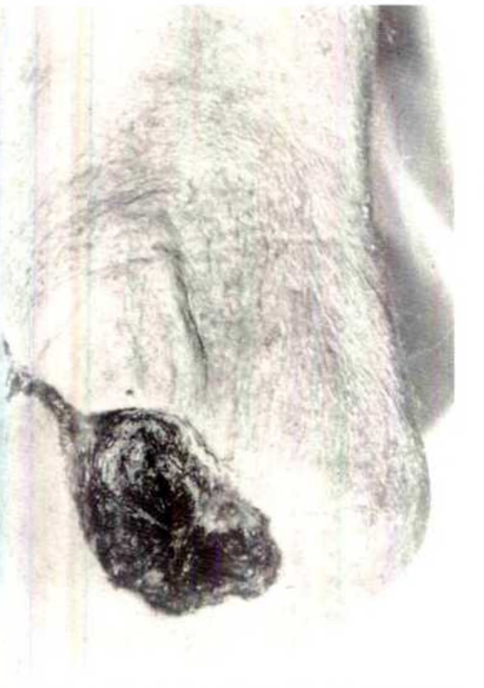

FIG. 5.—Necrosis of the anterior flap with slough over the femoral condyle.

Healing.—In view of the poor reputation that this procedure has acquired for primary healing (Taylor, 1967), particular attention has been paid to this aspect of the present study.

Taking the series as a whole, out of the 43 amputations performed, 2 patients died before healing could properly be assessed. Of the remaining 41 amputations, 26 (64 per cent) healed by primary intention, and 8 (19 per cent) healed after delay due to either wound infection or necrosis at the suture-line. In 7 cases the stump failed to heal, necessitating conversion to an above-knee amputation. Thus, a satisfactory outcome was achieved in 34 out of 41 through-knee amputations, i.e., a success rate of 83 per cent.

This is almost identical with the experience of Howard and others (1969), who found that of their 80 through-knee amputations, 65 ultimately healed—a success rate of 81 per cent. Although these results are inferior to the 91 per cent success rate of ultimate healing reported by Martin and others (1967) for the Stokes-Gritti procedure, they certainly cannot be regarded as unacceptably low.

When failure of healing occurred this was due in every case to full-thickness necrosis of a portion of the anterior skin-flap together with the underlying capsule, leaving the condyle of the femur exposed (*Fig.* 5). This complication led to conversion to an above-knee amputation except in 1 patient. Here the situation was dealt with by removal of the exposed portion of the condyle down to cancellous bone. After an interval of 3 weeks a sufficiently healthy bed of granulation tissue had formed on the bone to permit a split-skin graft to be applied successfully (*Fig.* 6). We believe that this technique may lead to a high rate of stump salvage where localized flap necrosis has occurred.

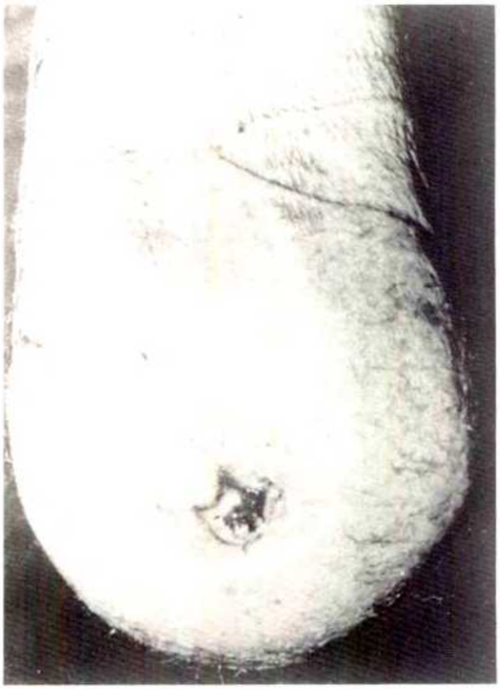

FIG. 6.—The stump has been salvaged by excising the slough and the underlying condyle. A second-stage Thiersch graft has yielded 80 per cent cover.

Table IV.—INCIDENCE OF HEALING IN THE THREE GROUPS OF PATIENTS STUDIED

GROUP	NO. OF AMPUTATIONS	PRIMARY HEALING	DELAYED HEALING	FAILED HEALING
1	10	10	0	0
2	21*	10	6	5
3	10†	6	2	2

* Two patients in group 2 had bilateral amputations, and 1 unilateral amputee died before healing could be assessed.

† One patient in group 3 died before healing could be assessed.

An analysis of the three groups of patients is presented in *Table IV*. The most striking feature is the 100 per cent primary healing rate achieved in group 1, contrasting with the 48 per cent primary healing in group 2. It will be recalled that the patients in group 2 were those who for different reasons were not thought fit for premeasurement at the limb-fitting centre. An analysis of these reasons in relation to healing in this group is given in *Table V*.

From this it will be seen that whereas the cases of *total* failure to heal appear to be unrelated to the preoperative condition, the cases of *delayed* healing were, with 1 exception, confined to those patients whose general condition was such as to make survival after operation uncertain. Eight patients came into this category, and of these, no fewer than 5 showed delayed healing. Two of these were in gross cardiac failure, 1 was hemiplegic on the side of the amputation, 1 was a senile diabetic, and 1 had widespread atherosclerosis with a failed aorto-iliac graft. *It should be noted that despite these disabilities every one of these patients was eventually fitted with a walking pylon and was successfully rehabilitated.* Indeed, although this group showed the highest incidence of delayed healing, the ultimate success rate was 78 per cent.

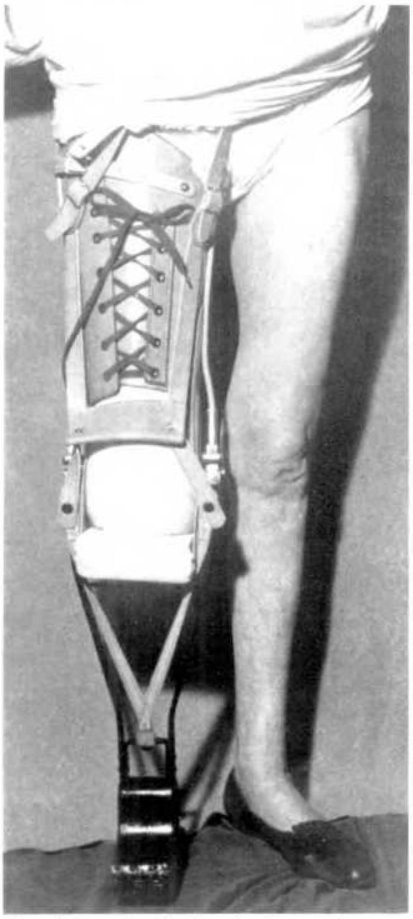

FIG. 7.—A walking pylon fitted on the fourteenth postoperative day.

Table V.—INCIDENCE OF HEALING IN THE PATIENTS WHO WERE THOUGHT UNFIT FOR PREOPERATIVE MEASUREMENT FOR THEIR PROSTHESIS (GROUP 2)

REASON FOR NO PREOPERATIVE MEASUREMENT	NO. OF AMPUTATIONS	PRIMARY HEALING	DELAYED HEALING	FAILED HEALING

d. Doubt that amputation stump would survive	4	3	0	1

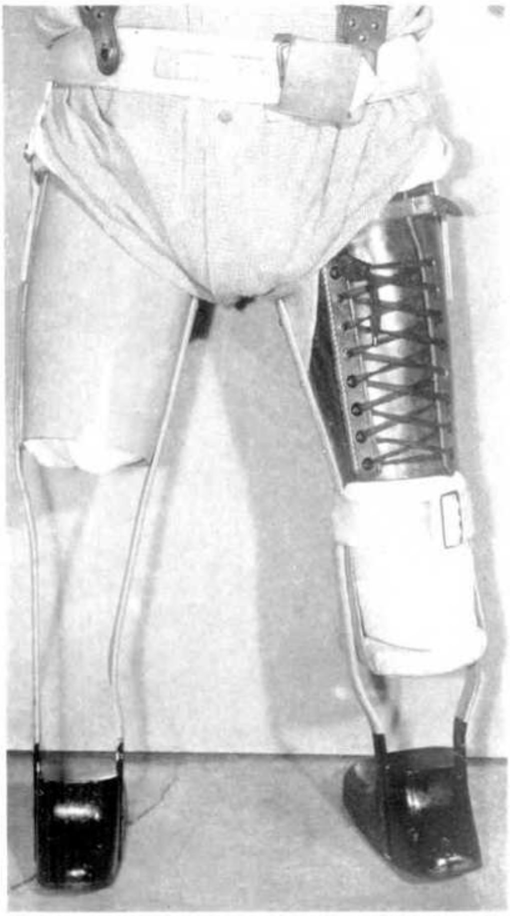

FIG. 8.—A bilateral amputee with short rocker pylons. Note the extra leverage given by the through-knee disarticulation compared with the mid-thigh amputation on the right side.

Rehabilitation.—One of the most important features of the through-knee amputation is the ease with which elderly patients learn to use a walking pylon (Harris, 1967).

The pylon (*Fig.* 7) is designed so that nearly all of the patient's weight is taken on the ischium. The end of the amputation stump rests with only slight pressure on a Sorbo-pad. Where preoperative measurement has been carried out it is usual to start walking training on the fourteenth day after amputation. This is continued until the patient is able to walk with two sticks confidently and without assistance. In addition, he should be able to walk both up and down stairs holding the hand-rail in one hand and a stick in the other. Some patients require the fitting of an additional hand-rail in their homes to give added security.

Even bilateral amputees can achieve a remarkable degree of independent mobility when fitted with short rocker pylons (Vitali, 1966). The patient in *Fig.* 8 is now 81 years old and has had an above-knee amputation of the right leg and a through-knee amputation of the left leg. With bilateral above-knee stumps he would be virtually immobilized. With the extra leverage on the left side he is entirely independent in his home and garden.

Table VI.—THE MEAN TIME FROM AMPUTATION TO FITTING OF A PYLON FOR PATIENTS IN GROUPS 1 AND 2 SURVIVING MORE THAN 6 MONTHS

GROUP	NO. OF PATIENTS SURVIVING 6 MONTHS	NO. WITH SUCCESSFUL UNILATERAL AMPUTATION	MEAN TIME FROM AMPUTATION TO FITTING OF PYLON (days)
1	9	9	14

1	8	28	1
2	6	36	5

Wherever possible, as soon as the stump has taken up its final contour and the patient has become sufficiently expert in the use of the pylon, he is fitted with a final prosthesis (*Fig.* 2). This differs from the pylon in several important respects. It is of a lighter construction and the thigh corset is accurately moulded to the stump to prevent rotation in use. Weight-bearing is now for the first time taken fully on the end of the stump, which is well adapted to bear this load. Murdoch (1967) has estimated that the total weight-bearing area here is of the order of 125 sq. cm. The knee mechanism may be of the locking or free-swinging variety. Most patients prefer the added security of the knee-lock, but some, especially the younger patients, learn to use a free-swinging prosthesis extremely well. The major disadvantage of these prostheses is that the joint mechanism must lie outside the limb if it is to be at the same level as the opposite knee. This disadvantage is, however, far outweighed, at least in male patients, by the ease of using it when compared with the difficulty of managing an above-knee prosthesis.

From *Table VI* it will be seen that in group 1 all the 9 patients who survived more than 6 months were fitted with their first pylon and commenced walking training at a mean time interval of only 14 days from the amputation. The mean total time from amputation to discharge in this group was 30 days, and it seems unlikely that this period can be significantly reduced. Even when immediate postoperative fitting of a prosthesis has been practised, the reported time from amputation to completion of walking training is 28 days (Vitali and Redhead, 1967).

In group 2, of the 15 survivors at 6 months, 2 were primary failures requiring conversion to above-knee amputations and 2 were bilateral amputees. In the remaining 11 unilateral amputees the mean interval from amputation to the commencement of walking training was 52 days. Analysis of the data showed that this time interval was the same whether the wound healed by primary intention or was delayed. It seems that the general factors rendering these patients unfit for premeasurement were also largely responsible for the long interval before postoperative measurements could be carried out.

The difference in the capacity for rehabilitation between these two groups is also illustrated by the relative numbers who were ultimately fitted with a prosthesis of the type shown in *Fig.* 2. *Table VII* indicates that 8 of the 9 survivors in group 1 were successfully fitted with this type of artificial limb, with a mean time interval of 28 weeks from the fitting of the first pylon. In group 2 only 6 of the 11 survivors were fitted with such a limb, the mean time interval from the first pylon being 36 weeks, i.e., 2 months longer than for group 1 patients. The remaining 5 patients in group 2 were fitted with a permanent walking pylon.

DISCUSSION

Although our method of subdivision into three groups may seem arbitrary, it has essentially achieved the aim of separating out for special consideration those patients with an exceptionally favourable outlook (group 1) and those with no prospect of rehabilitation (group 3).

The purpose of the operation in the latter group is entirely one of palliation in an otherwise hopeless situation, and the criteria of success are therefore more limited than in the other two groups. In group 3 only two factors are of real importance: primary mortality and the rate of healing. In fact only 1 patient died within 1 week of amputation in group 3, which was regarded as an acceptable primary mortality, but the extremely poor general state of these patients is emphasized by the subsequent survival figures (*Table III*). Six months after amputation only 1 patient out of 11 was still alive, and by 12 months all these patients had died.

In the other two groups the primary mortality of 2 out of 30 patients was considered satisfactory. At 6 months 24 patients were still alive, and there was only 1 further death in the subsequent 6 months. In other words, nearly 80 per cent of those patients for whom rehabilitation was possible survived for more than 12 months. This emphasizes the need for a programme of walking training which is both swift and effective. Perhaps the greatest advantage of the through-knee disarticulation procedure is the speed and quality of rehabilitation that it permits, even in the very elderly (Harris, 1967; Howard and others, 1969). Of the 28 patients in groups 1 and 2 who survived more than 1 month after amputation, all were taught to walk on a pylon. This is a very satisfactory result when it is considered that both groups included octogenarians, and in group 2 there were 2 patients who were hemiplegic on the side of the amputation. Moreover, we found that of the 20 unilateral amputees who survived more than 6 months, 14 were subsequently fitted with an artificial limb. The remaining 6 were given a permanent walking pylon. The important point is that all these patients were fitted with a useful prosthesis on which they could walk without assistance.

The high rate of successful rehabilitation after the through-knee disarticulation procedure is noted by other authors. Vitali and Redhead (1967) achieved a 92 per cent success rate in this respect. With the Stokes-Gritti amputation, on the other hand, the results appear to be inferior. Middleton and Webster (1962) and Lishman (1965) achieved approximately 70 per cent success with walking on either a pylon or an artificial limb, whereas Martin and others (1967) report only a 55 per cent rehabilitation rate in their series of 230 patients.

In the present series the outstanding difference between groups 1 and 2 is in the time interval from amputation to the commencement of walking training. However, these figures must be interpreted with care. It is not suggested that had the patients in group 2 been premeasured, their rate of rehabilitation would have been similar to that in group 1. Although a better performance may have been achieved in some individuals, in the majority of patients in group 2 the factors rendering them unsuitable for preoperative measurement were also largely responsible for the more prolonged postoperative course that they followed.

What is certain, however, is that a policy of *post-operative* measurement in all the cases would have unnecessarily prolonged the duration of hospital treatment of those patients who fell into group 1. Even the most favourable case would not have been fit to travel to the limb-fitting centre until at least the seventh post-amputation day, and many would have been delayed for a considerably longer period than this.

The importance of the excellent results obtained in group 1 is that they set a standard by which the data from group 2 may be judged. In particular, we wish to emphasize the great value of preoperative measurement whenever possible. Apart from the saving of time, which is considerable, this policy has the effect of creating a more positive approach to the operation. To know in advance the date on which the first walking pylon is to be fitted sets a definite target towards which both patient and staff can be encouraged to work.

Finally, the question of healing must be considered. The fact that every patient in group 1 healed by primary intention suggests that there is no inherent defect in this form of amputation with the technique described. It has also been noted that although group 2 patients showed a high incidence (6 out of 16 amputations) of delayed healing, it appeared that other factors were at least as important in determining the time between amputation and the commencement of walking training.

Taking the series as a whole, failure of healing due to full-thickness necrosis of part of the anterior flap occurred in 7 out of 41 amputations, an incidence of 17 per cent. This is considerably lower than the reported incidence of failure in the standard below-knee amputation for atherosclerotic gangrene (Dale and Capps, 1959), but is inferior to the healing record of the Stokes-Gritti procedure. However, with the technique described for dealing with localized flap necrosis, it is hoped that more cases of failed healing in the through-knee disarticulation will be salvaged.

Acknowledgements.—We should like to thank Dr. E. E. Harris and his colleagues at the Limb Fitting Centre, Roehampton, for the advice and the unfailing assistance that we have received in the fitting, training, and rehabilitation of all our patients.

BILIARY-PRESSURE STUDIES DURING CHOLECYSTECTOMY

By A. CUSHIERI,
UNIVERSITY OF LIVERPOOL

J. HOWELL HUGHES, AND M. COHEN
ROYAL INFIRMARY, LIVERPOOL

SUMMARY

A method of manometric choledochography is described by which three types of choledochal pressure/filling curves could be obtained in patients undergoing cholecystectomy. This work provides evidence that biliary pressures are mainly a function of the choledochal sphincter in man and are largely independent of duodenal muscular activity. Reflux of contrast medium into the pancreatic duct is not associated with either obstructive pathology of the lower choledochus or biliary hypertension.

BILIARY manometry has been extensively utilized as an ancillary procedure to choledochography in the operative investigation of extrahepatic biliary disease. However, no accurate information is available on the pressure dynamics of the radiologically normal common bile-duct in man, and such data as exist on the subject have largely been derived from animal experimentation (Elman and McMaster, 1926; Lueth, 1931; Parry, Hallenbeck, and Grindlay, 1955). It is not possible to extrapolate these experimental findings to man because of the anatomical differences of the periampullary region that exist between the various species (Didio and Anderson, 1968). There is considerable controversy as to whether the biliary pressures in man are a function of the choledochal sphincter or duodenal muscular activity. Some workers (Lueth, 1931; Bergh and Layme, 1940; Long, 1942) maintain that the choledochal sphincter is capable of independent activity and is responsible for the pressure changes in the choledochus, whilst others (Burget, 1925; Elman and McMaster, 1926; Potter and Mann, 1926) consider that the choledochal pressure is largely dependent on duodenal muscular activity.

A method of operative manometric choledochography is described which allows an accurate measurement of dynamic pressure changes in the common bile-duct before, during, and after the injection of radio-opaque medium. It has been applied to the investigation of choledochal pressures in cases with a radiologically normal common bile-duct.

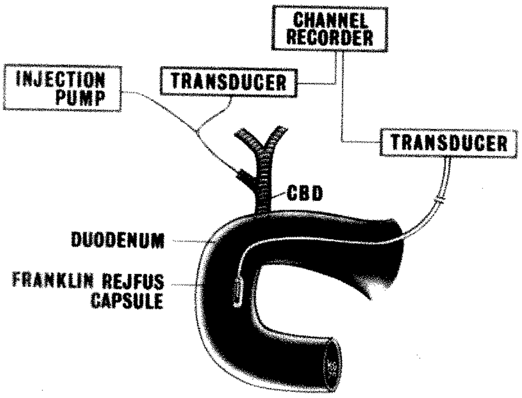

FIG. 1.—The apparatus used.

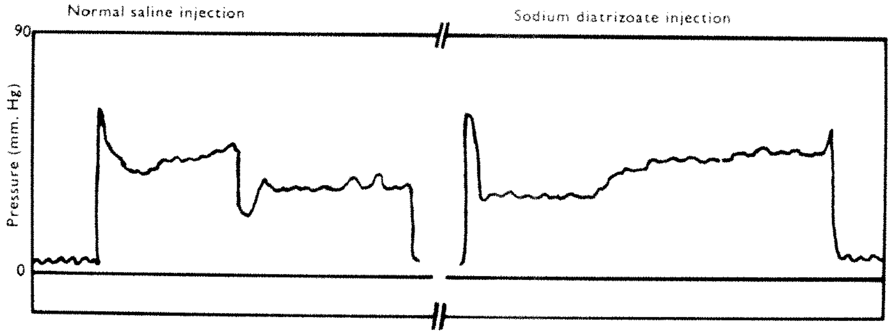

FIG. 2.—Choledochal pressure/filling curves using a constant-flow pump.

MATERIALS AND METHODS

Thirty-two patients undergoing cholecystectomy were studied. The age-range was 28–72 years. No drugs were administered for 10 hours before operation in all but 2 patients. The latter received atropine, 0·6 mg., 1 hour before surgery. Anaesthesia was carried out with thiopentone, nitrous oxide, and oxygen, a combination which has no effect on biliary pressures (Mallet-Guy, 1952). Muscle relaxation was achieved with D-tubocurarine. Each patient had an operative choledochogram using an electrically driven pump. This injected sodium diatrizoate, 40 per cent, at a constant rate of 6 ml. per minute through a Portex cannula inserted into the common bile-duct via the cystic duct (*Fig.* 1). The pressure exerted by the pump varied with the resistance to flow in the tubing but it averaged 25 mm. Hg. The system incorporated a side-tube leading to a pressure transducer which was connected to a multichannel recorder. Simultaneous duodenal pressure tracings were also recorded using a Franklin-Rejfus tube introduced nasogastrically, through which was threaded a Portex pressure line tubing. This was attached to another pressure transducer connected to the same recorder. Continuous visual monitoring of the biliary tree during the period of injection of dye was effected by means of a Siemens image intensifier.

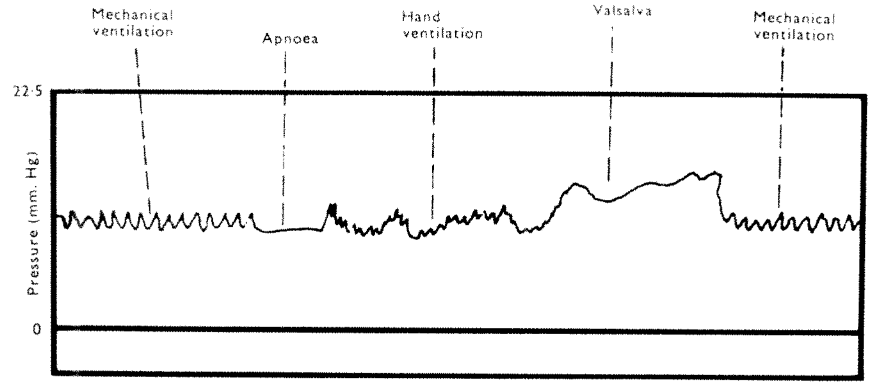

FIG. 3.—Changes in biliary pressure with alterations in ventilation.

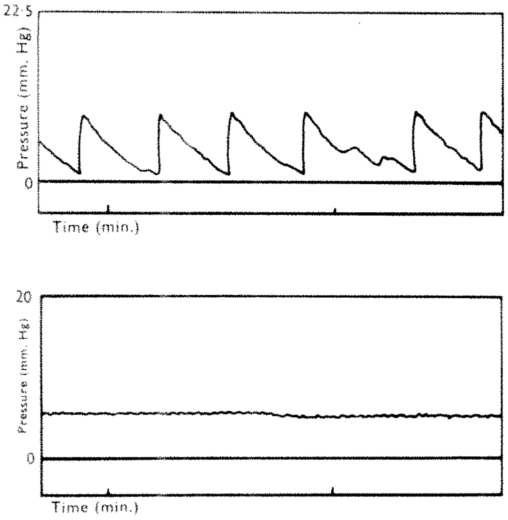

FIG. 4.—Changes in resting choledochal (above) and duodenal (below) pressures.

Table I.—BASAL CHOLEDOCHAL PRESSURES IN 30 CASES WITH A RADIOLOGICALLY NORMAL OPERATIVE CHOLEDOCHOGRAM

TYPE OF CASE	NO. OF CASES	COMMON BILE-DUCT PRESSURE (mm. Hg)
With good gall-bladder function at cholecystography	17	5·9 ± 3·3
With poor or absent gall-bladder function at cholecystography	13	6·3 ± 2·17
Total	30	6·1 ± 4·3

FINDINGS

Injection of methane iodine compounds into the biliary tree is said to cause biliary hypertension as these compounds are mucosal irritants (Mallet-Guy, 1952). However, choledochal pressure monitoring during injection with isotonic saline at the rate of 6 ml. per minute gives a very similar pressure/filling curve to that obtained during sodium diatrizoate injection at the same rate (*Fig.* 2).

It can also be argued that the introduction of the common bile-duct cannula through the cystic duct would result in an artificially high common bile-duct pressure as a result of the sudden exclusion of the gall-bladder reservoir effect from the extrahepatic biliary system. However, statistical analysis (t-test) showed no significant difference ($P > 0{\cdot}8$) in the basal choledochal pressure measured by this method between cases with good gall-bladder function and cases with poor or absent gall-bladder function at oral cholecystography (*Table I*).

Resting Pressures.—The average choledochal resting pressure was 6·1 ± 4·3 mm. Hg. Cases with good gall-bladder function at oral cholecystography had a mean resting common bile-duct pressure of 5·9 ± 3·3 mm. Hg. The mean resting choledochal

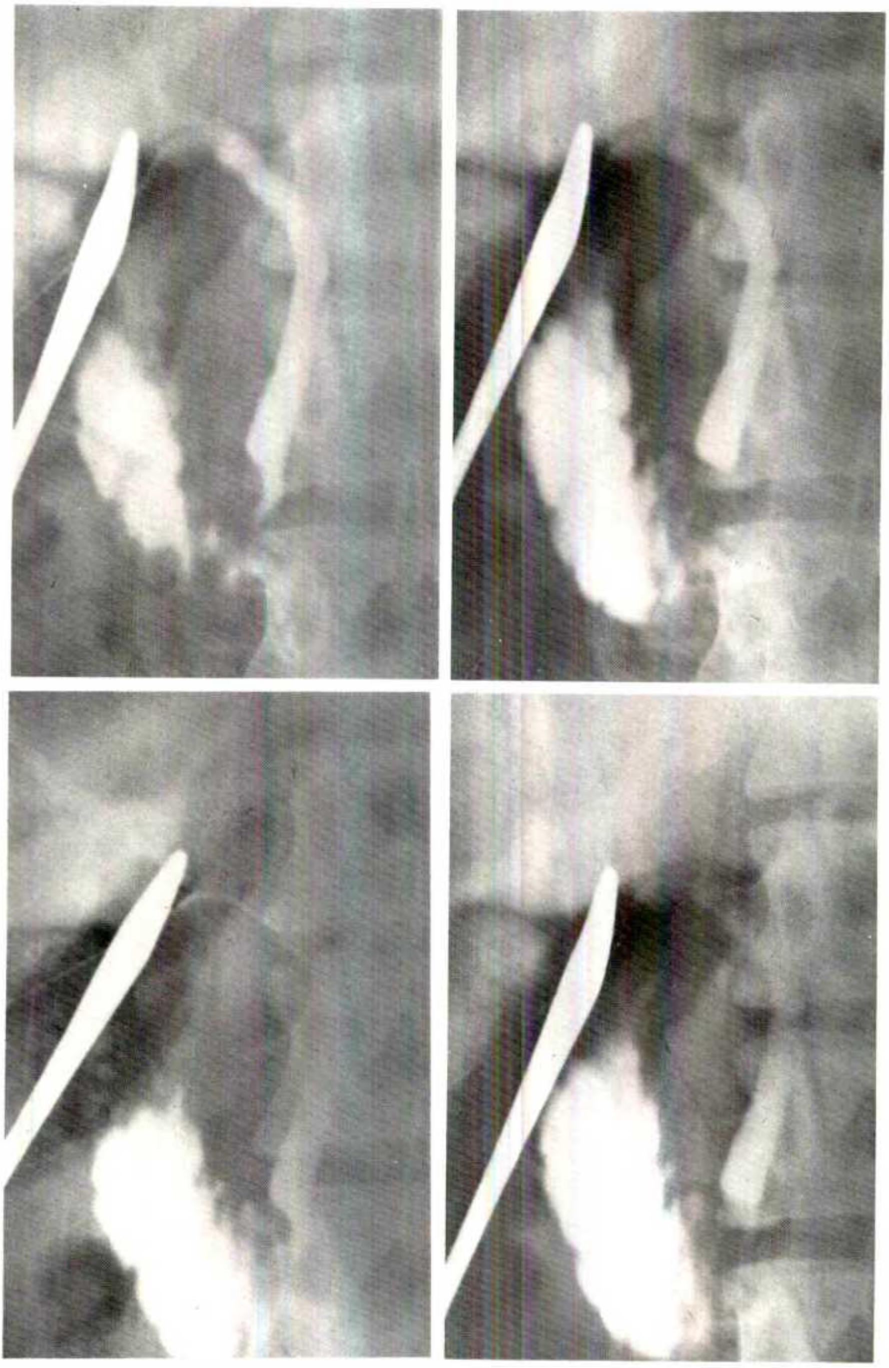

FIG. 7.—Contractions of the lower 2·5 cm. of the common bile-duct in a case showing a type-1 pressure/filling curve.

pressure in cases with poor or total absence of gall-bladder function was 6·3 ± 2·17 mm. Hg.

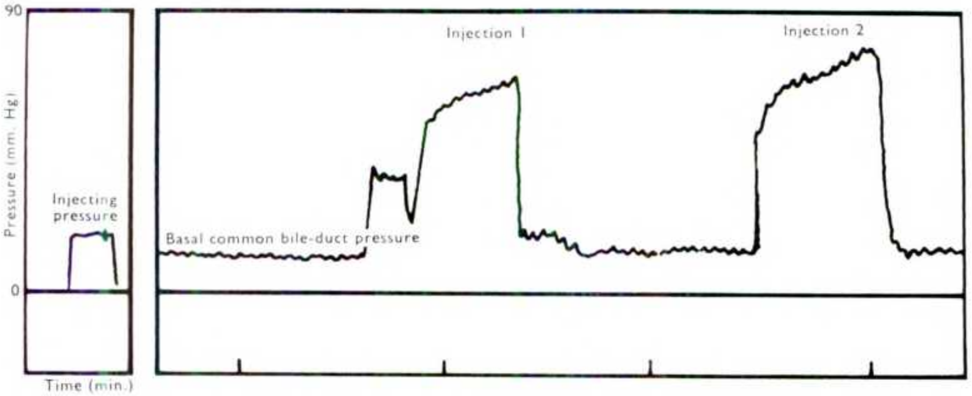

FIG. 8.—A type-2 (hypertonic) choledochal pressure/filling curve.

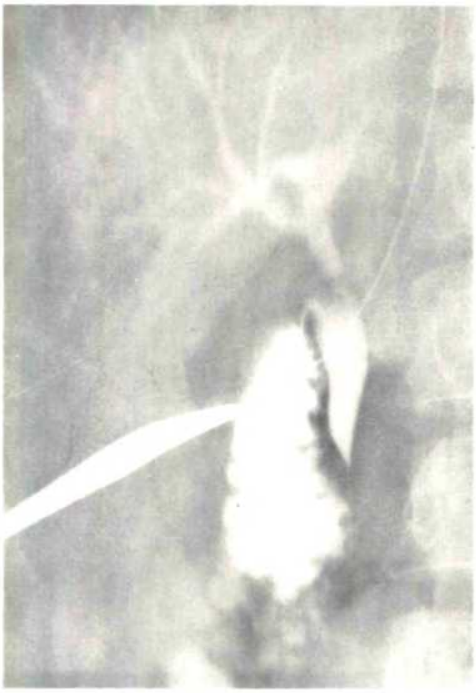

FIG. 9.—Choledochogram from a case showing a type-2 pressure/filling curve.

The resting choledochus exhibited pressure waves of an average amplitude of 2·2 mm. Hg coincident with the downward movement of the diaphragm and liver during respiration. These pressure waves were regular during mechanical ventilation, they disappeared during periods of apnoea, and were extremely variable during hand ventilation (*Fig.* 3). The choledochal pressure showed a steady rise during the Valsalva manœuvre.

The common bile-duct also exhibited pressure-wave activity independent of respiration and heart-beat. These pressure waves, noted in five tracings, were of a mean amplitude of 5·8 mm. Hg, they occurred at irregular intervals, and were not accompanied by any significant changes in either intra-duodenal pressure or duodenal muscular activity (*Fig.* 4). There was no correlation between the resting pressure in the common bile-duct and the mean duodenal pressure or muscular activity. Moreover, the choledochal pressure showed no appreciable alteration during periods of intense duodenal peristalsis induced by pentazocine, 15 mg. i.v. (*Fig.* 5).

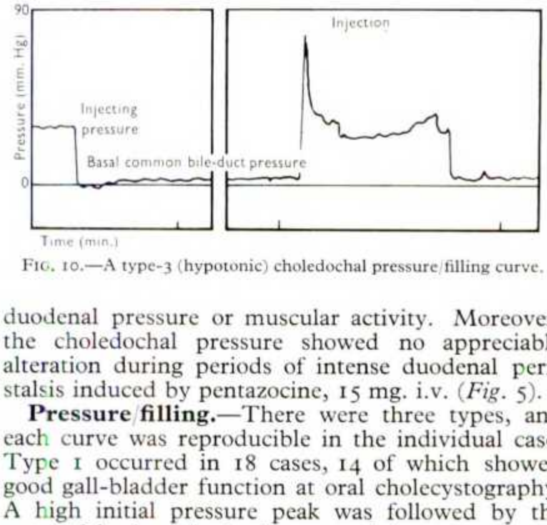

FIG. 10.—A type-3 (hypotonic) choledochal pressure/filling curve.

Pressure/filling.—There were three types, and each curve was reproducible in the individual case. Type 1 occurred in 18 cases, 14 of which showed good gall-bladder function at oral cholecystography. A high initial pressure peak was followed by the entry of dye into the duodenum and the appearance of pressure waves, averaging 10–15 per minute (*Fig.* 6). These were coincident with contractions of the lower 2 cm. of the common bile-duct (*Fig.* 7); the contractions spread from below upwards and relaxed in the reverse direction. The upper parts of the choledochus dilated passively when the lower muscular portion was contracted. After injection the common bile-duct pressure returned to the pre-injection level in all but 2 cases.

Type 2 was obtained in 7 cases, 5 of which showed poor or absent gall-bladder function at oral cholecystography. With injection the choledochal pressure showed a steady rise until the end of injection, there being no wave activity apart from that due to respiration (*Fig.* 8). Dye entered the duodenum in a steady trickle and at a later stage than in type-1 cases. During injection the lumen of the lower 2 cm. of the choledochus showed no change in calibre and the duct was dilated above this lower segment (*Fig.* 9). After injection 5 cases showed a residual pressure in the common bile-duct which lasted for periods up to

1 minute. This residual pressure could be lowered to, or below, the pre-injection level by propantheline bromide, 15 mg. i.v.

Type-3 filling/pressure curve was obtained in 7 cases. Six of these showed complete non-function at cholecystography. With injection there was a momentary rise in the common bile-duct pressure and early entry of dye into the duodenum, after which the pressure in the choledochus approximated to the pump pressure, indicating that the choledochal sphincter was offering little or no resistance to the flow of Hypaque into the duodenum. The choledochal pressure returned to the resting level immediately after injection (*Fig*. 10). Dye entered the duodenum in a constant flow, and the lower end of the common bile-duct remained patent throughout the period of injection without any radiologically visible contractions (*Fig*. 11). In some of these cases the common hepatic and the more proximal bile-ducts could not be visualized radiologically unless the rate of injection of dye was doubled to 12 ml. per minute.

Pancreatic Reflux.—Reflux of sodium diatrizoate into the pancreatic duct was observed in 7 cases. It was associated with a low resting choledochal pressure (mean, 2·3 mm. Hg; range, 0–6·0 mm. Hg). In 5 cases it occurred during injection but after the entry of dye into the duodenum. Three of these showed a type-3 pressure/filling curve, with early and rapid entry of dye into the duodenum (*Fig*. 12). In the other 2 cases pancreatic reflux occurred after the injection of dye at a time when the duodenum showed gross segmental activity (*Fig*. 13). One of these patients had chronic pancreatitis. Drugs which induce spasm of the choledochal sphincter, such as morphine, codeine, and pethidine, raised the choledochal pressure but did not precipitate reflux. On the other hand, pancreatic reflux occurred after the intravenous injection of propantheline bromide.

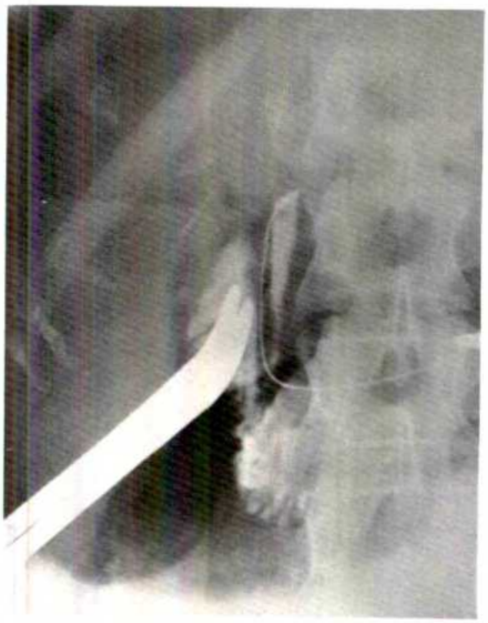

FIG. 11.—Choledochogram from a case with a type-3 pressure/filling curve.

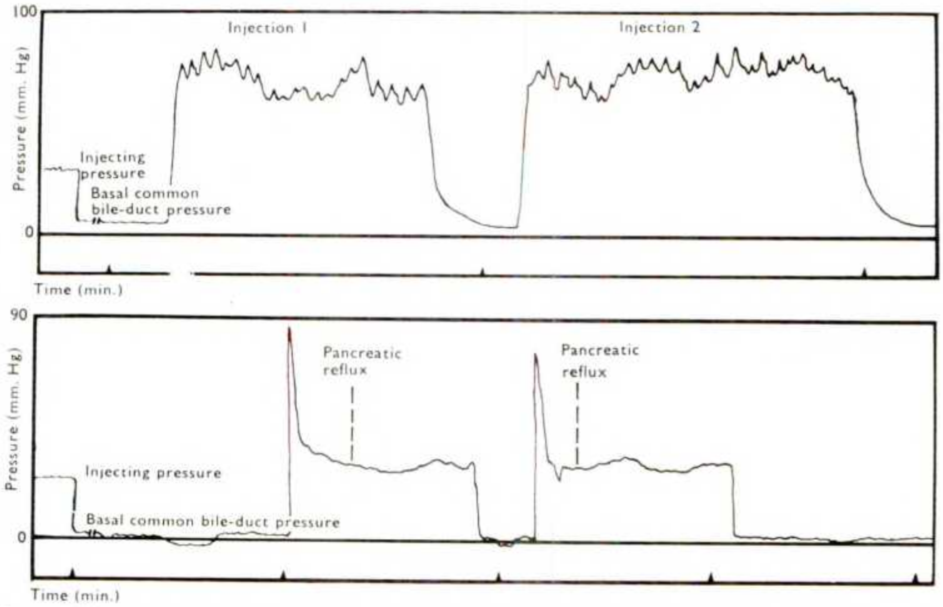

FIG. 12.—Pressure/filling curve in a case showing pancreatic reflux during injection of dye (below), compared with a normal choledochal pressure/filling curve (above).

DISCUSSION

The choledochal sphincter contains both intrinsic (circular and longitudinal) and extrinsic (duodenal) musculature. In man extrinsic musculature is less well developed than the intrinsic component (Didio and Anderson, 1968). According to Nuboer (1929), the choledochal sphincter acts both as a closing mechanism as well as an ejaculatory muscle, a view which is quite different from that of the majority of authors.

A great controversy has raged as to whether the resistance to drainage of both pancreatic and biliary outflows is dependent on sphincteric action or duodenal muscular activity or both. In the present authors' opinion the varying results may be accounted for by the varying experimental situations and species types used in these studies.

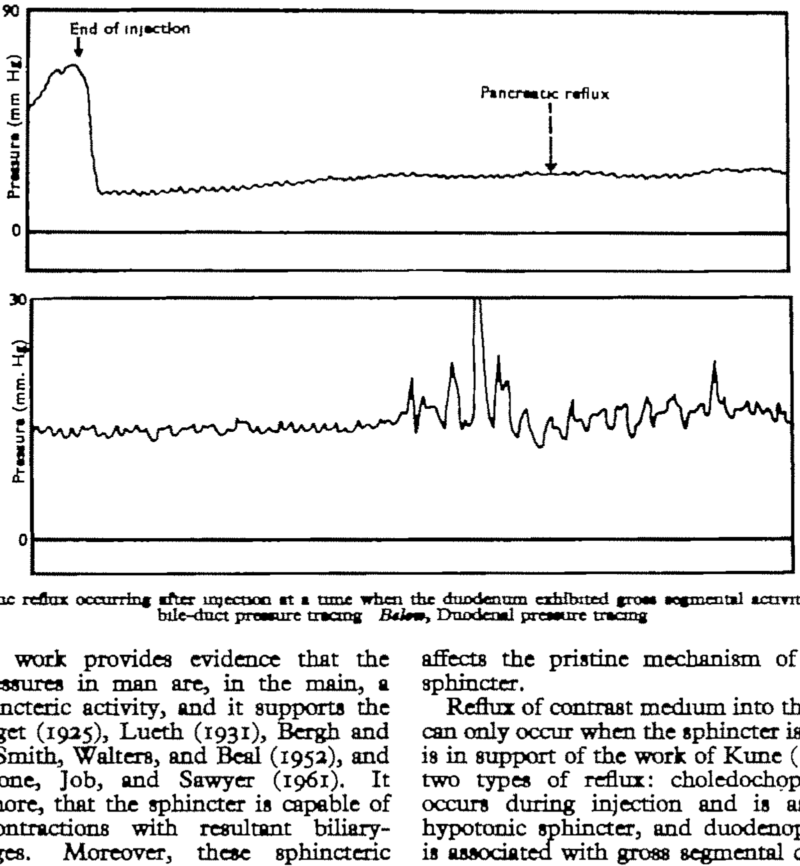

FIG. 13.—Pancreatic reflux occurring after injection at a time when the duodenum exhibited gross segmental activity *Above*, Common bile-duct pressure tracing *Below*, Duodenal pressure tracing

This present work provides evidence that the choledochal pressures in man are, in the main, a product of sphincteric activity, and it supports the findings of Burget (1925), Lueth (1931), Bergh and Layme (1940), Smith, Walters, and Beal (1952), and Daniels, McGlone, Job, and Sawyer (1961). It shows, furthermore, that the sphincter is capable of independent contractions with resultant biliary-pressure changes. Moreover, these sphincteric contractions are independent of duodenal muscular activity. Similar findings have been reported by Caroli, Porcher, Pequingnot, and Delattre (1960) and Nebesar, Pollard, and Potsaid (1966). However, Wyatt (1967, 1969) has produced experimental evidence in dogs to show that gastric peristalsis is related to changes of resistance at the sphincter, and disconnexion of the stomach from the duodenum, as occurs with Polya gastrectomy, results in changes in the dynamics of bile-flow. Unfortunately, gastric motility was not monitored in this study.

Cases showing a type-1 pressure/filling curve are the commonest and would seem to represent the normal situation. They show the existence of a physiologically active muscular portion of the distal common bile-duct. It follows from this and from the anatomical work of Hand (1963) that transduodenal sphincterotomy cannot divide the whole extent of the choledochal sphincter and is, therefore, incomplete.

Cases with a type-2 pressure/filling curve are examples of muscular hypertonia of the choledochal sphincter. They are associated with poor gall-bladder function at oral cholecystography, and can be distinguished from organic narrowing of the peri-ampullary region by intravenous injection of propantheline bromide.

Type-3 cases provide manometric evidence for the existence of hypotonia of the choledochal sphincter. They too are associated with poor gall-bladder function. It would seem that gall-bladder disease affects the pristine mechanism of the choledochal sphincter.

Reflux of contrast medium into the pancreatic duct can only occur when the sphincter is relaxed, and this is in support of the work of Kune (1970). There are two types of reflux: choledochopancreatic, which occurs during injection and is associated with a hypotonic sphincter, and duodenopancreatic, which is associated with gross segmental duodenal activity. One of the patients exhibiting the latter phenomenon had chronic pancreatitis, and this may be of significance as both Muller-Wieland (1963) and Anderson (1968) have reported abnormal duodenal motility in patients with chronic pancreatitis.

Acknowledgement.—This work was supported by a grant from the United Liverpool Hospitals.

TWELVE-HOUR LIVER PRESERVATION IN THE PIG USING HYPOTHERMIA AND HYPERBARIC OXYGEN

BY HAROLD SPILG, C. J. UYS, ROSEMARY HICKMAN, STUART J. SAUNDERS,
AND JOHN TERBLANCHE

THE DEPARTMENTS OF SURGERY, PATHOLOGY, AND MEDICINE, UNIVERSITY OF CAPE TOWN, AND
THE LIVER CLINIC, GROOTE SCHUUR HOSPITAL, OBSERVATORY, CAPE TOWN, SOUTH AFRICA

SUMMARY

In an attempt to prolong successful storage of the pig liver beyond the 6–8 hours previously described from this laboratory, the addition of cell-membrane-stabilizing drugs to the preserving solution and the use of a potassium-rich solution were investigated. Using simple hypothermia alone, 10- and 12-hour storage was unsuccessful. Using the previously described hypothermic technique, but with the addition of hyperbaric oxygen at 3 atmospheres absolute (A.T.A.), consistently successful 12-hour preservation was achieved.

A PREREQUISITE for any clinical liver transplantation programme is a simple and reliable method of organ preservation. Under favourable circumstances most liver transplants within a city can be completed within 6 hours (Calne, 1969; Orr, Charlesworth, Mallick, Jones, Harris, Jones, Keen, McIver, Testa, and Turnberg, 1969). Recent reports from various centres indicate that simple cooling provides adequate protection for this duration (Slapak, Baddeley, Wexler, Saravis, Sise, Garcia, Giourard, and McDermott, 1970; Abouna, Koo, Howanitz, Ancarani, and Porter, 1971; Hadjiyannakis, Calne, Marshall, and Davis, 1971; Mieny and Myburgh, 1971; Spilg, Uys, Hickman, Saunders, and Terblanche, 1971). Occasionally, however, preservation for a longer period is necessary (Starzl and Putnam, 1969). At present this can only be achieved by complicated perfusion systems (Brettschneider, Daloze, Huguet, Porter, Groth, Kashiwagi, Hutchison, and Starzl, 1968; Belzer, May, Berry, and Lee, 1970). The present study was undertaken to investigate simpler methods to prolong liver preservation for 12 hours.

MATERIALS AND METHODS

Large White, Landrace, or cross Large White × Landrace pigs of both sexes obtained from local farmers and weighing between 27 and 36 kg. were used. The donor and the recipient were matched for weight approximation with a preferred weight difference of no more than 5 kg. between the donor and the recipient. Some transplants were between litter-mates, while others were between unrelated animals.

Table I.—COMPOSITION OF THE PRESERVING SOLUTIONS

Solution II
400 ml. A.C.D. fresh-frozen pig plasma*
80 ml. 5 per cent dextrose water
20 ml. 4·2 per cent sodium bicarbonate
10 mg. heparin
1 MU. Penicillin G
1 g. streptomycin

Solution III
400 ml. A.C.D. fresh-frozen pig plasma
80 ml. 5 per cent dextrose water
20 ml. 4·2 per cent sodium bicarbonate
50 mg. chlorpromazine
50 mg. phenoxybenzamine
100 mg. hydrocortisone
1 g. magnesium sulphate (50 per cent w./v.)
10 mg. heparin
1 MU. Penicillin G
1 g. streptomycin

Solution IV
400 ml. kidney-preserving solution†
20 ml. 50 per cent dextrose
3 g. magnesium sulphate (50 per cent w./v.)
10 mg. phenoxybenzamine
1 MU. Penicillin G
1 g. streptomycin

A.C.D., Acid citrate dextrose.

* Preparation of plasma: A fully grown pig was anaesthetized and under sterile conditions a catheter was inserted into the femoral artery. Heparin, 2 mg. per kg., was given intravenously and the animal was exsanguinated. The blood was collected into sterile A.C.D. bottles and centrifuged at 1800 r.p.m. to pack the red cells. The supernatant plasma was drawn off aseptically and stored in a deep freeze at −20 to 40° C. Prior to use the plasma was thawed in a water-bath at 37° C. and then refrigerated at 4° C.

† Saphar Laboratories, Johannesburg. Each 100 ml. of kidney-preserving solution contains:—

Potassium acid phosphate	205 mg.
Potassium phosphate dibasic, $3H_2O$	970 mg.
Potassium chloride	112 mg.
Sodium bicarbonate	84 mg.
Procaine HCl	10 mg.
Heparin	500 U.

The donors were starved for 24 hours preoperatively. They were anaesthetized without premedication with halothane, nitrous oxide, and oxygen, and a large-bore stomach tube was passed to decompress the stomach. Through a midline incision extending between the xiphisternum and the pubis the liver was skeletonized. Heparin, 1 mg. per 2 kg., was then given intravenously and the donor was exsanguinated via an arteriotomy in the abdominal aorta. Without grouping or cross-matching, this blood was used for transfusion in the recipient animal. Following a warm ischaemic interval of 5–10 minutes, rapid core cooling of the liver was achieved by intraportal infusion with 3 litres of solution I (3 litres Tis-U-sol, 90 ml. Rheomacrodex 10 per cent w./v. in dextrose) at 4° C. with a hydrostatic pressure of 60 cm. using gravity drainage from a drip stand. The hepatectomy was completed during the period of cooling. Thereafter the cold liver was placed in a sterile plastic bag containing 1 litre normal saline at 4° C. and the liver was perfused via both the portal vein and hepatic artery with 500 ml. of a preserving solution (*Table I*) run in from a drip stand over a period of 20 minutes. For simple hypothermic storage the bag with the liver completely immersed in the preserving solution was sealed and surrounded by ice to maintain the temperature at 8–12° C. or was placed in an unpressurized hyperbaric chamber in a cold room at a temperature of 2–5° C. When hypothermic storage was combined with hyperbaric oxygen the bag containing the liver was left untied, placed in a portable hyperbaric chamber (Ackerman and Barnard, 1966), pressurized to 3 atmospheres absolute (A.T.A.) with pure oxygen, and stored in a cold room at 2–5° C.

Table II.—LENGTH OF SURVIVAL AND CAUSE OF DEATH IN PIGS UNDERGOING LIVER TRANSPLANTATION USING LIVERS WHICH HAD BEEN PRESERVED BY DIFFERENT TECHNIQUES

GROUP	PRESERVING SOLUTION	TEMPERATURE (° C.)	HYPERBARIC OXYGEN (A.T.A.)	ISCHAEMIC TIME (hours)	SURVIVAL TIME	CAUSE OF DEATH
A (3 experiments)	II	8–12	—	10	3 d. 2 hr. 7 mth.	Ascites Bleeding Alive
B (3 experiments)	III	8–12	—	10	28 hr. 4 hr. 5 hr.	Bleeding Bleeding Bleeding
C (3 experiments)	IV	8–12	—	10	2 hr. 2 hr. 2 hr.	Bleeding Bleeding Bleeding
D (3 experiments)	II	8–12	—	12	9 hr. — 8 hr.	Bleeding Bleeding Bleeding
E (3 experiments)	II	2–5	—	12	— — 6 hr.	Bleeding Bleeding Bleeding
F (5 experiments)	II	2–5	3	12	20 d. 40 d. 5 d. 10 d. 3 d.	Subphrenic abscess Strangulated incisional hernia Pulmonary embolus Rejection Bleeding

The recipient operation was similar to that described by Terblanche, Peacock, Bowes, and Hobbs (1968) except that only a splenojugular shunt was used to by-pass the portal circulation. Biliary drainage was by a direct bile-duct to bile-duct anastomosis (Calne, Yoffa, White, and Maginn, 1968; Dent, Uys, Hickman, Saunders, and Terblanche, 1971). A gastroduodenostomy without vagotomy was performed to eliminate gastric ulceration (unpublished data). Intra-operative fluids totalled between 1500 and 1800 ml., of which 1 litre was donor blood. Ten mg. vitamin K_1 and 20 ml. 50 per cent dextrose were given intravenously as soon as the liver was revascularized with portal blood. Postoperatively the recipient animal was transferred to a warm cage, maintained on intravenous fluids for 72 hours, and thereafter was fed a standard pig diet. Intravenous antibiotics (1 MU. Penicillin G, 0·5 g. streptomycin, and 1 g. chloramphenicol) were given for 10 days. No immunosuppressive agents were administered because of the low-grade rejection seen in pigs after liver transplantation (Calne, White, Yoffa, Binns, Maginn, Herbertson, Millard, Molina, and Davis, 1967; Terblanche, Peacock, Hobbs, Hunt, Bowes, Tierris, Palmer, and Blecher, 1968; Garnier, Clot, and Chomette, 1970).

RESULTS

The results are set out in *Table II.*

Group A: 10 Hours' Preservation with Solution II at 8–12° C.—Only 1 of the 3 animals survived and was still alive 7 months after transplantation. The animal which died 3 days postoperatively had massive ascites. The third animal died shortly after completing the operation from a generalized bleeding diathesis.

Group B: 10 Hours' Preservation with Solution III at 8–12° C.—All 3 animals died within 28 hours of completing the operation. Notable postoperative features in this group were a prolonged apnoea requiring assisted respiration, severe hypoglycaemia not readily responding to intravenous glucose, and gross histological disruption of the liver parenchyma.

Group C: 10 Hours' Preservation with Solution IV at 8–12° C.—All 3 animals survived the operation, woke up promptly after discontinuation of the anaesthetic, but died shortly afterwards from a generalized bleeding diathesis.

Group D: 12 Hours' Preservation with Solution II at 8–12° C.—One animal died shortly after complete revascularization of the liver from a generalized bleeding diathesis. The remaining 2 animals died 8–9 hours postoperatively from the same complication.

Group E: 12 Hours' Preservation with Solution II at 2–5° C.—Two animals died after revascularization of the liver but before completing the whole operation. The third animal died 6 hours postoperatively. All 3 deaths were due to a generalized bleeding diathesis.

Group F: 12 Hours' Preservation with Solution II at 2–5° C. with Hyperbaric Oxygen at 3 A.T.A.—This combination resulted in 4 consecutively successful experiments. In the only failure a leak in the chamber resulted in incomplete pressurization (1·5 A.T.A.). The postoperative behaviour of the survivors was similar to animals undergoing immediate liver transplantation without storage. The biochemistry (*Fig.* 1), however, showed increased elevation of the serum bilirubin, serum glutamic oxalo-acetic transaminase, and alkaline phosphatase, suggesting a more severe degree of ischaemic damage. These parameters returned to normal values within 4 days, demonstrating the remarkable regenerative ability of the hepatocyte. Serum-protein estimations were similar to those for non-stored livers.

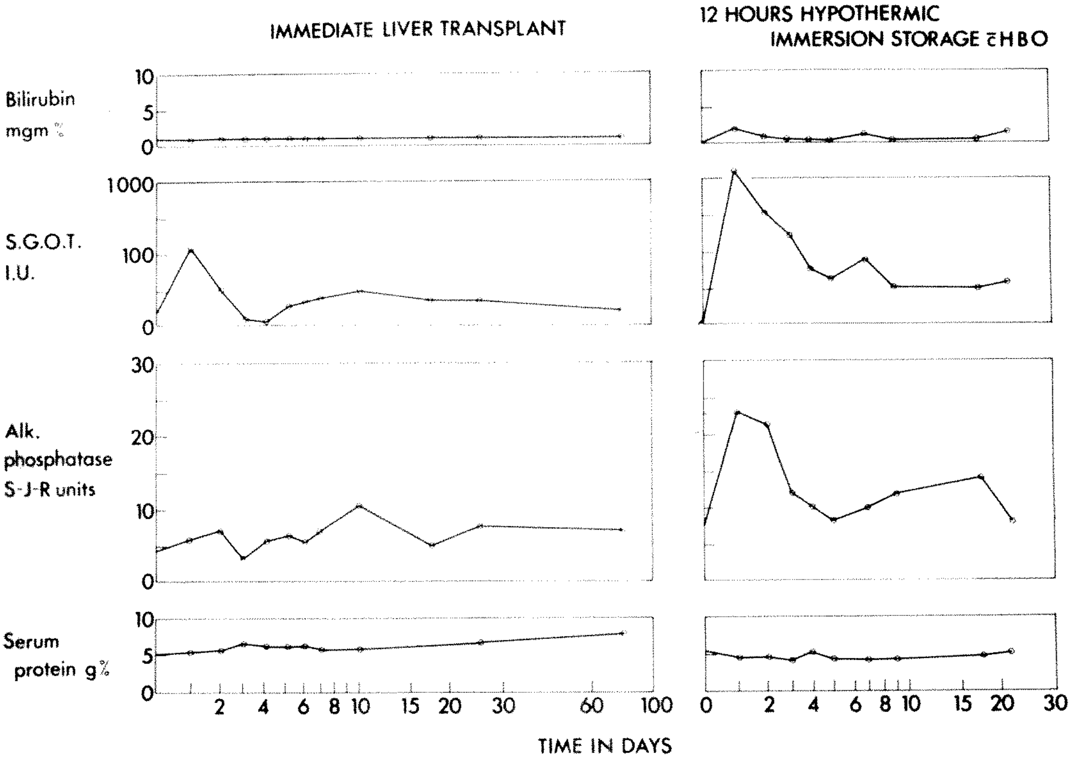

FIG. 1.—Comparative liver function in pigs following a typical immediate liver allograft and a liver allograft which had been preserved for 12 hours (group F).

DISCUSSION

Studies by Starzl, Kaupp, Brock, Lazarus, and Johnson (1960) established that cooling the canine liver with a balanced salt solution to a core temperature below 10° C. gave protection for up to 90 minutes of ischaemia. Later Schalm (1968), using the same species and a preserving solution of homologous plasma, bicarbonate, dextrose, procaine, and hydrocortisone at 4° C., extended this period to 3·5 hours with life-sustaining function. This observation and the reports of prolonged preservation of other organs by altering the constituents of the preserving media (Collins, Bravo-Schugarman, and Terasaki, 1969; Manax and Lillehei, 1969) supported the thesis that whilst hypothermia itself was an important factor in organ preservation the composition of the preserving solution assumed equal importance (Humphries, 1967). The inadequacies of the dog liver in experimental transplantation has led investigators to turn to other animals such as the pig or primates. Recently Abouna and others (1971), Hadjiyannakis and others (1971), and Spilg and others (1971), using three basically different preserving solutions, reported successful preservation of the pig liver for 6 hours. Slapak and others (1970) and Mieny and Myburgh (1971) preserved primate livers for similar periods using a balanced salt solution; Mieny and Myburgh (1971) even obtained a 50 per cent survival following 20 hours of cold ischaemia. These reports stress the importance of species differences as well as that of the composition of the preserving media. This is confirmed in the present series of experiments by the failure of the addition of cell-membrane-stabilizing drugs or the use of a potassium- and magnesium-rich solution to extend liver preservation beyond the 8-hour period achieved previously in our laboratory with solution II (Spilg and others, 1971). Reducing the temperature from 8–12 to 2–5° C. also failed to prolong the period of successful preservation.

The failure of other investigators (Kestens, Mikaeloff, Haxhe, Dureau, Alexandre, Rassat, Cuilleret, Hassoun, Dubernard, Descotes, and Morelle, 1966; Hobbs, Hunt, Palmer, Badrick, Morris, Mitra, Peacock, Immelman, and Riddell, 1968; Belzer and others, 1970) to prolong liver preservation significantly by continuous hypothermic perfusion stimulated the present investigation of combining simple hypothermia with hyperbaric oxygen. In 1964 Manax, Bloch, Longerbeam, and Lillehei published their first report on the technique and results of hypothermia and hyperbaric oxygen in the preservation of whole organs, and they clearly demonstrated the advantages of this combination over either of the two modalities used separately. Since then many other workers have confirmed this observation for the heart (Bloch, Manax, Eyal, and Lillehei, 1964), kidney (Lempert, Blumenstock, and Carter, 1965; Ackerman and Barnard, 1966), and lungs (Blumenstock, Lempert, and Margado, 1965). There is only one report in the literature of the combination of hypothermia and hyperbaric oxygen in liver preservation. Brettschneider and others (1968) unsuccessfully preserved 3 dog livers for 24 hours using this method of storage, but achieved occasional success when continuous perfusion was added.

In the present study the pig liver was successfully preserved for 12 hours in 4 out of 5 experiments using hypothermia at 2–5° C. and hyperbaric oxygen at 3 A.T.A. These organs were capable of immediately supporting life in a hepatectomized recipient for a minimum period of 4 days with biochemical evidence of satisfactory liver function. Further experimental work is required to determine the maximum duration of storage possible by this combination. These results using a relatively simple method are comparable to those previously described using more sophisticated and complex techniques.

Acknowledgements.—We wish to thank Professor J. H. Louw, Head of the Division of Surgery, University of Cape Town, for his interest and support, the staff of the Department of General Surgery Laboratory for their technical assistance, and the Provincial Blood Grouping Laboratories for the preparation of the fresh-frozen pig plasma.

This work was supported financially in the University of Cape Town by the Medical Research Council, the C. L. Herman Bequest, and the Cape Provincial Administration.

CHOLEDOCHODUODENOSTOMY*

A REAPPRAISAL OF ITS INDICATIONS BASED ON A STUDY OF 64 PATIENTS

By A. G. JOHNSON and A. J. HARDING RAINS
DEPARTMENT OF SURGERY, CHARING CROSS HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

The indications for choledochoduodenostomy in 64 patients are discussed and compared with those in other series from the literature. The essential indications are the presence of a dilated common bile-duct with calculous disease or associated pathology at the lower end of the common bile-duct, particularly in the elderly and poor-risk patients. It is a safe procedure with few complications provided that a stoma of 2·5 cm. or more is made.

SPRENGEL performed the first successful choledochoduodenostomy in 1891 and the operation has become well established on the continent of Europe (Finsterer, 1952; Mallet-Guy and Descotes, 1955). In Britain, however, it has only recently gained in popularity since Hosford drew attention to its merits in 1957, and it has been slow to win acceptance in the United States of America since the first paper on the subject by Sanders in 1946. It has been increasingly realized that the theoretical objections to the operation have not been experienced in practice, provided that it is properly performed (Capper, 1961; Madden, Chun, Kandalaft, and Parekh, 1970).

There is a wide variation in the indications for choledochoduodenostomy, some surgeons using it as the routine sequel to exploration of the common bile-duct, whether dilated or not (Magarey, 1966), whereas others consider it should only be used if no other alternative is possible (Smith, 1964). A critical reappraisal is needed and this paper discusses the indications for the operation in 64 patients in the light of other published series.

OPERATIVE TECHNIQUE AND COMPLICATIONS

A side-to-side anastomosis was performed in all except 1 patient, with a longitudinal incision in the common bile-duct and a longitudinal or transverse incision in the duodenum. In all cases the common bile-duct was dilated and the stoma was always over 2 cm. in diameter. The anastomosis was performed with a single layer of interrupted 00 chromic catgut, occasionally with 00 silk reinforcement externally as required. There were no operative deaths, but 2 patients had a bile leak which ceased spontaneously. Two patients had a single episode of cholangitis within 1 month of discharge from hospital, with no subsequent trouble over a 3-year and a 6-month follow-up period respectively. Barner (1966) reports a similar experience.

DETAILS OF PATIENTS IN THE PRESENT SERIES

Fifty patients were operated on for benign disease. The male to female ratio was 1 : 2 and the age range was 38–82 years, with an average of 66 years. Fifty per cent of the patients were over 70 years of age, 22 per cent being over 80 years. Only 18 per cent were younger than 50 years. During the same period, 14 patients underwent operation for malignant obstruction of the common bile-duct.

Table I.—INDICATIONS FOR OPERATION IN 50 PATIENTS WITH BENIGN DISEASE

Indication for Operation	*No. of Patients*
Dilated C.B.D.* with impacted stones, sludge, etc.	13

* This term implies 'external' choledochoduodenostomy as opposed to transduodenal or 'internal' choledochoduodenostomy (sphincterotomy or sphincteroplasty).

INDICATIONS FOR CHOLEDOCHODUODENOSTOMY

It is unlikely that a decision to employ this procedure is made preoperatively, because the indications only become apparent at laparotomy, and usually after carrying out peroperative cholangiography and choledochotomy with removal of free stones, sludge, etc.

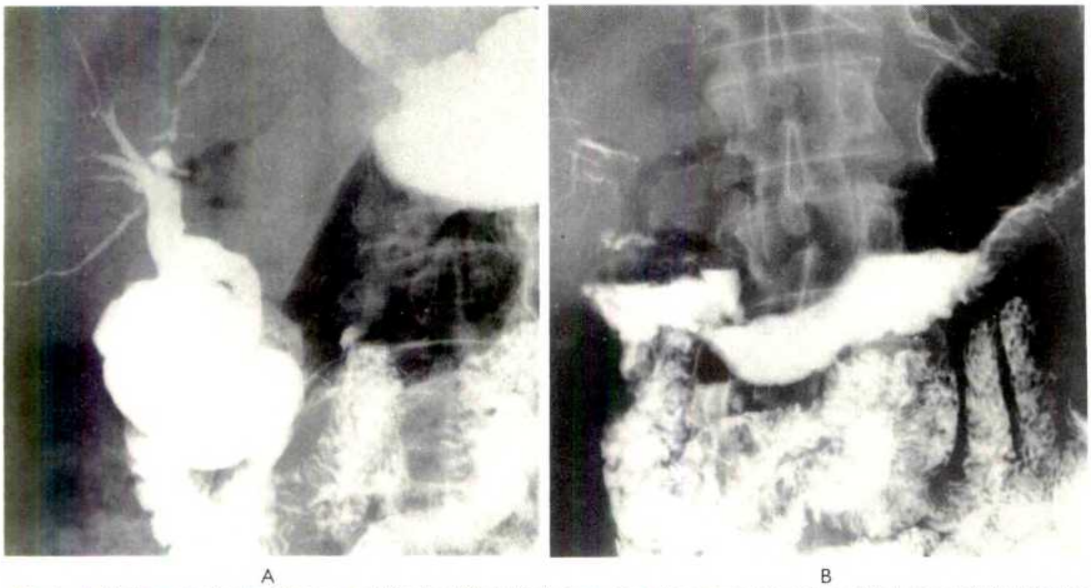

FIG. 1.—A, Radiograph showing the common bile-duct filled with barium. Note the convex obstruction of the lower end which has been unchanged since the original operation 3 years before. B, A few minutes later, showing the emptying of the duct including most of the lower portion.

Table III.—AVERAGE LENGTH OF TIME BETWEEN FIRST OPERATION AND CHOLEDOCHODUODENOSTOMY

PREVIOUS OPERATION	NO. OF CASES	AVERAGE TIME BETWEEN OPERATIONS
Cholecystectomy alone	9	11 years
Cholecystectomy and exploration of C.B.D.		
Residual stones	2	2½ months
Recurrent stones	5	5 years

Table I gives the indications for choledochoduodenostomy with benign disease in this series, and *Table II* compares these with two other series (Capper, 1961; Madden and others, 1970), in which the similarities will be noted.

1. Dilated Common Bile-duct.—The procedure should be performed only on finding a dilated common bile-duct, where the overriding consideration is the presence of some obstruction at the lower end of the duct (*see* (3) and (4) below), usually detected by palpation or 'on-table' cholangiography.

A wide dilated duct allows the necessary wide stoma to be constructed. A duct with a normal calibre does not indicate choledochoduodenostomy and an attempt at this results in a narrow stoma, postoperative problems, and a bad name for a valuable procedure in a surgeon's repertoire.

2. Age and General Condition of the Patient.—If the age and condition of the patient are weighed against the degree of difficulty and the risk of morbidity and mortality of a transduodenal exploration with sphincterotomy or sphincteroplasty, the surgeon may then judge that a choledochoduodenostomy is the quickest and safest alternative.

3. Obstructive Pathology at the Lower End of the Common Bile-duct at the First Operation.—

a. An impacted stone or stone in a false diverticulum adjacent to the sphincter of Oddi.

b. The presence of sticky biliary sludge and mucus.

c. Thickened wall of the common duct and some evidence of cholangitis, e.g., 'red-hot duct' (Rains, 1959).

d. Narrowing of the lower end of the duct as demonstrated by cholangiography or on careful exploration with a sound or dilator.

e. Thickening of the head of the pancreas owing to chronic pancreatitis or as a sequel to acute pancreatitis.

f. Discrete lump in the head of the pancreas—possibly a neoplasm or a stone.

4. Obstructive Pathology at the Lower End of the Common Bile-duct at a Second Operation.—This is usually due to recurrent stones in the duct. Indeed, in the present series, 16 of the 29 patients with stones in the common bile-duct had undergone a previous operation. Nine had had a cholecystectomy without exploration of the common bile-duct, whereas 7 had had a previous exploration of the common bile-duct, in 2 of whom the second operation was within 3 months of the first, which strongly suggests that the stones were residual rather than recurrent. *Table III* shows the average length of time between the first and second operations in each group. It will be seen that in those who had cholecystectomy alone the average time was 11 years.

The following case illustrates the danger of *not* performing choledochoduodenostomy when a recurrence of stones could be predicted from the findings at the first operation.

CASE REPORT

A 57-year-old female had undergone a cholecystectomy and exploration of the common bile-duct when no stones had been found in the gall-bladder but two large stones had been present in the dilated common bile-duct. Cholecystectomy had been performed. The sphincter of Oddi had become narrowed and therefore it had been dilated, the bile-duct being closed around a T-tube after removal of the stones.

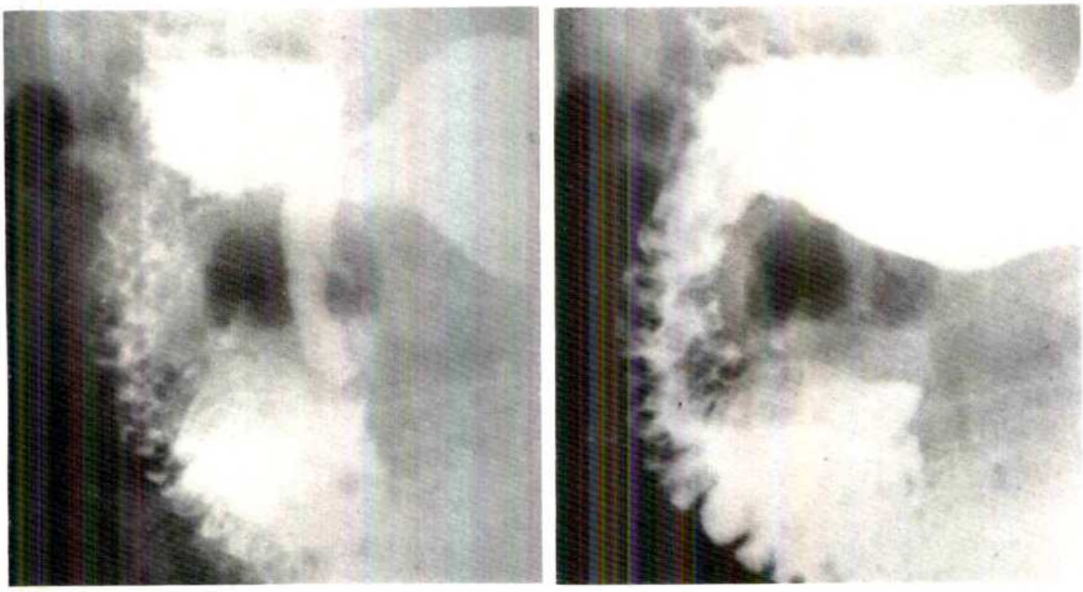

FIG. 2.—A, Radiograph 1 year after choledochoduodenostomy, showing the lower end of the duct filled with barium. B, Thirty seconds later, showing the duct emptying up into the duodenal cap.

The patient was admitted to Charing Cross Hospital 2 years later with suppurative cholangitis and Gram-negative septicaemia. At operation the dilated common bile-duct contained small stones and sludge. A choledochoduodenostomy was performed and the patient made a satisfactory postoperative recovery. This nearly lethal recurrence could have been avoided by choledochoduodenostomy at the original operation.

MALIGNANT OBSTRUCTION

The aim of any operation in this situation is to provide a satisfactory by-pass for the bile as far from the obstructing carcinoma as possible. The normal operation for inoperable carcinoma of the pancreas is a cholecystojejunostomy with either a Roux-en-Y or a loop with entero-anastomosis. Choledochojejunostomy or choledochoduodenostomy may be used in only two situations: (*a*) when the gall-bladder has previously been removed, and (*b*) when the cystic duct enters the common bile-duct low down and thus is likely to be obstructed before an anastomosis higher up the duct.

CRITICISMS OF CHOLEDOCHODUODENOSTOMY

1. That there is a Danger of Cholangitis due to Reflux of Duodenal Contents into the Bile-duct.—This seems to be a theoretical rather than a practical objection, provided that the stoma is more than 2 cm. and preferably 3 cm. in diameter (Johnson and Stevens, 1969). Madden and others (1970), in a collected series from the literature over the period from 1946 to 1968, give the incidence of cholangitis as 0·4 per cent of 1255 operations. In addition, they anastomosed the bile-duct to the unprepared colon of dogs and provided that there was no stomal obstruction cholangitis did not occur, despite the reflux of faecal contents into the biliary tract.

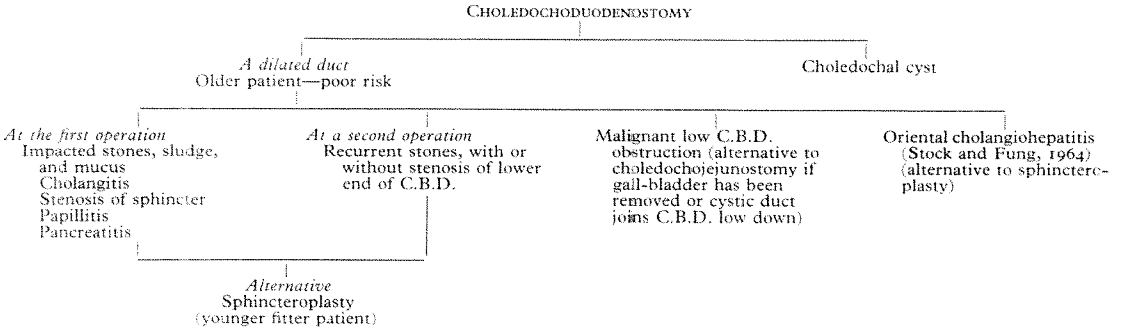
2. That the Blind Part of the Common Bile-duct below the Anastomosis becomes filled with Vegetable Debris, leading to Choledochitis and Possible Pancreatitis (Smith, 1964).—Stock and Fung (1964) and Madden and others (1970) point out that this is a rare occurrence. *Fig.* 1 shows the rapid emptying of the bile-duct of barium, including most of the lower part of the duct, in a patient who was radiographed 3 years postoperatively. *Fig.* 2 is the radiographs of another patient 1 year after operation, showing the emptying of the lower part of the duct a few seconds after it had filled with barium. On screening, the contrast was seen to empty back up into the duodenum. Despite these observations, it is agreed that there is occasionally recurrent stone formation in the blind segment (Wilson, 1970), but it may give no trouble.

3. That in Some Cases a Lump related to the Lower End of the Bile-duct will remain undiagnosed.—This is a valid criticism which implies that patients with ampullary carcinoma could be denied the chance of cure by a pancreaticoduodenectomy (Whipple's operation). Clearly, a circumscribed lump in the head of the pancreas related to the duct is best explored by incision via a duodenotomy (Rains, 1969). In the relatively younger and fitter patient with such a tumour, major excision can be undertaken. In the elderly unfit patient the duodenotomy, if suitably placed, can be used for making the choledochoduodenostomy.

SPHINCTEROPLASTY VERSUS CHOLEDOCHODUODENOSTOMY

Acute pancreatitis is a potentially serious complication of sphincteroplasty, and Farrar, Painter, and Betz (1969) give the mortality of the operation as 5–10 per cent. Keighley, Johnson, and Stevens (1969), in a small series, found that 56 per cent of patients who underwent sphincterotomy or dilatation of the sphincter had significantly raised postoperative serum amylase levels, whereas none of those who underwent choledochoduodenostomy had a raised level. Once postoperative pancreatitis has occurred the mortality is as high as 77 per cent (Thompson, Howard, and Vowles, 1957).

Table IV.—SUMMARY OF INDICATIONS FOR CHOLEDOCHODUODENOSTOMY



CHOLEDOCHODUODENOSTOMY
A dilated duct
Older patient—poor risk
Choledochal cyst
At the first operation
Impacted stones, sludge, and mucus
Cholangitis
Stenosis of sphincter
Papillitis
Pancreatitis
At a second operation
Recurrent stones, with or without stenosis of lower end of C.B.D.
Malignant low C.B.D. obstruction (alternative to choledochojejunostomy if gall-bladder has been removed or cystic duct joins C.B.D. low down)
Oriental cholangiohepatitis (Stock and Fung, 1964) (alternative to sphincteroplasty)
Alternative
Sphincteroplasty
(younger fitter patient)

There is also little doubt that dilatation of a stenosed sphincter or simple sphincterotomy is followed by a high incidence of restenosis. In practice, once it has been decided that decompression of the common bile-duct is required if a stone has been removed transduodenally or the sphincter has been inspected by this route, a carefully performed sphincteroplasty with mucosa-to-mucosa suture is the natural procedure. If, as in the majority of cases, the common bile-duct is explored from above the easiest and safest procedure is to perform a choledochoduodenostomy using the extended choledochotomy incision.

CONCLUSIONS

Choledochoduodenostomy is particularly suitable for the elderly patient where the minimum operative procedure is required for an unresolved and supposedly benign problem at the lower end of the common bile-duct, provided that the bile-duct is dilated and a stoma 2·5 cm. or more in size can be achieved.

In malignant lower bile-duct obstruction this operation should be limited to patients in whom the gall-bladder has previously been removed, or where the cystic duct joins the common bile-duct low down.

Choledochoduodenostomy is also useful in the treatment of choledochal cyst and oriental cholangiohepatitis. The indications are summarized in *Table IV*.

The incidence of complications is very small, but it is likely to increase if the operation is performed for inadequate indications, and it is obviously undesirable to produce a biliary by-pass unless this is really necessary.

Acknowledgements.—We are very grateful to Mr. A. E. Stevens for his help in the preparation of this paper and for allowing us to study patients under his care, and to Dr. J. McIvor for the radiological studies.

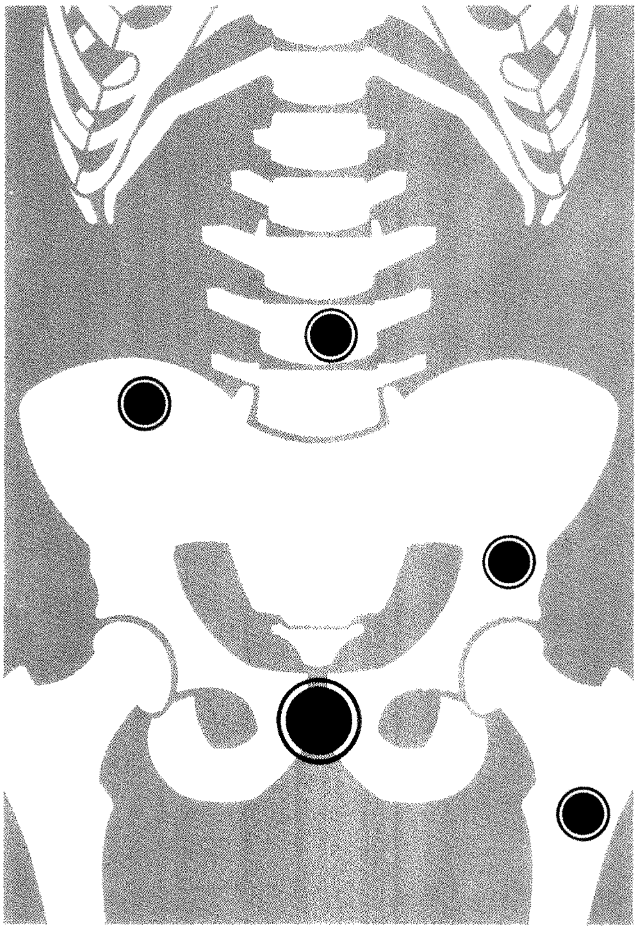
Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



Response is rapid. **Honvan** is a practical alternative to surgery in acute urinary retention caused by prostatic carcinoma.

Gastric tolerance of **Honvan** is good and side effects comparatively rare.

Honvan is available for both intravenous and oral administration.

a selective cytotoxic action – in prostatic carcinoma

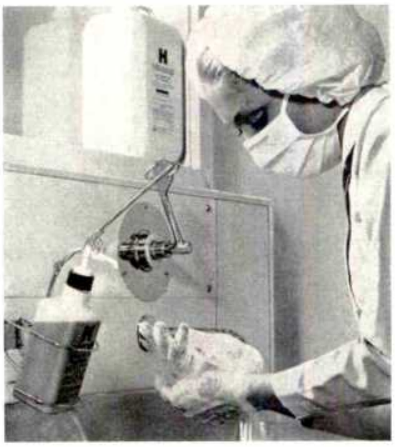
Now ICI bring to surgical scrubs the proven advantages of Hibitane in

TRADE MARK
hibiscrub



Antibacterial Activity

From the bacteriological point of view the demand is for a surgical scrub which combines maximum antibacterial activity with pronounced residual effect.

'Hibiscrub' fulfills these requirements. It is not only rapidly effective against both gram positive and gram negative organisms but also exhibits good residual activity – a major advance in the development of surgical scrubs.

Hand Care

The effect of prolonged usage on the hands of surgical staff is a critical factor in the acceptability of any surgical scrub. Sensitivity reactions, excessive detergency etc., can lead to the abandonment of certain scrub regimes.

'Hibiscrub' is positively pleasant to use – nurses using it regularly have reported on the excellent condition of their hands.

THE TREATMENT OF ACHALASIA BY CARDIOMYOTOMY

By H. V. WINGFIELD and A. KARWOWSKI
TEHIDY THORACIC SURGICAL UNIT, CORNWALL

SUMMARY

The results of treatment in 27 cases of achalasia carried out in the Tehidy Thoracic Surgical Unit are reviewed. The value of air insufflation of the oesophagus to assist in the division of the muscle and to ensure that the mucosa is not damaged is stressed. The advantages of early operation using a modified Heller's procedure are shown, and the results demonstrate that a poor outcome is most common in cases with a long history and that usually these cases have been treated by conservative measures.

HELLER'S procedure is safe and satisfactory, and should be considered as the primary treatment for achalasia because results are better when it is done early in the course of the disease. Inflation of the lower oesophagus by air is a great help in the division of muscle-fibres during operation.

The failure of cardiomyotomy shows as persistent dysphagia, and this may be due to either incomplete myotomy or secondary stricture formation following hiatus hernia. Great care should be taken to avoid both complications because reoperation is difficult and unsatisfactory.

In the series of 27 cases presented here the patients in the second half of the series had a repair of the right crus carried out when there was any hint of a lax oesophageal hiatus. It is thought that this additional procedure accompanying cardiomyotomy is worth while in all cases.

The symptoms, oesophagoscopic findings, and radiological appearances of achalasia of the oesophagus are well known. The pathogenesis has been extensively studied, but there is still little agreement regarding the choice of treatment. For this reason every report concerning this problem is worth while.

MATERIALS AND METHODS

Patients reviewed.—The present survey is based on a series of 27 patients with achalasia who were operated on between the years 1954 and 1969. All the patients were followed up, and the follow-up period of 25 of the cases was at least 1½ years and in some cases as long as 15 years. Two cases have been excluded from this series because they have been operated on too recently. There was a slight preponderance of women over men—16 to 11—which is of no significance. The age of the patients at the time of surgery was between 12 and 66 years; 15 per cent were less than 21 years old, half were between 21 and 44, and 35 per cent of the patients were more than 51 years of age. The average age was 37 years.

Symptoms.—Dysphagia and regurgitation were constant symptoms, and the degree of both varied. Dysphagia was usually the main complaint, and although in many cases it was severe, in some the diagnosis was first established because of other symptoms, mainly pulmonary. Some of the patients had had symptom-free intervals of many years' duration which were interrupted by bouts of progressive dysphagia. Dysphagia was aggravated in some cases by psychic stress. It was found that patients with long-standing disease often acquired some special manœuvres to allow food to pass into the stomach. These tricks varied from a simple Valsalva manœuvre to drinking large quantities of water before or after meals.

The pain was variously described as a heavy feeling causing distension and discomfort, as burning or acute in character, or sometimes as blunt or aching. When pain occurred it was usually retrosternal, but in some cases it was epigastric. It was referred to meals, but was not relieved by regurgitation or by antacids. Loss of weight was in some cases rapid and severe, and in some long-standing cases malnutrition was clearly evident. In younger patients a feature was failure to gain weight rather than a loss of weight. In 6 cases pulmonary complications such as aspiration bronchitis and bronchopneumonia were evident, clinically and radiologically.

The duration of symptoms prior to surgery varied between 1 year and 20 years, 80 per cent of the patients having had symptoms for 2 years or more before operation and 46 per cent for more than 5 years.

Diagnosis.—This was based on history, clinical examination, barium studies, and oesophagoscopy. In 3 cases, however, it was not possible to exclude completely the possibility of malignancy. Five patients had been treated extensively before admission to the unit, 4 having had repeated dilatations in hospital and self-bouginage at home. The fifth patient had had a cardiomyotomy performed through the right chest.

Operation.—It was considered that the treatment of achalasia should be surgical rather than conservative. Before operation the patients were given a liquid diet for 4–10 days, in some cases it being necessary to use parenteral feeding. The oesophagus was washed out repeatedly with sodium bicarbonate solution, and antibiotics were given as and if required after oesophagoscopy.

In all the cases a modified Heller's operation (6)* was performed through a left thoracotomy. After exposure of the oesophagus a longitudinal incision was made through the muscle coats of the oesophagus and stomach, the myotomy being extended for some 4–7 cm. on the oesophageal side of the oesophagogastric junction and approximately 2 cm. on the gastric side. It was found that distension of the oesophagus with compressed air via an intra-oesophageal tube introduced by the anaesthetist facilitated the procedure. Damage to the mucosa was most likely to occur at the oesophagogastric junction, and where it did occur the damaged mucosa was repaired with 0000 silk using atraumatic sutures.

---

* Reference, *see* p. 284.

Care was taken not to cut the oblique fibre bundles at the gastro-oesophageal junction in the hope that this would prevent gastro-oesophageal reflux (2, 13, 20, 64). After the myotomy had been completed the muscle was separated from the mucosa for about one-third of the circumference of the oesophagus. The mucosa bulged freely into the wound and this was further facilitated by distending the area with compressed air through an oesophageal tube. This also showed whether the mucosa was airtight and, if there was any further doubt, saline solution was poured into the chest to cover the mucosa while air was passed into the stomach.

In the first 7 years of the study no attempt was made to reapproximate the limbs of the right crus behind the oesophagus, except when the hiatus had been found widely opened. In the past 7 years it has been routine procedure to bring down the lower part of the oesophagus below the diaphragm and to suture the right crus behind the oesophagus (4) to prevent postoperative herniation and gastro-oesophageal reflux (7, 18, 21, 24, 25, 35, 46, 60, 64). No other procedure, such as fundoplication or repair of the phreno-oesophageal ligament, has been used.

For the first 24 hours postoperatively, fluids were given intravenously. The patients were then given fluids by mouth and after 24 hours the amounts were increased. On the third postoperative day patients were given semi-solids, and solid food was allowed after 7–10 days.

Complications following Surgery.—There were no postoperative deaths. In 1 case perforation of the oesophagus occurred 24 hours after surgery, although during the operation the mucosa was proved to be airtight. Perforation probably happened because of devascularization of the mucosa owing to too extensive dissection of the muscle. Immediate reoperation and suture were performed and the patient recovered. In 2 cases left lower-lobe atelectasis occurred postoperatively, but this cleared rapidly with intensive physiotherapy.

RESULTS

Following discharge the patients were seen at 1 month, then at 3-monthly intervals for the first year, half-yearly during the second year, and subsequently at yearly intervals. Barium swallow was carried out and repeated as necessary. During the barium swallow the presence of gastro-oesophageal reflux was looked for especially. Cases where symptoms recurred were readmitted to the unit for further assessment. Follow-up results have been considered for 25 cases, and the results have been classified into four categories (*Table I*).

Table I.—THE RESULTS OF CARDIOMYOTOMY

Group	*No. of Cases*	*Percentage of Cases*
Excellent	9	80
Good	9	
Satisfactory	2	
Bad	5	20
Total	25	

1. Excellent.—Patients in this group had no symptoms in the follow-up period. They all gained weight (as much as 19·5 kg. in 1 case), and the oesophagus on barium swallow appeared less wide than before operation.

2. Good.—This group was without symptoms, but radiological examination showed that the oesophagus was still dilated, often being as wide as before operation. The patients included in this group had neither dysphagia nor regurgitation and all had gained weight, but they did occasionally complain of retrosternal discomfort. Most were subjectively well satisfied and felt enormously improved by surgery.

3. Satisfactory.—These patients had occasional, minimal dysphagia, the symptoms being transient with food passing rather slowly down into the stomach. They could, however, eat all foods, whereas before operation most of them had only been able to have semi-solids and fluids and had required frequent bouginage.

These three categories of patients—excellent, good, and satisfactory—account for the majority of the patients of the series. Five cases come under the final category.

4. Bad.—In this group operation did not cure the symptoms of dysphagia, regurgitation, or pain, or surgery caused new complications. Five cases are included in this group.

Case 1.—For 1 year after cardiomyotomy this patient experienced considerable improvement but, after this, symptoms of reflux oesophagitis became manifest and dysphagia reappeared. A barium swallow was carried out and an oesophageal stricture was seen. Although a hiatus hernia was not proved by barium meal, we are now convinced of its existence and further surgery is to be carried out.

Case 2.—This patient developed dysphagia and regurgitation 5 years after what had appeared to be successful cardiomyotomy. Barium swallow was carried out and a hiatus hernia was seen with oesophageal reflux.

Case 3.—This woman was found to have a mucosal perforation 24 hours after cardiomyotomy. The chest was reopened and the perforation was repaired. During her postoperative convalescence the patient developed an oesophageal stricture. Three years after the original Heller's operation cardioplasty was performed, and was followed by reflux oesophagitis and recurrent oesophageal stenosis. One year later a partial oesophagogastrectomy and pyloroplasty were carried out. The patient died of bilateral bronchopneumonia in the postoperative period 5 years after her cardiomyotomy.

Case 4.—This patient had a cardiomyotomy via a right thoracotomy performed elsewhere. The operation was carried out at the same time that a right lower lobectomy for bronchiectasis was performed. The results were satisfactory for the first 9 years. At the end of this period the symptoms of achalasia manifested themselves again and a second cardiomyotomy was performed through the left chest in the Tehidy Thoracic Surgical Unit. For 5 months after the second operation the patient was asymptomatic, but after this time increasing dysphagia recurred, accompanied by heartburn and retrosternal pain. A further barium swallow and oesophagoscopy showed an oesophageal stricture to be present. The oesophagus remained distended and it was clear that the sigmoid deformity and kinking of the terminal thoracic oesophagus had become worse than ever. A laparotomy was carried out and the sigmoid bulge was pulled down into the abdomen and fixed there. This procedure resulted in considerable improvement, but the patient still had some dysphagia and occasional retrosternal pain. Fourteen months ago partial oesophagogastrostomy with vagotomy and pyloroplasty were carried out, with, to date, excellent results.

Case 5.—This patient developed dysphagia within a week of undergoing cardiomyotomy. His symptoms were similar to those which he had had before operation. Repeated radiological examinations have shown neither reflux nor the appearance of hiatus hernia, but the oesophagus remains the same size with marked narrowing of the terminal oesophagus and muscle spasm. Failure to control the symptoms in this patient was almost certainly due to incomplete myotomy.

In these 5 cases the causes of failure were incomplete cardiomyotomy in 1 case, the occurrence of hiatus hernia with reflux oesophagitis in 2 cases, reflux oesophagitis probably due to unsuccessful bilateral cardiomyotomy where a massive sigmoid loop existed in 1 case, and cicatricial stenosis as a result of mucosal perforation in the fifth case. In 3 cases, therefore—and this is to be expected from our experience with hiatus hernia—incompetence has been followed by reflux oesophagitis and secondary stenosis. Two patients in this series had postoperative reflux oesophagitis and stenosis because the lax oesophageal hiatus was not recognized and dealt with at operation.

DISCUSSION

The Choice of Treatment.—There is no satisfactory conservative medical treatment for achalasia. The surgical treatment which has been recommended has varied from endoscopic dilatations to oesophagogastric resection. Those who prefer conservative measures consider that the results are no worse than those of surgery, such as the Heller procedure. However, if dilatation is to be successful it is necessary to disrupt muscle-fibres, and such measures might result in perforation of the oesophageal wall. Successive dilatations tend to become more and more difficult, and when the oesophagus is grossly enlarged and sigmoid, dilatation becomes extremely difficult. We consider the only operation of value in the treatment of achalasia is a modified Heller procedure (single cardiomyotomy). Such operations as cardioplasty or oesophagogastric anastomosis can cause reflux oesophagitis (9, 14, 31, 50, 52, 64). Cardiomyotomy is a safe procedure—in most series the mortality is nil—and it is possible to divide all the muscle-fibres under direct vision.

For many years the conviction prevailed that surgery should be kept for cases of failure of dilatation (5, 11, 27, 30, 31, 32, 36, 37, 40, 41, 42, 45, 46, 48, 56, 57, 61, 62), but now increasing numbers of surgeons recognize surgery as a primary treatment for achalasia (2, 8, 17, 19, 22, 23, 25, 26, 28, 33, 34, 39, 49, 55, 58, 59, 60, 63). In the present series the results were better when cardiomyotomy was performed on patients with short histories. *Fig.* 1 shows the results obtained compared with the length of symptoms prior to surgery. Although the series is small it is obvious that bad results have occurred almost entirely in those patients with a long-standing history. This is an argument in favour of early surgery.

Finally, another advantage of surgical treatment is the early recognition of carcinoma occurring in a patient with achalasia. The incidence of carcinoma in mega-oesophagus is much higher than in the normal population (2, 10, 15, 22, 25, 29, 38, 39). In 1969 Just-Viera and Haight (38) collected 167 such cases from the literature. Ellis (22) stated that the incidence of carcinoma of mega-oesophagus in patients with achalasia was 19 per cent, and Belsey (10) mentioned a figure of 7·3 per cent. However, Ellis and others (25) from the Mayo Clinic could find no cases in 240 patients. If stasis is a precipitating factor it seems reasonable to eliminate this factor as early as possible.

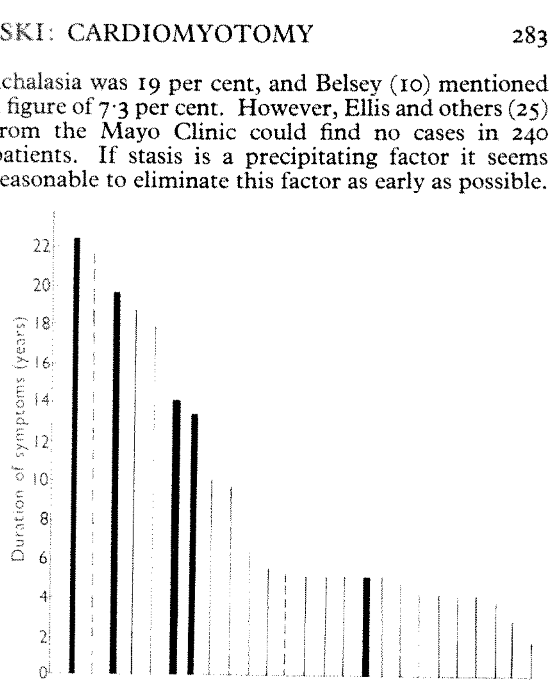

FIG. 1.—The results of myotomy compared with the duration of symptoms. ▬, Bad results. - - -, Satisfactory results. ——, Excellent and good results.

Whereas cardiomyotomy is certainly the best and almost certainly the most widely accepted operation for achalasia, there is some doubt whether it is of value in all cases (8, 16, 22, 33, 43, 47), as can be seen from the following quotes: 'In gross oesophagectasia . . . cardiomyotomy is only of limited value' (Ellis in (22)); 'the Heller principle is the best available except in extremely advanced cases' (Barlow in (7)); 'no satisfactory form of treatment has been found for the patient with the grossly dilated oesophagus, the distal end of which is kinked' (Le Roux and Wright in (41)); 'the myotomy technique has limited value in the patient with stenotic scarring from advanced stages of the disease. In these instances distal oesophageal resection with interposition of either jejunum or colon should probably be considered' (Root and Wangensteen in (52)). This raises the problem that if the Heller procedure is not carried out in advanced cases the only alternative is partial oesophagogastrectomy with oesophagogastroanastomosis or jejunal or colon transplant (3, 7, 15, 51, 53). Although all these operations have been proposed they are not generally accepted (8, 12, 26, 33, 49, 55). Adams (3) and Camara-Lopez (15) have different views. The latter believes that the operation for achalasia should not only relieve dysphagia but also should prevent the possibility of carcinoma. By 1963 he had performed some 80 oesophagogastrectomies with a 6 per cent mortality and good late results. Adams (3) produced 26 similarly treated cases. We believe that oesophagogastrectomy cannot be accepted as the primary treatment for achalasia and should be reserved only for failures after cardiomyotomy. In extreme cases of mega-oesophagus it may be wise to proceed to temporary gastrostomy (44) to enable proper preparation of the patient and gullet (10). The bad results achieved by cardiomyotomy in the long-standing advanced cases of achalasia suggest that surgery should be performed early without preliminary conservative treatment.

THE RESULTS OF FUNDOPLICATION FOR THE RELIEF OF OESOPHAGEAL REFLUX DUE TO HIATUS HERNIA

BY I. K. SHAH AND O. DANIEL
ROYAL ALEXANDRA HOSPITAL, RHYL

SUMMARY

Fundoplication has been performed in 25 patients suffering from symptoms or complications due to oesophageal reflux associated with hiatus hernia. There was no peri-operative mortality and only 1 failure to relieve symptoms of reflux. The procedure is benign and is well tolerated if it is performed without splenectomy.

IT is generally believed that the main symptoms and pathological sequelae of sliding hiatus hernia are due to gastro-oesophageal reflux. In the operation of fundoplication, as described by Nissen (1961), the fundus of the stomach is freed and wrapped around the oesophagogastric junction in the form of a cuff. This maintains an acute angle of entry from the oesophagus to the stomach, with the object of restoring competent valvular action at the cardia. The present trial was stimulated by the encouraging short-term results reported by Smiddy and Ross (1964).

MATERIALS AND METHODS

Twenty-five patients are included in this study and all had radiological evidence of sliding hiatus hernia with free reflux. Surgical treatment was advised only when the symptoms resisted medical management, or when necessary for the relief of blood-loss, spasm, or impending stricture of the oesophagus. There were no other criteria of selection and no other method of repair of hiatus hernia was used during the 7-year period of trial, commencing in 1964. Ages ranged from 36 to 88 years, with 4 patients aged over 70 years. The sex distribution was equal. Two of the operations were performed as emergencies for acute haematemesis. Vagotomy and pyloroplasty were performed in addition to fundoplication in 14 patients: in 4 because of the presence of chronic duodenal ulceration, and in the other 10 because either excessive gastric secretion was deemed to be present on the basis of the pentagastrin test, or there was radiological evidence of hypertrophy of the duodenal mucosa, or irritability of the duodenal cap. Cholecystectomy was performed in addition to fundal plication in 2 patients because of coincident chronic cholecystitis with cholelithiasis.

Technique.—Oesophagoscopy usually preceded laparotomy, which was always effected through a high left paramedian incision. To obtain better access to the duodenum or biliary tract, downward extension was made if necessary, crossing the midline above and to the right of the umbilicus. Exposure of the hiatus was improved by raising the head of the table and tilting the right side down. The triangular ligament was divided and the left lobe of the liver was folded on itself and retracted. In the first 10 operations elective splenectomy was performed as a means of mobilization of the fundus, but, later, great care was taken not to disturb or injure the spleen in any way. The fundus of the stomach was usually freed by incising the peritoneal reflection from its upper border to the diaphragm, starting medially near the oesophagus and working laterally and downwards, dividing and ligating the attachments of the stomach to the spleen. The upper part of the lesser omentum was then divided, starting above at the right border of the oesophagus and extending downwards 7–8 cm. Sometimes it was necessary to divide and ligate the ascending branch, or main trunk, of the left gastric artery. Mobilization from above was occasionally difficult, especially if the fundus was small and inaccessible owing to obesity or to depth of the chest. It was then expedient to open into the lesser sac below the level of the lower pole of the spleen and to free the fundus from this point upwards.

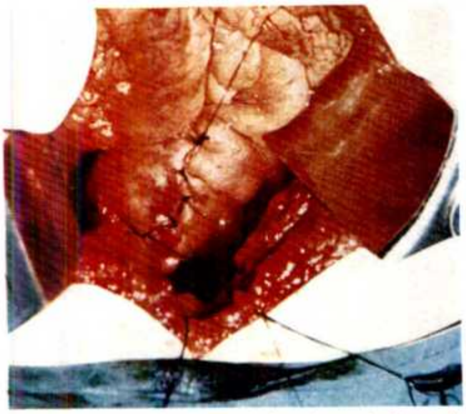

FIG. 1.—Showing the fundus encircling the terminal oesophagus and secured by black silk sutures.

The completely free fundus was pushed, by finger, behind and to the right of the oesophagus, and then drawn forward and around to the left as far as it would go with gentle traction exerted through dissecting forceps. The free anterior border of the fundus was secured in this position to the stomach lying behind it by interrupted seromuscular sutures of black silk placed at 5-mm. intervals. In this way a cylindrical or slightly conical cuff was made to envelop the whole oesophagogastric junction and the lower part of the abdominal oesophagus. This cylinder was usually 7–8 cm. long, 4–5 cm. in diameter, and composed on all sides of two full thicknesses of stomach wall (*Fig.* 1). A large-bore stomach tube was occasionally passed before the fundus was rotated. This formed a pivot about which the fundus could turn but was not essential. A finger passed upwards within the cylinder of stomach and alongside the oesophagus was aware of gentle elastic compression from all sides.

No attempt was made to narrow the hiatus or to perform any other form of repair or fixation.

RESULTS

All the patients remained under surveillance for periods which varied at the time of review from 18 months to 7 years, except for 1 who died of natural causes after 4 years of complete freedom from symptoms of oesophageal reflux.

Serious postoperative complications occurred in 3 of the 10 patients in whom elective splenectomy had been performed. These were left subphrenic abscess, empyema thoracis, and pneumonia respectively.

Diarrhoea with colicky abdominal pain troubled 3 patients for periods of 6–12 months following operation. These 3 were amongst the 14 in whom truncal vagotomy and pyloroplasty had been performed. Dysphagia with a large bolus of food was reported by 3 patients, but this gradually disappeared without treatment 1–3 months after operation.

Results have been assessed on the basis of a modified Visick grading (Goligher, Pulvertaft, de Dombal, Conyers, Duthie, Feather, Latchmore, Shoesmith, Smiddy, and Wilson-Peppter, 1968). Twenty-two patients classed as Grade I were completely relieved of all symptoms. One patient classed as Grade II was pleased with the results, although admitting on direct questioning to mild intermittent symptoms of reflux. One patient classed as Grade III believes the operation was worth while although he was still troubled by dysphagia secondary to oesophageal stricture, which was well established at the time of operation and still requires dilatation at yearly intervals.

One 44-year-old man classed as Grade IV submitted to fundoplication with splenectomy and truncal vagotomy with pyloroplasty, in November, 1965. There was then a 2-year history of severe epigastric and retrosternal pain after meals with distressing heartburn. Barium meal showed a chronic duodenal ulcer with a sliding hiatus hernia and free oesophageal reflux. Operation was followed by good symptomatic relief for 18 months. The previous symptoms then recurred in a milder form and have persisted intermittently since. Barium meal has shown the recurrence of slight reflux and a small chronic duodenal ulcer. The Hollander test suggests that vagotomy has not been complete. The patient's general condition has, however, improved and the offer of further surgical treatment has been refused. For many years this man has suffered domestic discord and poor eating habits.

The effect of operation on individual symptoms, as defined by Edwards, Phillips, and Rowlands (1964), is shown in *Table I*, where it can be seen that a high success rate has been achieved in the present series.

Barium-meal examination was performed before and after operation in all patients. In 20 patients there was no sign of reflux following surgery and 18 of these have remained completely symptom-free. Of the other 2 patients without radiological reflux, 1 was classed as Visick Grade II and the other as Visick Grade III. The latter's symptoms, as have been mentioned, are due to established oesophageal stricture. There was radiological evidence of slight reflux in 5 patients. Four of these have remained entirely symptom-free, but the other, who also has a chronic duodenal ulcer, claims to have benefited very little from fundoplication with vagotomy and has been classed as Visick Grade IV.

Table I.—THE EFFECT OF OPERATION ON INDIVIDUAL SYMPTOMS

SYMPTOM	RELIEVED	NOT RELIEVED	NOT PRESENT PREOPERATIVELY
Reflux pain	23	1	1
Heartburn	23	1	1
Regurgitation	20	0	5
Vomiting	10	1	14
Dysphagia	5	2	18
Excessive belching	7	10	8
Haematemesis	2	0	23

In 3 patients approximately one-third of the cylindrical mass formed by plication was seen to herniate through the hiatus during barium-meal examination, but there were no associated symptoms or signs of reflux.

DISCUSSION

The advances in the surgical treatment of hiatus hernia which have followed the realization of the significance of oesophageal reflux, as well as better understanding of the factors which normally prevent reflux, have been well described by Collis (1970) and Mustard (1970). The importance of the oesophagogastric angle has been emphasized, and the results of the present trial, in which the procedure of fundoplication has been used alone without any other attempt at fixation or closure of the hiatus, confirm that effective valvular action at the cardia can be restored by maintenance of an acute angle of entry from the oesophagus. Fundoplication not only restores the angle necessary for flap-valve action but also provides a seat for this valve, the firmness of which increases as pressure within the stomach rises.

The diameter of the mass formed by fundoplication depends on the size of the fundus and the thickness of its wall. In most cases the mass appears to be too big to pass through the hiatus, but when the hiatus is wide and the fundus small there is no apparent impediment to herniation, and radiological evidence that this could occur was found in 3 patients. The fact that herniation was not accompanied by symptoms or signs of reflux demonstrates again the paramount importance of an effective valve at the cardia.

The length of follow-up, which has been complete for periods of 18 months to 7 years, is probably adequate as it is known that recurrent symptoms usually appear fairly soon after operation (Tanner and Hardy, 1970). Fundoplication has given entirely satisfactory symptomatic relief to 23 out of 25 patients. Failure in 1 patient is attributed to an established oesophageal stricture, and although dilatation at yearly intervals is still required there is radiological evidence that the operation has succeeded in stopping further reflux. Without fundoplication, repeated dilatation might well have been followed by extension and exacerbation of the stricture (Barrett, 1960).

The patient for whom the operation has been an almost complete failure had a chronic duodenal ulcer as well as a hiatus hernia with free reflux, and this combination presents a difficult problem. It is particularly unfortunate that vagotomy proved to be incomplete as it is likely that persistent symptoms are due to continued activity of the ulcer. Other patients in whom radiology shows reduction without complete abolition of reflux have usually had good symptomatic relief in our experience, as well as in that of Edwards and others (1964).

Table II.—A COMPARISON OF THE RESULTS OBTAINED IN THE PRESENT SERIES WITH THOSE OBTAINED IN SERIES USING OTHER METHODS OF TREATMENT

	EDWARDS AND OTHERS (1964)	MUSTARD (1970)	TANNER AND HARDY (1970)	PRESENT SERIES (fundoplication)
No. of patients	63	87	41	25
Percentage of patients of Visick Grades I and II	77	78	81	92
Percentage of patients free of reflux pain and heartburn	90	91	54	95
Percentage of patients with post-operative radiological reflux	63	21	Not stated	20

An attempt has been made to compare the results of the present series with those obtained from other methods, as described by Edwards and others (1964), Mustard (1970), and Tanner and Hardy (1970). The need for such a comparison has been considered sufficient to outweigh the risk of fallacies owing to the different numbers involved or unknown variables, but it should be noted that Tanner and Hardy (1970) have excluded patients with peptic ulcer, cholelithiasis, or other abdominal abnormality. Otherwise the basic criteria of selection appear to be the same in each series. It would appear from *Table II* that fundoplication has given comparatively favourable results both in respect of the proportion of Visick Grades I and II as well as in the relief of the predominant symptoms of reflux and the low incidence of post-operative radiological evidence of reflux.

The postoperative complications which have followed fundoplication are believed to be mainly due to other procedures performed at the same time, particularly splenectomy and vagotomy with pyloroplasty. The latter is now omitted unless there is definite evidence of chronic duodenal ulceration. The most serious complications of subphrenic abscess, empyema, and pneumonia occurred in 3 of the first 10 operations, and in these elective splenectomy had been performed as a means of mobilizing the fundus, as described by Smiddy and Ross (1964). Our unfortunate experience with iatrogenic splenectomy has been shared by Devlin, Evans, and Birkhead (1969). From the time this danger was appreciated, great care has been taken to avoid injury to the spleen, and the last 15 operations have been satisfactorily performed without splenectomy. The simple expedient of starting mobilization of the fundus from below has proved most helpful in difficult cases. Fundoplication performed in this way is the most benign of upper abdominal operations, and, by comparison, is much better tolerated by frail or elderly patients than either cholecystectomy or vagotomy with pyloroplasty. Furthermore, when performed in conjunction with the above procedures, fundoplication has caused no recognizable additional stress or complication. Fundoplication by abdominal incision is far less traumatic than repair of hiatus hernia by the thoracic or abdominothoracic route, and it has the advantage of compatibility with other abdominal procedures which are often necessary in these patients.

On the basis of our experience we would agree with Franklin (1969) that Nissen's procedure of fundoplication has not always received the recognition it deserves.

Acknowledgements.—We are grateful to Dr. R. I. Green, Dr. H. G. Row, and Dr. I. Pierce-Williams for the reports on the radiological investigations, and to the Research Committee of the Welsh Hospital Board for generous support, without which this study would not have been possible.

PERFORATED DUODENAL ULCER IN CHILDHOOD

BY J. M. S. JOHNSTONE
WESTERN GENERAL HOSPITAL

AND R. F. RINTOUL
ROYAL INFIRMARY, EDINBURGH

SUMMARY

Perforation of an acute duodenal ulcer in an infant and a child, both with other illness, is reported. Surgical management in both cases was successful. The importance of awareness of this complication is stressed and the cause, presentation, and management are discussed.

PERFORATED peptic ulcer in infants and children occurs so infrequently that it is not usually considered in the differential diagnosis of the acute abdomen (Rubell, Leix, and Clelland, 1952). In the literature 118 cases of perforated duodenal ulcer in neonates (under 1 month), infants (1 month–2 years), and children (2–15 years) have been reported, and of these, only 50 survived. Raffensperger and Greengard (1966), in a series of 80 patients with peptic ulcer, reported 23 with perforated duodenal ulcer, and of these, 80 per cent died. In two series an incidence of 1 and 1·5 per cent for perforated peptic ulcer was found at autopsy of infants dying from other causes. Two children with perforated duodenal ulcer who were treated successfully are reported in this paper.

CASE REPORTS

Case 1.—M. P., aged 1 year 11 months, was admitted with a 4-day history of vomiting and reluctance to feed. Two days before admission he had passed several loose, greenish bowel motions. Following admission his condition deteriorated, his vomitus became faeculent, and he was treated by intravenous infusion and nasogastric suction. A radiograph showed the presence of a pneumoperitoneum and he was transferred to the Paediatric Surgical Unit.

On examination the patient was lethargic and flushed but apyrexial. His pulse-rate was 108 per minute and his blood-pressure was 115/70. The abdomen was soft but deep palpation in all areas was resented. Bowel-sounds were present. At laparotomy a perforated acute ulcer was found on the anterior aspect of the first part of the duodenum. The perforation was closed in two layers with chromic catgut and the peritoneum was drained. The postoperative course was uneventful and the child made a full recovery.

Six weeks after admission the gastric acid secretion of the patient was assessed. In the first hour after pentagastrin, 52 ml. of gastric secretion were obtained, giving a total acid response of 4·5 mEq. The result of gastrin assay was within the normal limit for an adult, but we do not know the normal range for a child.

Case 2.—J. R., a 9-year-old boy, was admitted to hospital seriously ill with pneumococcal meningitis. Despite treatment his conscious level deteriorated and he developed generalized convulsions followed by respiratory arrest. He was transferred to the Assisted Ventilation Unit. His conscious level had not altered after 2 days of ventilation, and a tracheostomy was carried out. On the third day he vomited small amounts of coffee-ground material. On the fifth day his conscious level had improved and he was able to recognize his father. A routine chest radioagraph at that time showed a pneumoperitoneum.

On examination the patient's temperature was 37·8° C., his pulse-rate was 120 per minute, and blood-pressure was 120/70. There was slight abdominal distension with generalized guarding but no rigidity. Laparotomy was carried out under general anaesthesia. A 2-mm. perforation of an acute anterior duodenal ulcer was found with slight bilious soiling of the peritoneum. The perforation was closed by simple suture with an omental overlay. A vacuum drain was placed below each hemidiaphragm. The patient's postoperative recovery was uneventful, the tracheostomy tube being removed the following day and a light diet being commenced 2 days postoperatively. At follow-up examination he has had no symptoms of duodenal ulceration. Gastric acid secretion and gastrin assay were not carried out.

DISCUSSION

Perforation may complicate acute or chronic duodenal ulceration. Acute ulcer in the neonate may develop with prematurity, anoxia, abdominal distension, or hyperacidity. It has been suggested that anoxia may be associated with selective shunting of blood leaving relatively ischaemic areas in the gastrointestinal tract (Lloyd, 1969). Acute ulceration in the infant and child may be secondary to stress, such as lesions of the central nervous system (Cushing's ulcer), sepsis, burns, malnutrition, trauma, steroid therapy, and major surgery. *Case* 2 exemplified this, but in *Case* 1 the accompanying illness would have been associated with considerably less stress.

Chronic duodenal ulcer is more common in the older child and resembles the adult pattern where an ulcer diathesis is presumed. Adverse emotional factors may be present, and Muggia and Spiro (1959) stressed lack of security as an aetiological factor. Proctor (1925) stated that 2 per cent of adults with a peptic ulcer give a history dating back to childhood. Goldberg (1957) and Milliken (1965) reported gastric hypersecretion in 1 of 10 cases and in 5 of 15 cases respectively. Both, however, felt that gastric analysis in the child was unreliable.

In the neonate and infant the clinical findings after perforation of an acute duodenal ulcer may be those of an acute abdomen, but the signs may be masked, especially in the presence of other illness. The diagnosis is frequently overlooked because of its rarity. An abdominal radiograph in the lateral or erect position is of value, as a pneumoperitoneum in the neonate may be due to a perforated ulcer (Muggia and Spiro, 1959).

In the healthy child abdominal signs of perforation become more reliable and the diagnosis may be confirmed radiologically. Gastrografin may be helpful in the localization of the site of perforation.

Both the children in this paper presented in an atypical manner, the abdomens being soft and bowel-sounds present. A pneumoperitoneum was shown radiologically in each case.

Perforation may complicate chronic peptic ulceration in the older child. Evidence of a chronic ulcer may be difficult to establish. Symptoms are frequently atypical. The pain may be referred to the umbilical region, may be unrelated to meals, may last only a few minutes, and may not be present at night. Some children have undergone elective appendicectomy. The condition more closely resembles that of the adult as the age approaches 15 years.

The neonate and infant are at particular risk from abdominal sepsis. Successful surgery in the neonate depends on early diagnosis, intensive care in the pre- and postoperative periods and expert anaesthesia. Ten out of 21 infants and neonates reported in the literature survived after surgery but none survived without operation. In all age-groups closure of the perforation is carried out with care not to obstruct the lumen and using an omental plug. The acute duodenal ulcer in young children rarely recurs after treatment of the presenting problem (Schuster and Gross, 1963).

The principle of simple closure is usually followed in perforation of chronic duodenal ulcer. A history of previous complications may indicate definitive surgery. Consideration in choice of operation must then be given to the extra nutritional demands of the growing child, so that gastric anatomy and physiology are altered as little as possible (Gross, 1953). Swenson (1962) reported that vagotomy in children causes more gastro-intestinal dysfunction than in adults, but Raffensperger and Greengard (1966) did not confirm this in their series of 11 cases.

Acknowledgements.—We would like to thank Dr. G. S. Sangster, Consultant Physician, City Hospital, Edinburgh, the late Mr. E. L. Farquharson, Consultant Surgeon, Royal Infirmary, Edinburgh, and Mr. I. S. Kirkland, Consultant Paediatric Surgeon, Western General Hospital, Edinburgh, for their permission to publish these cases.

TUBERCULOSIS OF THE GALL-BLADDER

By LEIF BERGDAHL and LENNART BOQUIST[*]
DEPARTMENTS OF SURGERY AND PATHOLOGY, UNIVERSITY OF UMEÅ, SWEDEN

SUMMARY

Three female patients with tuberculous cholecystitis are reported. They had symptoms of cholecystopathy of varying duration. No jaundice was recorded. Cholecystograms disclosed non-functioning gall-bladders in 2 cases and a functioning gall-bladder with two stones in the other case. At cholecystectomy, cholelithiasis was found in all the patients, and in addition 1 of them showed tuberculous peritonitis. Microscopic examination showed tuberculous changes in the gall-bladders. Postoperative tuberculostatic treatment was given. The presence of stones is believed to have been of importance for the development of the tuberculous infection in the present cases.

Although the frequency of cholecystitis has increased during the past decades (Kettler, 1958), the incidence of gall-bladder tuberculosis is still very low (Schöndube, 1956). This may be due to a failure to recognize the condition, or to a special resistance of the gall-bladder to the tubercle bacillus (Rankin and Massie, 1926). Farkas (1960) has concluded that only about 50 of the hundreds of thousands of gall-bladders that have been examined microscopically have shown a tuberculous inflammation. We have been able to find only 41 cases of tuberculous cholecystitis who have undergone surgery reported in the literature up to 1970 (Weitz, 1955; Leng-Lévy, David-Chaussé, Martin, Lagoarde, and Herné, 1965; Vojtisek and Zrustova, 1965; Rybkowski, 1966; Krejczy and Krejczy, 1967; Gonzales, Donoso, and Chamorro, 1967; Mlynek and Engel, 1968). Because of this, reports of new cases may still be of interest. The present communication is an account of 3 cases with tuberculosis and stones in the gall-bladder who underwent surgery.

CASE REPORTS

Case 1.—A 50-year-old woman who had had pulmonary tuberculosis 25 years previously presented with a 15-year history of typical biliary symptoms. On two occasions the urine had been bile-stained and the stools had been decolorized. She had never been icteric. A peroral cholecystogram 9 months previously had shown a non-functioning gall-bladder.

At cholecystectomy extensive adhesions were found around the gall-bladder. The gall-bladder had a thickened wall and contained about fifty stones with diameters of 3–10 mm. Operative cholangiograms were normal. No signs of peritoneal tuberculosis were observed.

Microscopic examination of the extirpated gall-bladder showed an atrophic and partly ulcerated mucosa, moderate hyperplasia of the muscular coat, and marked fibrosis. Granulomas of varying size occurred mainly in the fibrous portions. They were composed of epithelioid cells, with an admixture of Langhans' giant cells, peripheral lymphocytes, and occasional central caseous necroses (*Fig.* 1). These alterations made the diagnosis of tuberculosis probable.

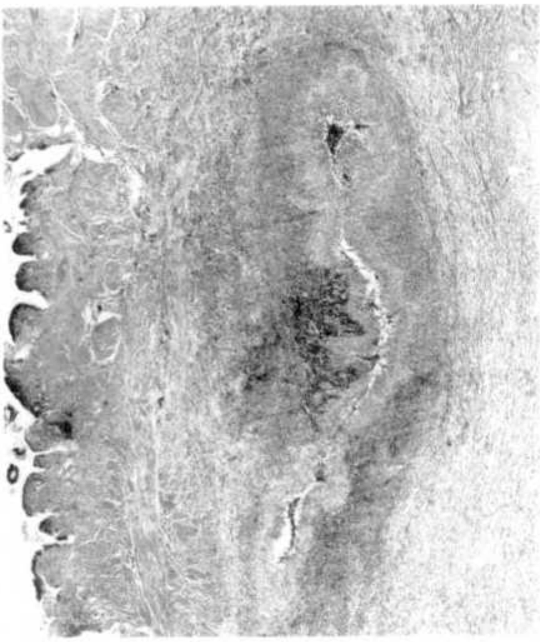

FIG. 1.—*Case* 1. Photomicrograph of the gall-bladder showing fibrous thickening of the wall and a large tubercle with central necrosis.

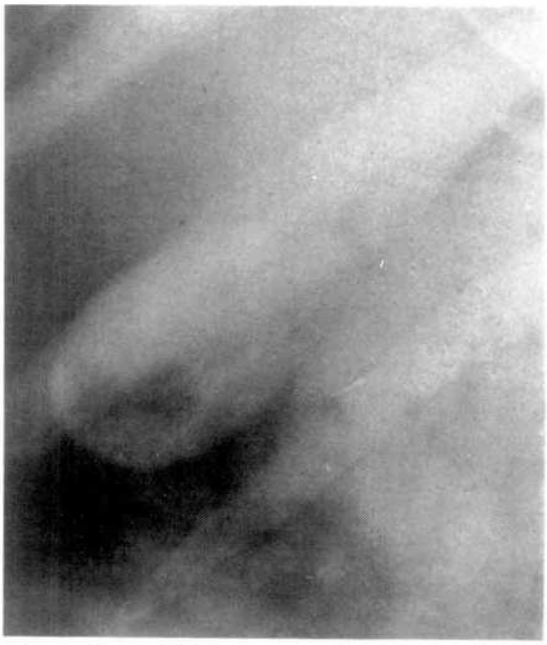

FIG. 2.—*Case* 2. Oral cholecystogram demonstrating a functioning gall-bladder with two radio-opaque stones.

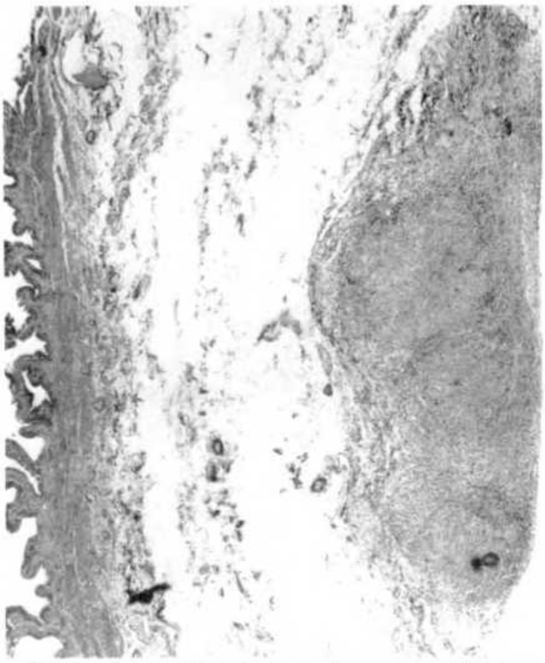

FIG. 3.—*Case* 2. Photomicrograph showing the gall-bladder with preserved mucosa (left) and a large tubercle with an occasional giant cell in the serous layer.

Direct microscopy of sputum as well as guinea-pig inoculation of sputum, gastric lavage, and urine were negative. Pulmonary radiographs showed no active tuberculous foci. Postoperatively the patient received tuberculostatic treatment. At repeated control investigations no complications have been recorded.

Case 2.—A 54-year-old woman had a 1-year history of cholecystopathy. Jaundice had not been present, but she had had periods of diarrhoea. A peroral cholecystogram 2 weeks before the operation showed two stones in a functioning gall-bladder (*Fig.* 2).

Cholecystectomy was performed and 3 litres of yellowish fluid were found in the peritoneal cavity. Small yellowish-white knots, which seemed to be of a tuberculous nature, were widely disseminated over the peritoneal surfaces. Around the gall-bladder there were numerous adhesions, and the gall-bladder itself exhibited a thickened wall and contained two stones. Operative cholangiograms were normal. Microscopic examination of the gall-bladder showed numerous, small, epithelioid granulomas with associated Langhans' giant cells and lymphocytes, mainly in the serous layer (*Fig.* 3). Postoperatively, tuberculostatic treatment was instituted. The subsequent course has been uneventful.

Case 3.—A 59-year-old woman who had previously had good health was seen with fever, an elevated sedimentation rate, and pains in the upper right quadrant. No jaundice was recorded. A peroral cholecystogram showed a non-functioning gall-bladder.

Cholecystectomy was performed and numerous adhesions were seen around the gall-bladder which also had a thickened wall with scattered necrotic portions. About forty stones with diameters of 5–15 mm. were found in the gall-bladder. Operative cholangiograms were normal. Microscopic examination of the extirpated gall-bladder showed hyperplasia of the muscular layer, extensive fibrosis, and caseous necroses surrounded by epithelioid cells with intermingled giant cells of Langhans' type and peripheral infiltrates of lymphocytes (*Fig.* 4). The alterations were mainly confined to the fibrous portions. The microscopic changes indicated tuberculosis. Direct microscopy of gastric lavage as well as guinea-pig inoculation of gastric lavage and urine were negative. After operation tuberculostatic treatment was given. The patient remains in good health at the present time.

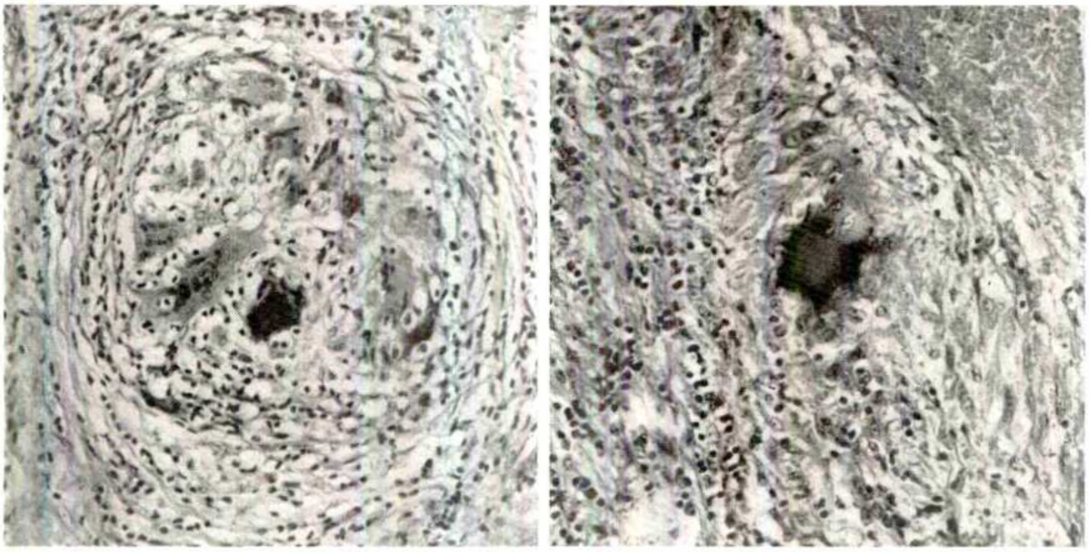

FIG. 4.—*Case* 3. A, Portion of the gall-bladder showing a tubercle composed of central epithelioid cells and giant cells with more peripherally localized lymphocytes and fibroblasts. B, Portion of another tubercle demonstrating necrotic material, epithelioid cells, a giant cell, lymphocytes, and fibroblasts.

DISCUSSION

Simmonds (1908) differentiated between an acute form of tuberculous cholecystitis, which is caused by an infection through the biliary passages, and a chronic type, which is caused by secondary infection of a gall-bladder that has already been damaged by non-specific inflammation. Weitz (1955) has proposed the following classification of tuberculosis of the gall-bladder:—

1. Miliary tuberculosis in children with ulcerating tubercles in the gall-bladder.
2. Gall-bladder tuberculosis in association with severe general tuberculosis.
3. Tuberculosis limited to the gall-bladder, often discovered accidentally at microscopic examination of extirpated gall-bladders.
4. Gall-bladder involvement in association with tuberculosis in other peritoneal organs.

According to this classification *Cases* 1 and 3 of the present study belong to group 3, whereas *Case* 2 belongs to group 4. There are only two previous reports of patients belonging to the latter group (Latronche, 1911; Pohl, 1949). The cholecystograms from *Case* 2 showed stones in a functioning gall-bladder. Such a finding does not seem to have been reported previously in cases of tuberculosis of the gall-bladder. The preserved function may be due to the fact that the inflammatory process mainly involved the serosa.

The symptoms in our cases were similar to those encountered in patients with non-specific cholecystitis. No jaundice was recorded. This conforms with the findings of Vallejo (1950), who stated that pain after meals, nausea, diarrhoea, and fever are common symptoms, and that jaundice is infrequent in cases of tuberculosis of the gall-bladder. Alterations in the biliary tracts seem to occur only seldom in cases of tuberculous cholecystitis. Autio, Virtanen, and Antila (1963) have, however, reported changes in the biliary tracts in a patient with tuberculous infection of the gall-bladder.

There are several possible routes by which tuberculous infection may reach the gall-bladder. Haematogenic or lymphogenic dissemination from neighbouring or distant organs may occur (Rankin and Massie, 1926; Vojtisek and Zrustova, 1965). Another possibility is infection by direct extension from neighbouring foci (Pohl, 1949; Weitz, 1955). An ascending or descending canalicular infection via the biliary passages has been suggested by Simmonds (1908) and Ajello (1940). The possibility of an ascending canalicular dissemination has, however, been denied by others (Rankin and Massie, 1926; Elfving, 1949; Weitz, 1955; Remmele and Lennert, 1957). Kettler (1958) has proposed that the absence of tubercles from the mucosa indicates a haemato- or lymphogenic spread of the infection, whereas tubercles mainly localized in the mucosa denote canalicular dissemination. Wohlgemuth, Herrmann, and Vogel (1960) found involvement of the ducts of Luschka in gall-bladder tuberculosis, which was believed to indicate infection from the gall-bladder lumen.

In 2 of the present cases (*Cases* 1 and 3) the histological changes were mainly absent from the gall-bladder mucosa, which might denote that the infection was carried by the lymph or blood from some other focus. In *Case* 2 the microscopic alterations were mainly confined to the serous layer of the gall-bladder and there were tubercles scattered over the peritoneal surfaces, which might indicate dissemination via the peritoneal cavity to the gall-bladder.

It is not quite clear whether tuberculous infection can occur in the absence of changes in the biliary tracts and gall-bladder. Fraenckel and Krause (1918) reported tuberculous manifestations in gall-bladders without previous disease. However, it has been suggested that the intact gall-bladder has a special resistance to tuberculous infection. The factor or factors responsible for this resistance are not clearly known. It has been suggested that anti-tuberculous activity is present in salivary and pancreatic secretions (Hirsch, 1955). Autio and others (1963) have reported that pure bile contains bile acids in concentrations high enough to inhibit the growth of the tubercle bacillus, which might contribute to the resistance. They also suggested that cystic-duct obstruction leads to the disappearance of bile acids from the gall-bladder and to a lowered resistance against tuberculous infection.

Experimental evidence emphasizes the importance of previous damage for the development of tuberculous cholecystitis. Delitalia (1935) tried to evoke tuberculosis of the gall-bladder by intravenous injection of tubercle bacilli in rabbits. This was not possible when the gall-bladder was normal. Only after experimental induction of cholelithiasis were tuberculous manifestations of the gall-bladder obtained.

Clinical studies denote that stones may be of pathogenetic significance for the development of tuberculosis in the gall-bladder. Of the 44 cases of tuberculosis of the gall-bladder (the present 3 cases have been added to those reported in the literature), only 2 seem to have been acalculous. One patient reported by Vallejo (1950) showed an obstruction of the cystic duct caused by a 'granulomatous whitish mass'. In another case reported by Rankin and Massie (1926) there was no information about any obstruction, but this possibility remains since the gall-bladder was filled with 'caseous material'. The frequency of gall-stones in these 44 cases seems to be approximately the same as in non-specific cholecystitis. In acute cholecystitis stones occur in about 95 per cent of cases (Glenn and Mannix, 1956).

Common-duct stones were found in 5 of the 44 cases (11 per cent), which denotes that the frequency of choledocholithiasis is about the same in non-specific as in specific cholecystitis. Two of these 5 cases had stones in the common duct but not in the gall-bladder (White, 1932; Peruzzo and Zannini, 1952).

It is well known that stones are important pathogenetic factors for non-specific cholecystitis. Spontaneous delivery of concrements may be involved in the formation of acalculous cholecystitis (Andersson, Bergdahl, and Boquist, 1971). We believe that the presence of stones with associated non-specific inflammatory alterations may also play a prominent role in the development of tuberculosis of the gall-bladder. In *Case* 1 there was a 15-year history and in *Case* 2 a 1-year history of cholecystopathy. Fibrous thickening of the gall-bladder wall occurred in *Cases* 1 and 3, denoting the existence of chronic inflammatory alterations. Cholelithiasis which was present in all of our cases is believed to have induced inflammatory changes of varying severity that diminished the resistance of the gall-bladder to the tuberculous infection.

morphine without vomiting

CYCLIMORPH* provides the benefits of morphine without the distressing side-effect of vomiting because, in addition to morphine, it contains the rapid-acting anti-emetic cyclizine.
CYCLIMORPH is indicated whenever the benefits of morphine are required, especially where nausea and vomiting would be harmful, as in myocardial infarction, pre-operative medication, post-operative pain and debilitated patients.

Cyclimorph

CYCLIMORPH Injection is subject to the DDA. It is issued in two strengths:
CYCLIMORPH 10 containing Morphine Tartrate (10mg) and Cyclizine Tartrate (50mg);
CYCLIMORPH 15 containing Morphine Tartrate (15mg) and Cyclizine Tartrate (50mg).
Full information is available on request.

DRAINAGE FOLLOWING CHOLECYSTECTOMY

By C. B. WILLIAMS,* D. S. HALPIN, and A. J. S. KNOX
DEPARTMENT OF SURGERY, ROYAL DEVON AND EXETER HOSPITAL, EXETER

SUMMARY

The effect of intraperitoneal drainage and incidental appendicectomy has been studied in 309 patients who had undergone routine cholecystectomy.

Patients who did not have drainage fared better than those in which drains were used. There was an increase in postoperative morbidity when the drain was left in position for more than 48 hours. But when the drain was removed during the first 48 hours the results obtained were the same as for cases in whom no drain was used. Incidental appendicectomy while carrying out cholecystectomy did not affect the morbidity or mortality of the operation.

It is concluded that in the absence of bile leakage, drains from the hepatorenal space should be removed within 48 hours, and incidental appendicectomy should be carried out when it can be performed with ease and without undue manipulation.

In recent retrospective studies that have included 1000 or more patients the mortality following cholecystectomy has been found to vary between 0·6 and 3·8 per cent (MacVicar, McNair, Wilken, and Bruce, 1967; Meyer, Capos, and Mittlepunkt, 1967; Holm, Edmunds, and Baker, 1968; Magee and MacDuffee, 1968; Seltzer, Steiger, and Rosato, 1970). MacVicar and others (1967) noted in their review of 2043 operations for benign conditions of the gall-bladder and common bile-duct that the majority of the 77 deaths (3·8 per cent) were associated with leakage of bile, and they concluded that prevention and early treatment of this complication would reduce the mortality. They also observed that deterioration in the condition of these patients occurred shortly after the operation, usually within the first 48 hours. Their study supported the routine use of intraperitoneal drainage after cholecystectomy to allow the escape of bile from (*a*) an insecurely tied cystic duct, (*b*) a small accessory bile-duct cut and unrecognized at operation, or (*c*) a damaged biliary duct.

Drainage, however, is associated with a small but significant morbidity that includes the introduction of infection and the formation of incisional herniae. Also, a syndrome of fever and pain in the right upper quadrant of the abdomen has been described by Myers (1962) and termed 'drain fever'. This occurred in 5·3 per cent of his cases following manipulation of a drain that had been present for more than 48 hours. The pain persisted for 1–3 days and subsided with the fever, although daily rises of temperature of up to 38° C. occasionally persisted for as long as 2 weeks. It has also been suggested that the surgeon may rely completely on a drain to indicate a biliary leak and, because of this false security, may miss the signs of a hidden collection of bile.

The length of time for which drainage is advised in the absence of bile leakage varies, Myers (1962) recommending less than 48 hours, Maingot (1964) 2–3 days, and George (1964) 4–5 days. To add to the confusion it has been estimated that 16 per cent of surgeons do not routinely drain after cholecystectomy but rely on the physical signs to indicate biliary leakage (Lazarus, Baum, and Briedenbach, 1954). Dreese (1963) reported a series of 667 simple cholecystectomies in which drainage had been omitted in 230 cases. His cases had to satisfy strict criteria when no drainage was used. These included no spillage of purulent material during the operation, absence of bleeding or biliary ooze from the gall-bladder fossa, double ligation of the cystic duct, and tying of the cystic artery under direct vision. Only 1 patient required secondary drainage and there were no deaths in the series.

A survey was carried out by the Public Health Laboratory Service (1960) to estimate the incidence of sepsis following surgical operations and found it to be as high as 20·6 per cent following cholecystectomy. This figure was among the highest for general surgical operations and may be the result of several factors, including spillage of infected bile, the presence of a drain, and incidental appendicectomy. Komarn and Kaufman (1963) found a higher incidence of wound infection when appendicectomy was carried out with cholecystectomy and concluded: 'transection of a faecal-containing organ in an otherwise clean operation violated established surgical principles'. This conclusion was not supported by either Lowery and Lenhardt (1962) or Bogart and Sebesta (1969), who found that appendicectomy did not affect the incidence of wound infection in their series of cholecystectomies. Unfortunately, none of these studies took into account the presence or absence of intraperitoneal drainage.

Our study was carried out to assess the place of intraperitoneal drainage as a routine practice following cholecystectomy with and without incidental appendicectomy.

MATERIALS AND METHODS

The operations included in this study were carried out at two hospitals in the same city. At one hospital it was the policy never to use intraperitoneal drainage after simple cholecystectomy but to rely on physical signs to diagnose biliary leakage. At the second hospital this was not the policy and drains were inserted for periods that varied according to the whims of individual surgeons. Surgical registrars rotated between the two hospitals and adopted the policy of drainage of each hospital accordingly. This produced two random groups of patients on whom the effects of drainage could be compared.

---

* Present address: Bristol Royal Infirmary, Bristol 2.

All routine cholecystectomies carried out at these two hospitals during the 5-year period 1965–9 were included in this study. Cases where exploration of the common bile-duct or any other surgical procedure, except appendicectomy, was carried out were excluded. Also excluded were operations for carcinoma of the gall-bladder.

A total of 309 cases were reviewed and included in the study; 170 had been drained and 139 not drained.

Table I.—THE GROUPS OF PATIENTS STUDIED

Group	*No. of Patients*
Drainage with appendicectomy	34
Drainage without appendicectomy	136
No drainage and appendicectomy	62
No drainage or appendicectomy	77
Total	309

Twenty-six per cent of the patients in both groups were male and the average ages for the groups with and without drainage were 54·3 years (range, 15–89 years) and 53·3 years (range, 23–80 years) respectively.

These two groups were further subdivided according to whether or not appendicectomy had been carried out at the time of the cholecystectomy (*Table I*).

The operations were carried out by 28 different surgeons who used either corrugated-rubber strips, rubber tubes, or Penrose wick drains. No significant difference was found between the results obtained for the various drains.

Four criteria were studied in each group and were compared statistically:—

1. Mortality.
2. Incidence of infection and biliary peritonitis.
3. Duration of the postoperative pyrexia. This was calculated as the period immediately after operation that the temperature remained above 38° C.
4. Length of postoperative stay in hospital.

RESULTS

1. Mortality.—Two patients (0·65 per cent) died during the postoperative period, 1 from a pulmonary embolus and the other from septicaemia (infecting organism, *Clostridium welchii*). Both died on the third postoperative day and were not included in the rest of this study.

2. Infection and Biliary Peritonitis.—There were 13 cases (7·8 per cent) of wound infection in the group of patients with drains, and 2 cases (1·4 per cent) of wound infection in the group without drains. It is interesting to note that in only 3 of these cases, all in the group with drainage, was incidental appendicectomy carried out.

Two patients, both in the group with drainage, developed a subhepatic abscess, and each required a further operation to drain the collection of pus. Two other patients required second operations: 1 for bleeding which in spite of the presence of a corrugated-rubber drain was concealed for 48 hours, and the other for a collection of 300 ml. bile which also failed to escape along a corrugated-rubber drain. The diagnosis of a collection of bile was made clinically on the third postoperative day and the patient made a satisfactory recovery after a second operation to drain it.

3. Postoperative Pyrexia.—The temperature remained above 38° C. for a significantly longer period when a drain was present (*Table II*), and the duration of postoperative pyrexia was not affected by carrying out an appendicectomy with the cholecystectomy (*Table III*).

Table II.—COMPARISON OF THE DURATION OF POSTOPERATIVE PYREXIA AND STAY IN HOSPITAL IN PATIENTS WITH AND WITHOUT DRAINAGE

GROUP OF PATIENTS	NO. OF PATIENTS	POSTOPERATIVE PYREXIA (hours)		POSTOPERATIVE STAY IN HOSPITAL (days)	
		Mean ± S.E.	*P*	Mean ± S.E.	*P*
Total with drainage Total without drainage	168 139	97·7 ± 5·0 72·0 ± 4·8	< 0·001	12·00 ± 0·41 10·30 ± 0·27	< 0·01
Drainage without appendicectomy No drainage or appendicectomy	135 77	94·1 ± 5·3 68·6 ± 5·8	< 0·01	11·94 ± 0·48 10·62 ± 0·40	0·05
Drainage with appendicectomy No drainage with appendicectomy	33 62	112·1 ± 6·5 75·1 ± 7·0	< 0·01	12·21 ± 0·82 9·65 ± 0·31	< 0·001

The effect of the period of drainage was assessed by comparing the duration of postoperative pyrexia when the drain was removed within 48 hours with (*a*) the group without drainage and (*b*) when the drain remained for more than 48 hours (*Table IV*). No difference was found between the group without drainage and patients in whom the drain was removed within 48 hours. However, there were significant differences between those patients in whom the drains were left for more than 48 hours and the other two groups.

In our study 7 patients (4·3 per cent) complained of pain at the drain site associated with a pyrexia after manipulation of the drain. Each drain had been left in position 48 hours or more.

4. Length of Postoperative Stay in Hospital.—The same comparisons were made as were carried out for postoperative pyrexia. The patients with drains remained in hospital for a significantly longer period than those without drains (*Table II*). When the effect of appendicectomy was considered, varying results were obtained (*Table III*). No difference was found between the groups with drainage, but in the groups without drainage patients who had incidental appendicectomy had a shorter postoperative stay in hospital.

Patients in whom the drain had been left in position for more than 48 hours had significantly longer postoperative stays in hospital than either the patients without drainage or those drained for less than 48 hours (*Table IV*). No difference was found between these latter two groups.

The results of individual surgeons for both postoperative pyrexia and length of stay in hospital were compared statistically. No significant differences in distribution were found (*Table V*).

DISCUSSION

Drainage of the hepatorenal space after simple cholecystectomy is advised by the majority of authors to allow bile that might leak from the biliary tract and produce peritonitis to escape. When this complication occurs there is a significant increase in the postoperative mortality and morbidity. In our study the presence of a drain was associated with an increased incidence of wound infection and significantly longer periods of postoperative pyrexia and stay in hospital when compared with a group of patients in whom no drain was used. This increase in postoperative morbidity was independent of the type of drain used. The better results for the group without drainage may be the result of several factors. These include the more meticulous technique used by a surgeon who knows that he will not have a drain to warn him of biliary leakage or blood-loss—complications that are usually the result of technical errors. Also drains, particularly when made of rubber, are an irritant in the tissues and may predispose to infection. However, if in the absence of bile leakage the drains were removed within 48 hours, results no different from those of the group without drainage were obtained.

As this is a retrospective study, other factors have to be considered before conclusions can be made from the results. Drains may have been left in position for longer than 48 hours because signs or symptoms of infection were present and a more cautious approach to the removal of the drain was indicated. Careful examination of the notes revealed no leakage of bile or excessive loss of serous fluid from any of the drains which were left for longer than 48 hours, and no obvious reason for their continued presence was found. Also, if evidence of infection had been present in this group, then similar evidence would have been found in the group of patients without drainage if the infection had not been due to the presence of the drain itself.

Although the two groups of patients were treated at separate hospitals the majority were operated upon by the same surgeons using the same basic techniques. The hospitals received patients from the same geographical districts and social classes, so that these factors could not have accounted for any of the differences observed. Other factors exist that may have affected the length of postoperative stay at the two hospitals. These include the pressure on beds and the availability of convalescent facilities, neither of which could be accurately assessed in this study.

However, the findings in this study are particularly relevant when considered with the findings of Myers (1962) and MacVicar and others (1967). MacVicar and others (1967) found that deterioration in the condition of a patient as a result of bile leakage following cholecystectomy usually occurred during the first 48 hours. Myers (1962) described a syndrome of pain and fever occurring in approximately 5·3 per cent of patients following manipulation of a drain that had been present for 48 hours or more. A similar syndrome was observed in 4·3 per cent of our patients. Therefore, when no bile is escaping there is no indication for leaving the drain in position for longer than 48 hours. By that time it will have served its purpose and its presence for a further period will only produce an increase in postoperative morbidity.

It is of interest that the 4 cases in our series requiring second operations for intraperitoneal collections had been drained during the initial procedure. One of the 2 patients who developed a subhepatic abscess had been drained with a tube drain and the other with a corrugated-rubber strip. Both the patients who formed collections of bile and blood had been drained with corrugated-rubber strips, and in neither case was the condition recognized until the patient had developed symptoms. The reliability of corrugated-rubber strips for intraperitoneal drainage is therefore open to doubt.

In this study the practice of carrying out an appendicectomy at the time of the cholecystectomy did not affect the postoperative morbidity. Komarn and Kaufman (1963) claimed that it increased the incidence of wound infection, but the results obtained by Lowery and Lenhardt (1962) and Bogart and Sebesta (1969) did not support this conclusion. Incidental appendicectomy was advocated by Lowery and Lenhardt (1962) and Bogart and Sebesta (1969), as they found histological evidence of either active or chronic disease existing in 28·4 per cent and 35·9 per cent of the appendices removed respectively. None of these papers took into account the effect of drainage which we found to affect the morbidity, but in our study, which takes drainage into account, no adverse effects were found when incidental appendicectomy was carried out. In fact, patients who had appendicectomy and cholecystectomy without drainage had shorter postoperative stays in hospital. On analysis of this group it was found that 4 of the patients who had not had appendicectomies had longer stays in hospital than usual: 2 because of deep-vein thrombosis and 2 because of pneumonia. Our study supports incidental appendicectomy when it can be carried out with complete ease and without undue manipulation.

ANTERIOR DISLOCATION OF THE HIP AND DIASTASIS OF THE CONTRALATERAL SACRO-ILIAC JOINT—THE REAR-SEAT PASSENGER'S INJURY?

BY D. E. MARKHAM

SENIOR REGISTRAR, ORTHOPAEDIC DEPARTMENT, ROYAL HOSPITAL, SHEFFIELD

SUMMARY

A mechanism of injury is described to account for the combination of anterior dislocation of the hip and diastasis of the contralateral sacro-iliac joint occurring in rear-seat car passengers. Two cases are described and discussed in relation to precipitating factors and how the injury may be prevented.

THE association between comminuted fracture of the patella and posterior dislocation of the ipsilateral hip in 'dashboard' injuries has long been recognized as a hazard to front-seat passengers in cars which are involved in head-on collisions.

Two recent cases of anterior dislocation of the hip occurring in rear-seat passengers have indicated the manner in which the injury was produced. In 1 of these cases the dislocation was associated with diastasis of the contralateral sacro-iliac joint, suggesting that the injuries are connected and produced by the same forces.

CASE REPORTS

Case 1.—W. P., a 62-year-old man, was seated behind the driver in a small family car which was involved in a

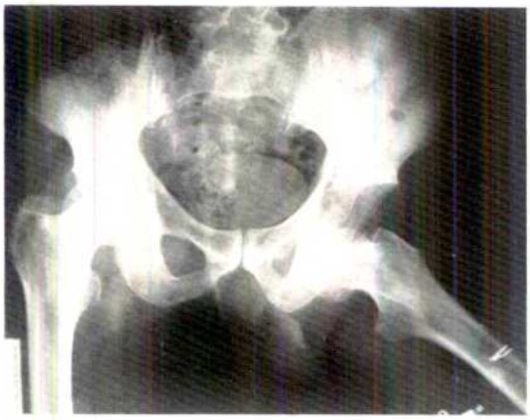

FIG. 1.—*Case* 1. Radiograph of the pelvis and both hips showing anterior dislocation of the left hip.

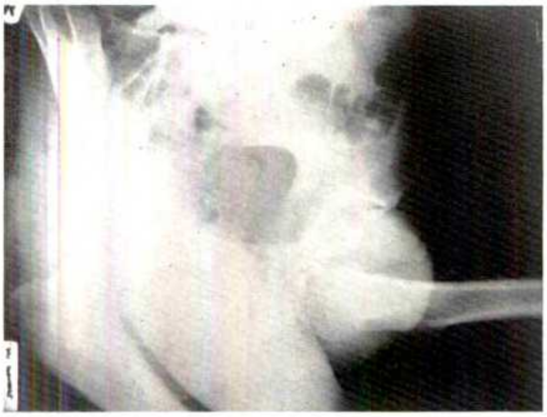

FIG. 2.—*Case* 2. Radiograph of the pelvis and both hips showing anterior dislocation of the left hip with diastasis of the right sacro-iliac joint.

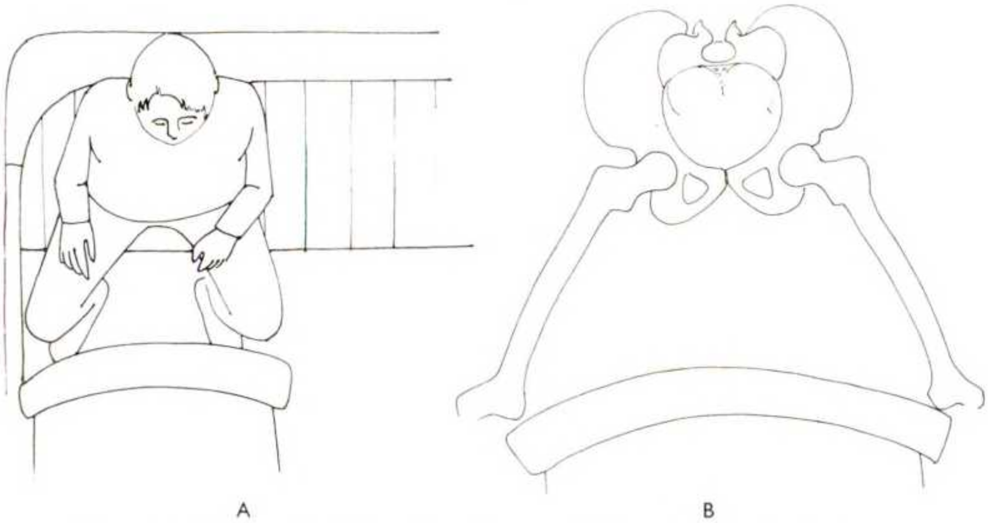

FIG. 3.—A, Position of rear-seat passenger prior to impact. B, Anatomical position prior to impact.

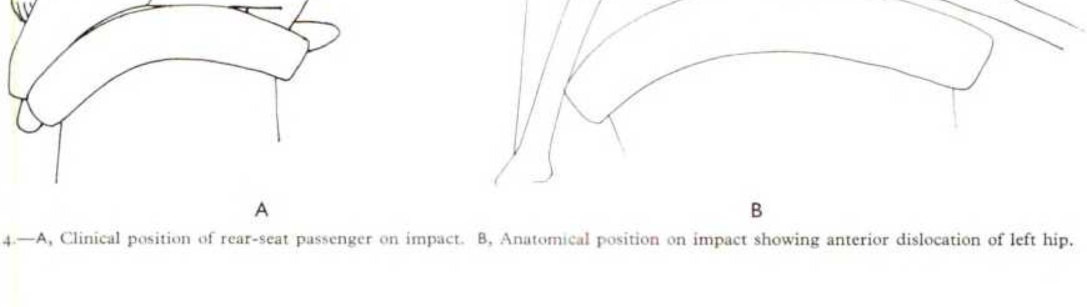

FIG. 4.—A, Clinical position of rear-seat passenger on impact. B, Anatomical position on impact showing anterior dislocation of left hip.

head-on collision. The force of the impact threw him forward against the back of the driver's seat and he sustained an anterior dislocation of the left hip (*Fig.* 1). This dislocation was subsequently reduced and, after a period of immobilization on traction, the patient made a full and uncomplicated recovery.

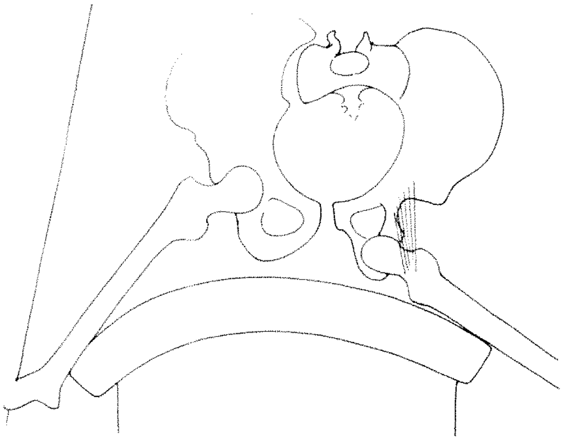

FIG. 5.—Anterior dislocation of the left hip with separation of the contralateral sacro-iliac joint.

Case 2.—W. J., a 19-year-old man, was sitting behind the driver in a saloon car when it was involved in a high-speed, head-on collision with another vehicle. He was thrown forward against the driver's seat and sustained an anterior dislocation of the left hip and a diastasis of the right sacro-iliac joint (*Fig.* 2). The dislocation was reduced under general anaesthesia and the pelvic separation was treated successfully in a pelvic sling. Subsequent progress was uneventful.

DISCUSSION

Front-seat car passengers tend to sit with their knees together and their hips flexed at a right-angle. This is the optimum position from which to sustain a posterior dislocation of the hip on forcible impact of the knee against the dashboard. The impact also produces a comminuted fracture of the patella in many cases.

Rear-seat car passengers tend to sit with knees and hips flexed to a right-angle but with their hips in abduction and slight external rotation (*Fig.* 3). When such a passenger is subjected to sudden deceleration he is thrown forward against the front seat. The leg nearest the side of the car becomes wedged between the front seat and that side of the vehicle, thus becoming fixed and relatively safe from injury. However, the leg nearest the centre of the car has freedom of movement and is subjected to an abducting and externally rotating force, which produces an anterior dislocation of the hip-joint (*Fig.* 4). If the deceleration is very rapid and results from high-velocity impact, any unspent force remaining after the hip has dislocated will be transmitted through the ligaments of that hip to the pelvis. The innominate bone adjacent to the side of the vehicle is already fixed in the same way as the femur on that side, and separation of the pelvis occurs at that sacro-iliac joint, being the point between its fixed and potentially mobile parts.

In the 2 cases described here both patients were seated behind the driver and in each case the left hip was dislocated. Clearly the same mechanism would apply in the case of a person seated behind an occupied front-passenger seat, but in this case the right hip and the left sacro-iliac joint would be injured.

Other marginal factors affecting the extent of injury are illustrated in the cases described. In *Case* 1 the speed at impact was much less than that in *Case* 2, which may account for the hip alone being affected in the first patient. In both cases the vehicles were fitted with individual front seats which probably contribute to this type of injury.

Should a rear-seat passenger be thrown against an unoccupied front seat it is a matter for conjecture whether his injuries would be severe or whether the seat would itself become deformed by absorbing some of the force of impact. The construction of the vehicle and whether or not the front seats are anchored would have some bearing on the injury pattern.

The only way in which these particular injuries can be prevented is for rear-seat passengers to wear safety belts and thus be prevented from being thrown forward on vehicle impact.

Acknowledgements.—I am grateful to Mr. F. W. Taylor for permission to publish details of patients under his care, and for his help in the preparation of this paper; also to Mrs. I. Blincow for the drawings and Mrs. B. M. Wilson for secretarial help.

SURGICAL RESEARCH SOCIETY

A meeting of the Surgical Research Society was held in the Medical School, St. Bartholomew's Hospital, London, on 7 and 8 January, 1972, with Professor R. B. Welbourn (President of the Surgical Research Society) in the Chair. The following papers were presented:—

1. Effects of Expanding Intracranial Lesions on Cerebral Blood-flow: J. D. Miller, A. E. Stanek, and T. W. Langfitt (W. B. Jennett), Pennsylvania, and Department of Neurosurgery, University of Glasgow.

Maintenance of cerebral blood-flow (C.B.F.) during increased intracranial pressure (I.C.P.), produced experimentally by the infusion of cerebrospinal fluid (C.S.F.), depends on the preservation of autoregulation (A.R.) of the C.B.F. to changes of mean arterial pressure (M.A.P.) (Miller et al., 1971).

To produce a more relevant model of increased I.C.P., extradural balloons were inflated in 13 anaesthetized ventilated dogs in which the C.B.F., M.A.P., and I.C.P. were continuously measured; the arterial blood-gases and body temperature were controlled.

In all dogs A.R. was first tested by reducing the M.A.P.; after the return of M.A.P. to the control level the I.C.P. was increased by balloon inflation. The balloon was then deflated and the sequence was repeated.

With intact A.R. a fall in the M.A.P. of 23·4 ± 3·2 (S.E.) mm. Hg caused no change in the C.B.F.; a succeeding increase in the I.C.P. from 9·4 ± 1·0 to 27·2 ± 1·3 mm. Hg did not alter the C.B.F. When A.R. was impaired, an M.A.P. decrease of 23·4 ± 1·7 mm. Hg reduced the C.B.F. by 5·9 ± 0·7 ml. per min.; increasing the I.C.P. from 10·7 ± 1·5 to 29·4 ± 1·7 mm. Hg now reduced the C.B.F. by 5·1 ± 0·7 ml. per min. These changes were significant ($P < 0{\cdot}001$).

It is concluded that if the A.R. is intact in most of the brain the initial increase in I.C.P. due to an expanding intracranial mass will not reduce the total C.B.F.; if the A.R. is impaired, however, the C.B.F. will fall as soon as the I.C.P. increases.

2. Catgut—An Analysis and Immunological Study in Rabbits: I. Capperauld (H. L. Duthie), Ethicon Research Unit, Kent.

Catgut hypersensitivity has been reported, both clinically and experimentally (Hopps, 1944). An analysis of catgut coupled with immunological testing in rabbits was performed.

Plain and chromic catgut was made into solution by autoclaving at 20 lb. per in.^{2} for 24 hours. Each solubilized catgut was separated into six component fractions by high-voltage electrophoresis. Individual components were eluted and a quantitative analysis of the twenty-one amino-acids in each component was carried out. Methionine was found to be absent, and its absence was confirmed by cyanogen bromide extraction.

Immunological tests (Timpl et al., 1968) were carried out in rabbits using the extracted components of solubilized plain and chromic catgut. Samples were dissolved in water and emulsified with Freund's complete adjuvant. This was injected into rabbits on days 1, 15, and 30. Serum was obtained on day 37 and precipitation tests were performed against all the original component 'antigens'. These tests proved negative.

Hypersensitivity to plain or chromic gamma-irradiated catgut was not demonstrated in rabbits in this investigation.

3. Evaluation of Mammary Thermography: B. E. Nathan, J. I. Burn, and D. MacErlean, Royal Postgraduate Medical School, London.

Recent interest in mammary thermography has been stimulated by its potential in identifying asymptomatic disorders of the breast. We have assessed its value in the differential diagnosis of 359 patients with established mammary symptoms. Patients in whom a confident clinical diagnosis of cancer had been made were not included.

The thermograms were interpreted as being 'normal' or 'abnormal', as judged by well-defined localized areas of heat or clear inequality between the two breasts. There were 164 patients with normal thermograms and 195 (54 per cent) with abnormal thermograms.

Of the 164 patients with normal thermograms, 116 had no confirmed organic lesion, 7 had malignant disease, and 41 had benign lesions (29 per cent false negatives). Of the 195 patients with abnormal thermograms, 27 had malignant disease, 53 had benign lesions, and 115 had no confirmed organic lesion (58 per cent false positives).

Sixty-nine of the patients with benign organic lesions had localized mammary dysplasia (fibro-adenosis, cystic disease). Forty (58 per cent) of these had abnormal thermograms, the remainder being normal. Seven (20 per cent) of the 34 patients with cancer had normal thermograms.

We conclude that mammary thermography is of no practical value in the differential diagnosis of symptomatic mammary disease.

4. Skin Organisms beyond the Reach of Disinfectants: S. Selwyn (H. Ellis), Westminster Medical School, London.

Skin bacteria are regarded usually to be confined to the epidermal surface and therefore accessible to thorough disinfection (Marples, 1969). This view is based on the results of insensitive and mainly qualitative tests that can detect only those organisms that are indeed accessible to disinfectants. The fallacy is revealed by a quantitative technique using skin biopsies. Unprepared and disinfected skin areas are excised at routine operations. Bacteria are counted both by microculture of frozen sections and in suspensions from biopsies agitated in Triton X-100.

On abdominal skin mean counts of accessible organisms in 35 patients were 30,000 per cm.^{2}, reducing by 95·5 per cent after disinfection with alcoholic iodine. Other disinfectants proved less efficient. However, approximately one-fifth of the total microflora was beyond the reach of even the most vigorous sampling methods and could be seen surviving in frozen sections cultured from doubly disinfected biopsies. Moreover, skin areas rich in sebum have a 'protected' flora that is often larger than the accessible flora. Comparable findings were obtained in parallel experiments using less sensitive tape-stripping methods and studies on the restoration of numbers in occluded skin areas after disinfection.

5. A Trial of Two Different Régimes of Subcutaneous Heparin in the Prophylaxis of Deep-vein Thrombosis: L. P. LE QUESNE, J. BRAMBLE, I. C. GORDON-SMITH, D. GRUNDY, and J. NEWCOMBE, The Middlesex and Central Middlesex Hospitals, London.

Sharnoff (1966) claimed that small doses of subcutaneous heparin, insufficient to cause prolonged anticoagulation, given subcutaneously before and after operation could diminish the incidence of pulmonary embolism. Kakkar et al. (1971) produced strong evidence that such treatment significantly reduced the incidence of postoperative deep-vein thrombosis (D.V.T.).

The majority of postoperative D.V.T. start within 24 hours of operation. It may be that the major benefit from prophylactic heparin treatment accrues in the first 24-hour period after operation. To test this hypothesis and to confirm the observations of Kakkar et al. (1971) a trial is in progress on patients undergoing abdominal operations, allocated randomly to three groups: group I, no heparin (controls); group II, heparin, 5000 I.U. subcutaneously, 1 hour preoperatively and 12 and 24 hours later; group III, heparin, 5000 I.U. subcutaneously, 1 hour preoperatively, thereafter 12-hourly for 5 days. D.V.T. was detected by the ^{125}I-fibrinogen technique.

To date 114 patients have been studied. The incidence of D.V.T. was significantly less in both group III (5·9 per cent; $P < 0{\cdot}0005$) and group II (13·2 per cent; $P < 0{\cdot}005$) than in group I (42·9 per cent). No significant difference could be demonstrated between groups II and III, though the numbers so far studied are too small to allow of firm conclusions about the comparable efficacy of these two dosage régimes.

6. The Nature of the Reflux Material in Reflux Oesophagitis: E. W. GILLISON, L. M. NYHUS, and K. KUSAKARI (J. D. Hardcastle), Universities of Nottingham and Illinois.

The role of bile in reflux oesophagitis was studied in the Rhesus monkey. The oesophagogastric junction prevents reflux of gastric juice into the oesophagus in the monkey. Reflux could be produced after oesophagogastrectomy when the anastomosis was situated 2 cm. above the diaphragm.

Four groups of monkeys were studied:—

Group I had the reflux procedure alone and their progress was followed by endoscopy for 6 months.

Group II had a bile diversion procedure consisting of pylorectomy, closure of the duodenal stump, and a Roux-en-Y anastomosis. This was followed by the reflux operation 4 weeks later.

Group III had cholecystogastrostomy to produce bile contamination, followed by the reflux operation 4 weeks later.

Group IV differed from group III by having daily depot histamine in bee's wax injections (2 mg. per kg.).

About a third of the control monkeys in group I developed mild oesophagitis. Groups II, III, and IV were evaluated endoscopically at 1 and 3 months. Surviving monkeys were killed at 3 months to check the accuracy of the endoscopy.

At 3 months only 1 out of 7 monkeys in group II had oesophagitis despite daily reflux of pure gastric chyme. All the monkeys in groups III and IV showed oesophagitis, including ulceration and stricture. Administration of depot histamine did not increase the severity of oesophagitis.

The maximal acid outputs were followed in all the groups. The output was not significantly changed in group I over 6 months, but the level fell in the other three groups. Groups III and IV were almost equally achlorhydric after 3 months.

7. Insensible Water Loss in Operative Patients: C. D. BAUMBER, R. G. CLARK, and P. HOWLETT, Department of Surgery, University of Sheffield.

Large increases in insensible water loss have been reported in operative patients. In the operating theatre Coller and Maddock (1932) reported an increase of 500 per cent. In the first few postoperative days insensible water loss increased by more than 100 per cent (Paquin, 1958).

We wish to report a study of insensible water loss before and after operation measured by direct weighing and the use of tritiated water in 10 patients undergoing moderately severe abdominal operations.

The mean preoperative insensible water loss was 0·6 ml. per kg. per hr. The insensible water loss increased significantly during the period of operation to 1·65 ml. per kg. per hr. In those patients receiving intravenous fluids postoperatively the insensible water loss increased to 0·7 ml. per kg. per hr. ($P < 0{\cdot}05$). In those patients receiving restricted oral fluids alone it fell to 0·4 ml. per kg. per hr. ($P < 0{\cdot}01$).

Under modern operating conditions abdominal surgery is not accompanied by the gross increases in insensible water loss previously reported. In the postoperative period insensible water loss is a function of the state of hydration of the patient as well as of the environment.

8. The Effect of a Long-acting Anabolic Steroid on Nitrogen Balance during the Anabolic Phase of Recovery from Abdominal Surgery: D. E. F. TWEEDLE, CHRISTINE WALTON, and I. D. A. JOHNSTON, Department of Surgery, University of Newcastle upon Tyne.

The results of giving anabolic steroids to minimize the catabolic response to trauma are often difficult to interpret owing to variations in the body-weight and the nutritional intake of the patients studied. It has been suggested that anabolic hormones may exert their maximal effect during the anabolic phase of recovery when nitrogen is being retained by the body.

A study was planned to examine the effect of a long-acting anabolic steroid (nandralone decanoate, 50 mg. intramuscularly) on both the catabolic and anabolic phases of recovery from vagotomy and pyloroplasty.

Nitrogen balances were performed for 8 days after operation in 24 men. Patients were allocated randomly to four groups:—

Group I: Low calorie (13 cal. per kg. per 24 hours).
Group II: Low calorie + anabolic steroid.
Group III: High calorie (31 cal. per kg. per 24 hours).
Group IV: High calorie + anabolic steroid.

The total 8-day balances of groups II, III, and IV were improved significantly compared with that of group I ($P < 0{\cdot}05$).

Daily nitrogen balance was improved significantly during both the catabolic phase (days 1–4) and the anabolic phase (days 5–8) in group II compared with group I ($P < 0{\cdot}05$). Nitrogen balance in the high-calorie group was enhanced by anabolic steroids also, but not significantly ($P = 0{\cdot}1$).

The difference between the low-calorie groups represents a sparing of 663 g. of protein tissue in a 70-kg. male when anabolic steroids are given.

9. Haemorrhagic Shock in Afibrinogenaemic Dogs: D. H. Lewis, H. Myrvold, and P. Olsson (N. Matheson), Göteborg and Stockholm.

A double-isotope technique using ^{133}Xe and ^{131}I has been developed for the simultaneous measurement of capillary blood-flow and capillary transport in skeletal muscle. The isotope mixture is injected i.m. (0·1 ml.) and clearances are measured by external detection. Xenon clearance estimates capillary blood-flow, and iodide clearance, at the observed flow level, is an estimate of capillary transport function, calculated from Renkin's (1959) formula for permeability/surface area product (P.S.).

In haemorrhagic shock there is a deficit in capillary transport out of proportion to the existing capillary flow (Appelgren and Lewis, 1971). One possible explanation could be disseminated intravascular coagulation. To investigate this 6 dogs were made afibrinogenaemic with reptilase (Pentapharm A.G./A.B. Bofors), 3·4 mg. per kg. i.v. on 3 successive days. Haemorrhagic shock was induced by bleeding up to 60 per cent of the calculated blood volume and the animals were followed with repeated isotope clearances for up to 10 hours. After 4–5 hours all the dogs had an iodide clearance lower than that expected for the flow value obtained, that is, the same pattern of response as in animals with normal fibrinogen levels.

The results indicate that the observed alteration in the skeletal muscle microcirculation cannot be attributed to intravascular coagulation.

10. The Pathological Basis for Skeletal Scintigraphy: C. S. B. Galasko, Nuffield Orthopaedic Centre, Oxford.

It has been shown previously that skeletal scintigraphy, using ^{18}Fl and the gamma camera, is useful both for the early detection of skeletal metastases (Galasko, 1969) and for the assessment of the response of these metastases to therapy (Galasko and Doyle, 1970). The underlying pathological changes which allow us to use isotopes to study these lesions were investigated.

Ninety-six histological sections obtained at autopsy from 20 patients who had died from malignant disease were examined for the type of bone and the amount of osteoid which was present. Where metastases were present, 27·8 per cent of the total bone was osteoid; in the absence of metastases only 5·2 per cent was osteoid tissue. In the presence of tumour 36·3 per cent of the bone consisted of immature woven bone; where no tumour was present, only 1·9 per cent was woven bone.

Tumour-cell suspensions of the VX2 carcinoma were injected into the tibiae and ilia of experimental rabbits. Autoradiographs obtained after the injection of ^{47}Ca and ^{18}Fl showed that the isotope was localized in the new bone which was laid down in response to the tumour. Where the VX2 carcinoma was successfully treated the remaining bone lost its osteoid reaction and its increased avidity for 'bone-seeking' isotopes.

These studies suggest that the clinical use of isotopes in skeletal metastases depends on the osteoid reaction which the tumour invokes in the invaded bone.

11. The Quantitative Colour T.V. Image Analyser—A New Method of Assessing Bone Density: R. A. Dickson, F. Paice, and J. S. Calnan, Royal Postgraduate Medical School, London.

The progress of osteoporosis in rheumatoid disease has been studied by measuring cortical width (Virtama et al., 1968). We have followed its course with a television camera, a colour monitor, and an electronic counter.

The quantitative colour T.V. image analyser, developed by the M.R.C. Cyclotron Unit, converts seven shades of grey in an optical image into seven characteristic colours. Furthermore the image can be analysed numerically in terms of total area, number of intercepts, and number of discrete areas for each colour. The serial radiographs of 20 rheumatoid hands were analysed in this manner, and for each digit the densities of three fields were examined: the metacarpophalangeal joint, the middle two-fourths of the metacarpal, and the middle two-fourths of the proximal phalanx.

Metacarpal density was always greater than that of the corresponding joints and proximal phalanges, irrespective of the stage of the disease. Both bones showed a continuous loss of density at a rate of up to 17 per cent per year. Approximately 75 per cent of the joints showed a similar continuous density loss, but 25 per cent showed increased density and this occurred in joints that had collapsed, subluxed, or grown new bone. Losses in the three fields examined did not appear to be interrelated.

12. Cellular Immunity to Tumour Factors in Human Breast Carcinoma: D. J. Evans, Gillian Simpson, A. Campos, and J. I. Burn, Royal Postgraduate Medical School, London.

The existence of a host defence response in human breast carcinoma has been a matter of controversy.

We have searched for a lymphocyte-mediated response to tumour factors in patients with early breast carcinoma.

In patients with a cellular immunity to an antigen the exposure of the patients' lymphocytes to the antigen results in a small percentage of them undergoing blast transformation. We exposed patients' lymphocytes to homogenates of their own tumours as putative antigens using standard methods of lymphocyte culture and of assessment of response. With this technique twenty breast carcinomas tested showed an entirely negative response, as did a variety of benign lesions and extracts of muscle.

Four tumours gave a positive response. Three of these were medullary carcinomas with a lymphoid stroma. The fourth was an unusual tumour of the type designated adeno-osteoclastoma by Willis (1967). Extracts from these tumours did not produce transformation in the lymphocytes of normal controls.

These preliminary results suggest that there is no lymphocyte-mediated response to the majority of breast carcinomas but that in some carcinomas lymphocytes in the stroma are reacting against tumour antigens.

Willis, R. A. (1967), *Pathology of Tumours*, 4th ed., p. 216. London: Butterworths.

13. The Morbidity of Mastectomy: M. Maureen Roberts, Isobel G. Furnival, and A. P. M. Forrest, Department of Clinical Surgery, University of Edinburgh, and Department of Diagnostic Radiology, The Welsh National School of Medicine, Cardiff.

Few studies of the morbidity of breast surgery have been performed (Eisenberg and Goldenberg, 1969). This we have attempted to assess in 112 women. Eighty-six were included in a randomized trial comparing conservative and radical methods of treatment. Patients in both groups also received radiotherapy if the removed axillary nodes were positive. A further 26 patients had an elective standard Halsted radical mastectomy.

Morbidity was assessed by interview at home, by completion of a questionnaire, and by clinical examination. Particular attention was paid to the social and psychological effects of the operation and to objective measurements of arm oedema and arm movements.

Fifty per cent of all patients admitted anxiety or depression, with no significant variation between the treatment groups. Thirty-six per cent complained of phantom breast sensations and this was most common in premenopausal women. Arm oedema of more than 2 cm. occurred in 15 per cent of women treated by simple mastectomy alone and rose significantly to 46 per cent in those who had had axillary clearance. Arm movement was normal in those treated by simple mastectomy alone, but the incidence of restriction of movement increased significantly (25 per cent) when the axilla had been cleared surgically.

It is concluded that there is important psychological and physical morbidity associated with all operations for primary breast cancer, and that physical morbidity increases with the extent of treatment.

14. Comparison of the Inhibitory Effects of Lymphocytes from Patients with and without Cancer on the Growth of Human Tumour Cells in Culture: C. W. JAMIESON, St. Mary's Hospital, London.

Apparently unsensitized murine lymphocytes may inhibit the growth of tumour cells in culture (Jamieson and Wallace, 1970). The effect of human lymphocytes on allogenic tumour cells in culture was studied in a large group of patients. Lymphocytes from 90 patients with a variety of cancer and 72 control patients were cultured with HeLa cells using the method of Jamieson et al. (1969). Their inhibitory effect on the growth of these tumour cells in culture was measured over 48 hours.

A great variation was found to exist between patients but the results were reproducible in an individual. The lymphocytes from patients with cancer had a mean inhibitory effect on the growth of HeLa cells which was significantly greater than the mean effect of lymphocytes from patients without cancer ($P < 0{\cdot}001$). This effect was not related to an effect of the serum or general lymphocyte reactivity when measured by lymphocyte transformation studies.

It is not claimed that this difference is related necessarily to tumour-associated antigens, but the increased responsiveness of patients with cancer does not support suggestions that such patients have impaired cell-bound immunity.

15. The Vascular Dissemination of Tumour Cells by Manipulation of an Artificially Produced Bowel Tumour in the Rat: D. G. JAGELMAN (H. Ellis), Westminster Hospital, London.

The spread of tumour cells at operation owing to manipulation has been realized for some years but little importance seems to have been attached to it. An experiment was designed to demonstrate whether manipulation of a malignant bowel tumour liberated cancer cells into the circulation.

The Walker 256 tumour was implanted by means of a gelatin capsule into the invaginated caecum in 30 animals. Two weeks following implantation the artificially produced bowel tumour was subjected to trauma at a second laparotomy. Portal vein blood samples were taken before and after trauma to the tumour. The blood samples were spun down and the buffy coat removed. Smears were made on standard laboratory slides and stained with acridine orange to differentiate RNA and DNA. By means of this stain it was possible to differentiate tumour cells from normal blood elements.

In the pre-trauma blood samples 3 out of 30 animals showed malignant cells in the portal venous blood, whereas after trauma 19 blood samples were positive.

It is concluded that after trauma or manipulation of a malignant tumour in this experimental model an increased number of cancer cells are liberated into the blood-stream.

16. Treatment of Patients with Hypotonic Bladder by Radio-implant: S. ALEXANDER and D. ROWAN, Royal Infirmary, Glasgow.

Detrusor hypotonicity associated with difficulty in voiding and high residual and overflow incontinence were evaluated by recording transvesical pressure during 50-ml. filling increments and during attempted micturition.

The radio-implant consisted of two pairs of stainless-steel loop electrodes sited on the bladder fundus connected directly to an implanted receiver stimulator linked by radio-signal to an external transmitter delivering rectangular pulses with a duration of 1 millisecond, a frequency of 20 pulses per second, and an amplitude of 5–10 volts (Bradley et al., 1963; Hald et al., 1967).

The neurological diagnosis of the 8 patients in this series was as follows: multiple sclerosis, 3; stroke, 1; traumatic paraplegia, 1; cervical and lumbar myelopathy, 1; spina bifida, 1; no neurological lesion, 1—or: upper motor neuron, 6; lower motor neuron, 1; normal, 1.

At the operative insertion of the implant the rise in vesical pressure evoked by stimulation was found to be small (2–14 cm. water), whereas application of the stimulus several weeks later evoked a significantly larger rise in vesical pressure (25–60 cm. water).

Four of the 6 patients with upper motor neuron lesions had improved ability to void and 2 of these were restored to continence. The patient with the lower motor neuron lesion had a much improved ability to void and partial restoration of continence. The patient without neurological disease derived no benefit and this was probably related to an abnormal bladder-neck.

17. Evaluation of Prostatic Disease by Ultrasound: S. S. MILLER, A. D. CHRISTIE, and G. SMITH, Department of Surgery, University of Aberdeen.

Accurate assessment of prostatic size is of considerable value to the surgeon. With this information it is possible to determine the correct operation for any particular patient whether by open or endoscopic approach.

A new method of evaluation of prostatic enlargement is described, utilizing an ultrasonic scanning technique, which is simple and rapidly performed with no discomfort to the patient.

The benign prostate appears as a smooth, homogeneous structure, approximating to a sphere in outline. Serial transverse sections are taken at different levels to estimate the outline, the largest section is selected, and the volume is calculated from the measured radius.

Twelve patients with prostatic disease were studied using this technique and a comparison was made with clinical and radiographic methods of estimation of prostatic volume. This ultrasonic technique was shown to be superior and to give an extremely accurate estimate of prostatic size as measured at operation.

In the 2 malignant cases studied the prostate appeared as a non-homogeneous structure with an irregular outline. In the case of prostatic cancer ultrasound may prove to be of diagnostic value. It may also help in assessing the results of endocrine treatment.

18. Antibiotics, Postoperative Infection, and Deep-vein Thrombosis: A. N. Nicolaides, V. V. Kakkar, E. S. Field, and J. Spindler, King's College Hospital, London.

It has been suggested that infection may be an important factor in the aetiology of deep-vein thrombosis (D.V.T.), particularly by wall-deficient bacteria ('L' forms) which are often induced by antibiotics (penicillin) with an action against cell-wall formation (Altemeier et al., 1969).

The incidence of postoperative D.V.T. has been studied in 424 surgical patients, using the ^{125}I-fibrinogen test, and related to the administration of antibiotics and postoperative infection. In 310 patients who received no antibiotics and who had no evidence of postoperative infection the incidence of D.V.T. was 20·3 per cent. In 72 patients who were operated on under ampicillin cover the incidence was 32 per cent. This difference was significant ($P < 0{\cdot}02$). In 42 patients who developed postoperative infection and were treated with ampicillin the incidence was 54·7 per cent. This was also significant ($P < 0{\cdot}0001$) when compared with the control group. The higher incidence in this group of patients was due to an increase in the number of thrombi occurring between the third and eighth postoperative days.

The results show that patients who develop postoperative infection and those who receive prophylactic antibiotics have a high incidence of deep-vein thrombosis.

19. The Effect of Treatment on Postural Blood-flow Changes in Limbs with Varicose Veins: G. Patrikios and O. Murphy (W. G. Fegan), Sir Patrick Dun's Hospital, Dublin.

Change of posture from horizontal to erect results in considerable reduction in blood-flow in the lower limbs. Femoral vein oxygen saturation during passive tilting has been used as an index of blood-flow changes in the lower limb. Seven normal volunteers and 7 patients with varicose veins were examined before and after treatment (compression sclerotherapy) (Fegan, 1963).

Measurements were made in the horizontal and 60° head-up position. All changes in blood-flow were expressed as a percentage of the average in the normal controls in the horizontal position (100 per cent; range 74–114 per cent). After tilting the mean flow in normal limbs was 59 per cent (range 49–72 per cent). In limbs with varicose veins before treatment the mean blood-flow in the horizontal position was 130 per cent (range 100–195 per cent) and after tilting 77 per cent (range 56–98 per cent). After treatment the blood-flow in these limbs was 144 per cent (range 120–195 per cent) in the horizontal position and 62 per cent (range 46–83 per cent) in the tilted position.

These findings indicate that blood-flow in limbs with varicose veins is higher than that in normal limbs in both the horizontal and tilted positions, and after treatment the flow in the horizontal position remains high while in the tilted position it is reduced to near-normal levels. It is postulated that one of the effects of treatment is to enhance the reflex reduction in blood-flow in the lower limb on assuming the upright position (Gaskell and Burton, 1963).

20. A Study of Normal and Abnormal Femoral Venous Flow Velocity using a Directional Doppler: J. D. Lewis, J. T. Hobbs, and S. T. Yao, Surgical Unit, St. Mary's Hospital, and Wayne State University, Detroit.

As an aid to the differential diagnosis of the swollen limb, femoral venous flow velocity was monitored with a directional doppler (Parkes models 805 and 806) in 50 patients. Thirty-eight patients were diagnosed as having iliac vein occlusion; a 94 per cent correlation with radiology. During this investigation it became apparent that in normal subjects in the horizontal position the femoral venous signal shows a phasic change with respiration, rising on expiration and falling to a minimum on inspiration. This phenomenon has been described (Strandness et al., 1967; Sigel et al., 1968) but never presented before as being the reverse of that occurring in the subclavian vein.

Simultaneous recordings from the femoral and subclavian veins, monitoring respiratory movements with a strain gauge, were made with the patient on a tilt table. Regardless of posture the subclavian venous signal tended to remain in the same phase with respiration. The femoral signal, however, became reversed at about 45° (reversed Trendelenburg), falling to a minimum on expiration and increasing on inspiration. In the erect position at rest flow occurred only on deep inspiration. In trained subjects phasic change with respiration could be produced by altering the mode of respiration from thoracic to abdominal regardless of posture.

In incompetence in the upright position excessive back-flow may be demonstrated on quiet respiration alone and enhanced by a Valsalva manœuvre. The Trendelenburg position resulted in a continuous signal over the femoral vein. Following paralysis under anaesthesia a continuous signal also occurred which was interrupted by the inspiratory phase of positive-pressure ventilation.

Patient position is important in interpreting femoral venous signals, and variations of posture may improve diagnostic accuracy.

21. A Comparison of Flow Patterns in the Long Saphenous Vein of Normal and Abnormal Subjects using an Atraumatic Technique: A. L. Kline and P. Byrne (W. G. Fegan), Sir Patrick Dun's Hospital, Dublin.

Flow patterns were studied in the long saphenous vein in asymptomatic patients with gross varicosity of the long saphenous vein, in patients with minimal varicose veins but gross signs and symptoms of calf pump dysfunction, and in control subjects.

All 20 patients with varices had valvular incompetence in the long saphenous system indicated by the presence of retrograde flow seen during deep breathing and the Valsalva manœuvre. This was not seen in normal people, indicating valvular competence.

Ambulatory subjects studied on a treadmill produced three reproducible and fundamentally different patterns.

Normal subjects produced an initial peak of forward flow as walking began and then no net flow during rhythmic walking or when walking stopped.

The first group of patients (no symptoms) showed a pattern of rapid turbulent retrograde flow during walking, and when walking stopped this increased in velocity and was prolonged for an average of 10 seconds (range 7–14 seconds). In the second group (with symptoms) there was less retrograde flow down the long saphenous vein while walking and when walking stopped the flow lasted an average of 2·5 seconds (range 1–4 seconds).

In patients with varicose veins retrograde flow down the long saphenous vein depends on the functional ability of the muscle pump to empty the superficial veins. The more efficient the pumps, the greater is the retrograde flow during and immediately after walking.

22. Soleal Veins and Stasis during Operation: A. N. Nicolaides, V. V. Kakkar, E. S. Field, and J. Spindler, King's College Hospital, London.

It has been demonstrated by using a venographic technique that there is considerable stasis in the soleal veins of conscious patients (Nicolaides et al., 1971b). However, this technique cannot be used during surgery.

A new technique has been developed to assess stasis during operation. Thirty ml. of sodium diatrizoate (45 per cent) mixed with 10 μc. of ^{125}I-fibrinogen were injected into a vein on the dorsum of the foot and directed into the tibial and soleal veins using pneumatic cuffs (Nicolaides et al., 1971a). The time taken by the contrast medium and the radioactive fibrinogen to disappear from the tibial and soleal veins of 8 conscious patients was determined simultaneously by intermittent fluoroscopy and scintillation counting. It has been shown that the clearance of the radioactive fibrinogen is an accurate method of assessing stasis without fluoroscopy.

This technique was used in another 8 patients just before and during operation. In these the mean clearance time of ^{125}I-fibrinogen in the tibial veins before and during operation was the same (1 minute). In the soleal veins it was 4·5 minutes before and 8·5 minutes during operation ($P < 0{\cdot}05$). These results indicate that stasis in the soleal veins is increased markedly during operation and may explain the high incidence of thrombi starting there.

23. The Value of Cinephlebography in detecting Incompetent Venous Valves in the Post-phlebitic State: E. S. Field, V. V. Kakkar, G. Stephenson, and A. N. Nicolaides, King's College Hospital, London.

Ligation of incompetent perforators of the calf is not always successful in preventing recurrent varicose ulceration. Popliteal vein ligation (deTakats, 1951) and superficial femoral vein ligation (Linton, 1953) have been employed with similar results. The implication is that in any patient there might be more than one site of valvular incompetence leading to superficial venous hypertension.

Ascending functional cinephlebography and venous pressure measurement have been used in 42 limbs to examine calf perforators and deep-vein valvular function. In 27 normal or mildly post-phlebitic limbs 12 with incompetent perforators were found, and 4 limbs with incompetent popliteal valves and 5 with absent valves were also discovered. In 15 limbs with persistent ulcers or healed ulcers incompetent perforators were demonstrated in all 15 and non-functioning or absent popliteal valves in 14.

All patients with venous hypertension had incompetent perforators. In addition, the more severely afflicted had absent popliteal valves. Preoperative cinephlebography will distinguish these groups

24. The Effect of Pregnancy on Normal and Varicose Veins: Mary Fogarty and P. J. Byrne (W. G. Fegan), Sir Patrick Dun's Hospital, Dublin.

Increased venous distensibility in the calf has been reported during pregnancy (Goodrich and Wood, 1964) and also associated with varicose veins (Eiriksson and Dahn, 1968).

Four groups of patients were studied (15 patients in each): (1) non-pregnant without venous disease; (2) pregnant without venous disease; (3) non-pregnant with varicose veins; (4) and pregnant with varicose veins.

Using a water-filled plethysmograph, venous volume was measured at effective transmural pressures of 10, 20, and 40 mm. Hg., and elasticity of the vein was measured by recording the volume change on decreasing the effective transmural pressure from 40 to 20 mm. Hg.

It was found that pregnancy was associated with a 20 per cent increase in venous volume ($P < 0{\cdot}05$) in both the varicose and non-varicose groups. The two groups with varicose veins were similar and showed a wide range of elasticity, many falling in the normal range but most having increased elasticity. The pregnant patients without varicose veins had normal venous elasticity.

It is concluded that the increased venous distensibility during pregnancy is due to the increased blood-volume and that this, associated with varicose veins, is due to a weakness of the vein wall. Pregnancy does not increase the elasticity of the vein wall in normal patients or in those with varicose veins.

25. The Detection of Incompetent Perforating Veins: J. Noble and A. A. Gunn (C. V. Ruckley), Edinburgh.

Methods advocated for the detection of incompetent perforating veins include clinical examination, thermography (Patil et al., 1970), and fluorescein injection (Chilvers and Thomas, 1970). This study aimed to determine the most effective method.

In a controlled series 44 legs were examined using standardized techniques. The legs were marked for each method by a different observer who was unaware of previous markings.

Each marked site was explored at operation and the results were recorded on standardized diagrams which were analysed on punch cards. Incompetent perforators were found at 135 of the 198 sites explored (66 per cent), there being 34 per cent false positives. Sixty-two per cent of the 135 perforators were demonstrated by thermography alone or together with another method; similarly 54 per cent were demonstrated by clinical examination, and 47 per cent by fluoroscopy. Although simple and free from adverse reactions fluoroscopy is only useful below the knee.

Diagnostic success rates were lower than in the series of Patil et al. (1970) or Chilvers and Thomas (1970). Conversely, our average yield of 3·1 incompetent perforators per leg at operation was much higher. Thus, claims as to diagnostic accuracy carry little weight since the true number of incompetent perforators remains unknown.

26. An Insulin Infusion Test of Gastric Secretion: D. C. Carter, J. R. Kirkpatrick, and R. R. Dozois, Royal Infirmary, Edinburgh.

The conventional insulin test is a potentially dangerous procedure (Read and Docherty, 1970), and its interpretation is hindered by variations in the timing and magnitude of the peak acid response (Baron, 1970). A continuous infusion test has been developed to produce a steady-state acid secretion with minimum insulin administration.

Dose–response curves were constructed in 5 healthy subjects relating insulin dosage to acid output and concentration, fall in blood-glucose, and hypoglycaemic symptoms. Doses investigated ranged from 0·025 to 0·10 I.U. per kg. per hour. The highest secretory response compatible with minimal side-effects was achieved with a dose of 0·04 I.U. per kg. per hr.

The typical secretory response to this dose in 11 healthy subjects was a gradual fall in blood-glucose during the first 60 minutes of infusion to a level which remained constant for the remaining 120 minutes of the test (mean level 21·9 ± 9·43 mg. per cent). This hypoglycaemia was accompanied by a plateau of acid output attained within 90 minutes of commencing infusion.

It is concluded that the test is safe at the dose level described, is accompanied by minimal side-effects, and may be less difficult to interpret than conventional insulin tests. Its application to vagotomized subjects is being explored.

27. Relationships between Serum Gastrin and Gastric Acid Secretion during Insulin Hypoglycaemia in Normal Subjects and in Patients with Duodenal Ulcer: D. J. Cowley, J. H. Baron, J. Hansky, and M. G. Korman, Royal Postgraduate Medical School, London, and Monash University, Melbourne.

Insulin hypoglycaemia produces an increase in serum gastrin levels, which is greater in patients with duodenal ulcer than in normal subjects (Hansky et al., 1971). The role of this released gastrin in stimulating gastric secretion was examined.

Serum gastrin was measured in normal subjects and n patients with duodenal ulcer at intervals after the njection of insulin, 0·2 U. per kg. i.v., with and without concomitant gastric aspiration, and also during intragastric neutralization with sodium bicarbonate. The radio-immunoassay of gastrin used antibodies to synthetic human gastrin I.

No significant relationship was found between peak serum gastrin and peak acid output after insulin. Serum gastrin was correlated inversely with blood-glucose. The timing of peak serum gastrin and lowest blood-glucose coincided, but peak acid output lagged behind, occurring n the period 15–30 minutes later. The rise of serum gastrin after insulin during gastric aspiration almost discriminated completely between patients with duodenal ulcer and normal subjects: discrimination was absolute when serum gastrin was measured during hypoglycaemia with simultaneous intragastric neutralization.

The results suggest that vagally released gastrin may prime parietal cells for direct cholinergic stimulation, hat there is an increased G-cell mass with or without an increased parietal cell mass in patients with duodenal ulcer, and that measurement of hypoglycaemia-stimulated serum gastrin during intragastric neutralization may prove a discriminating test for the duodenal ulcer diathesis.

28. Gastric Acid Secretion and Changes in Blood-glucose after Insulin in another Healthy Man: D. J. Cowley and J. H. Baron, Royal Postgraduate Medical School, London.

The gastric acid response to insulin is not an 'all-or-none' phenomenon; it is dose-dependent (Baron, 1970). In one healthy man (Baron, 1970) insulin hypoglycaemia provided a quantitative glycopenic stimulus producing a quantitative vagal acid response, but such relationships were not found by others (Isenberg et al., 1969). Another healthy man has therefore been tested with eight doses of insulin, 0·003–0·4 U. per kg. In each test gastric secretion was collected in 15-minute periods for 1 hour before and 2 hours after the intravenous injection of insulin.

There was a correlation between peak acid output after insulin (P.A.O.$_I$) and log dose, with maximal secretion after 0·05 U. per kg. There was a similar, and parallel, linear correlation between the percentage decrease in blood-glucose and log dose of insulin. After doses greater than 0·05 U. per kg. blood-glucose decreased still further, but P.A.O.$_I$ also decreased. The best fit for correlation of P.A.O.$_I$ and lowest blood-glucose was a quadratic curve. In this man insulin-stimulated gastric acid increased as blood-glucose decreased to a blood-glucose level of 20 mg. per 100 ml., below which acid output was inhibited.

The results strongly support the postulated insulin hypoglycaemia/acid-output relationships (Baron, 1970). Although 0·2 U. per kg. may be an optimum dose of insulin no specific dose can be guaranteed to achieve that degree of hypoglycaemia (? 20–25 mg. per 100 ml.) which provides maximum vagally stimulated acid output.

29. The Effect of Propranolol on Acid and Pepsin Secretion in Cats: W. L. Bruckner and C. Muller-Rabe, University of Munich, Germany.

The role of the sympathetic nervous system in affecting gastric secretion has not been investigated as thoroughly as that of the parasympathetic nervous system. Literature on the sympathetic system, though controversial, shows antisecretory effects (Code, 1951).

Attempts were made to investigate further the nature of this adrenergic inhibition. A classic β-receptor-blocking agent was tested. Propranolol (Dociton) was injected in subcutaneous doses of 90 mg. per kg. The spontaneous and the histamine-induced gastric secretions were studied in 6 cats with gastric fistulas.

Propranolol reduced significantly the volume (24 per cent) and the pepsin output (60 per cent) of spontaneous gastric secretion, whereas the output of acid was increased markedly (150 per cent).

Propranolol increased the volume (25 per cent) and the output of acid (36 per cent) of histamine-induced secretion and reduced the output of pepsin (20 per cent).

On the basis of these experiments it appears that acid and pepsin secretions are related to different receptors.

30. A Study of Pathways for the Co-ordination between Myoelectric Activities of the Antrum and Duodenum: B. S. Bedi and C. F. Code, Western Infirmary Glasgow, and the Mayo Clinic, Rochester, Minnesota.

There is good evidence of co-ordination between the motor activities of the gastric antrum and those of the duodenum (Thomas and Crider, 1935). The pathway of co-ordination between the antral and duodenal electric activities was investigated.

Myoelectric activities from the antrum and duodenum were recorded using chronically implanted silver–silver-chloride electrodes in fully conscious dogs. Recordings were made after the ingestion of a meat meal or the instillation of saline into the stomach. After a controlled study the gastroduodenal junction was transected and the continuity restored by anastomosis of either the mucosa alone (3 dogs) or the gastric and duodenal walls (3 dogs). A method of cross-correlation (Allen et al., 1964) was applied to the electric recordings obtained before and after the division of the gastroduodenal junction. A relationship between the antral pace-setter potentials and the occurrence of duodenal action potential was observed in the control studies. This relationship was lost after transection of the gastroduodenal junction. Gastric emptying time and radiological examination of these dogs showed no obstruction at the site of transection. The correlation between the myoelectric activities of the antrum and duodenum is accomplished by impulses transmitted via the neural elements in the wall of the gastroduodenal junction.

31. Histological Changes in the Enteric Plexuses following Truncal Vagotomy in Pigs:

A. J. B. MISSEN (G. W. Taylor), St. Bartholomew's Hospital, London.

In contrast to the physiological sequelae of truncal vagotomy the degenerative changes in the distal fibres of the vagus have been studied but little, and then mainly in small laboratory animals. The low mortality from vagotomy performed for duodenal ulceration in man makes it difficult to obtain material for examination. This paper reports the histological changes seen in the enteric plexuses following bilateral truncal vagotomy in pigs in the course of a liver-transplant programme.

The plexuses were examined by a modification of Schofield's silver-impregnation technique in specimens of stomach and small bowel taken from vagotomized pigs at intervals varying from 36 hours to 3 weeks after operation. Corresponding tissues from normal (donor) pigs were used as controls.

This study demonstrated that degenerative changes taking the form of axonal swellings and fragmentation of the terminal branches of efferent vagal fibres occurred throughout the myenteric and submucous plexuses of the stomach and small bowel. These changes were detectable 36 hours after vagotomy and persisted throughout the period of study. The changes were most marked in the small bowel, where the large number of vagal terminations demonstrated by the degenerative process implied a far greater degree of branching in vagal efferents than had been recognized previously.

32. Gall-bladder Size and Emptying after Truncal, Selective, and Highly Selective Vagotomy in Man:

G. PARKIN and D. JOHNSTON, Department of Surgery, University of Leeds.

After vagotomy the gall-bladder may dilate (Rudick and Hutchison, 1965), the bile-flow may decrease, and the bile may become more lithopenic in composition. Although truncal vagotomy (T.V.) is incriminated usually, the work of Tinker and Cox (1969) suggests that bilateral selective vagotomy (S.V.) may also denervate the gall-bladder.

The resting volume of the gall-bladder was measured by oral cholecystography, and its contraction in the 90 minutes after a normal meal was also determined (with barium to the time of entry into the duodenum) in 1 patients with duodenal ulcer before operation (D.U.) an in patients more than 1 year after T.V. + P. (pyloroplasty (13), S.V. + P. (4), and highly selective vagotomy withou a drainage procedure (H.S.V.) (10). The groups wer matched for sex, age, weight, maximal acid output, insuli negativity, and Visick status.

Mean resting volumes of the gall-bladder in ml. ± 1 S.E were: D.U., 27·6 ± 1·6; T.V. + P., 44·5 ± 4·7; S.V. + P. 41·2; H.S.V., 26·1 ± 2·0. After a meal the gall-bladde contracted by: D.U., 54 per cent; T.V., 79 per cent H.S.V., 52 per cent. The results confirm that the gall-bladder is significantly ($P < 0·2$) dilated after T.V. Afte H.S.V. it is normal. After S.V. the gall-bladder wa dilated in 3 out of 4 patients. The rate and degree o contraction after a meal were similar in all four groups

Highly selective vagotomy without drainage maintain normal biliary function.

33. The Comparison of Gall-bladder Bile i patients with Gall-stones and in Patients wit Duodenal Ulcer before and after Vagotomy

D. C. SMITH, J. N. CROOK, R. A. MCALLISTER, an C. MACKAY, Western Infirmary, Glasgow.

Gall-stones are reported to occur more commonly i vagotomized patients (Fletcher and Clark, 1968). Gall-bladder bile was obtained from 9 patients with cholestero gall-stones and from 10 patients with duodenal ulcer b duodenal aspiration following cholecystokinin administration. Further specimens were obtained from the ulce patients 1 week after vagotomy and drainage. The completeness of vagotomy was confirmed by an insuli test. The concentrations of bile-salt, cholesterol, an phospholipid were estimated and the relative compositio of each sample was calculated and plotted on triangula co-ordinates (Admirand and Small, 1968).

The relative composition of bile-flow from both gall-stone and ulcer patients lay well within the zone o cholesterol solubility on the phase diagram, although th former lay closer to the limits of solubility. The relativ amount of cholesterol was significantly greater in bil from gall-stone patients compared with that from ulce patients. Vagotomy produced no significant alteration i the relative composition of gall-bladder bile in th immediate postoperative period. If vagotomy has lithogenic action it does not appear to be mediated b altering the relative composition of bile in the immediat postoperative period.

Patients	*Bile-salt* (per cent)	*Cholesterol* (per cent)	*Phospholipid* (per cent)
With gall-stones	69·4 ± 6·7	8·8 ± 3·1	21·8 ± 4·0
With duodenal ulcer			
Before operation	72·6 ± 6·2	4·9 ± 0·9	22·5 ± 5·9
After operation	75·0 ± 4·9	5·3 ± 1·3	19·7 ± 4·0

34. Trickle Perfusion for Organ Preservation

R. Y. CALNE, D. C. DUNN, R. GAJO-REVERO, E. J HADJIYANNAKIS, and A. J. ROBSON, Department o Surgery, University of Cambridge.

The two most successful methods of preserving canin kidneys are those described by Belzer et al. (1967) an Collins et al. (1969). The Collins system has the advantag of extreme simplicity. The main disadvantage is that t obtain the best results it is essential that there should b no warm ischaemic damage to the kidney.

The Belzer system allows a longer period of preservation at 10° C. with better initial function on transplantation after 24 hours and is successful with kidneys that have suffered ischaemic damage. The apparatus, however, is complicated, expensive, and difficult to transport.

A simple perfusion system is described here for hypothermic organ preservation in which the perfusate passes through the organ and is then discarded. This has permitted 24–26-hour preservation of canine kidneys and 11-hour preservation of a porcine liver, with immediate life-sustaining function of the preserved organs after transplantation. Analysis of the perfusate compared with the effluent permits the metabolism of the organ to be studied at low temperatures and appropriate adjustments can be made to improve the preservation.

35. Seventy-two-hour Preservation of Canine Kidneys: M. E. SNELL, W. I. HOPKINSON, and R. R. SHEPHERD (J. R. Kenyon), St. Mary's Hospital, London, and Vickers Research Establishment, Sunninghill.

Canine kidneys were stored for 72 hours in a Vickers THS/4 unit. The conditions of storage were hypothermia (5° C.), hyperbaric oxygen (4 A.T.A.), and pulsatile perfusion at a rate of 2 ml. per minute. The perfusate was recirculated and passed through a 25-μ filter. The perfusate was a modified Collins's solution (Collins et al., 1969) with magnesium sulphate omitted and dextran 40 and chlorpromazine added.

Immediately prior to nephrectomy phenoxybenzamine, 2·5 mg., was injected into the renal artery. The excised kidney was flushed with chilled perfusate and then stored under the conditions described. Perfusion was discontinued after 4 hours.

At the end of the period of storage the kidneys were reimplanted as autografts into the iliac fossa following a further injection of phenoxybenzamine, 2·5 mg., into the renal artery. Immediate contralateral nephrectomy was performed.

Six out of 7 dogs survived and in all survivors the blood-urea nitrogen and serum creatinine had returned to normal limits when they were killed.

COLLINS, G. M., BRAVO-SHUGARMAN, M., and TERASAKI, P. I. (1969), *Lancet*, **2**, 1219.

36. Experimental Preservation of Ischaemically Injured Kidneys by Ice Storage and Subsequent Perfusion: R. W. G. JOHNSON, MARILYN ANDERSON, R. M. R. TAYLOR, and JOHN SWINNEY, Department of Surgery, University of Newcastle upon Tyne.

Continuous perfusion is a better method for preserving kidneys damaged by warm ischaemia than is simple ice storage (Johnson et al., 1971). Facilities for continuous perfusion, however, are not always immediately available. It may therefore be necessary to store kidneys in ice for short periods until perfusion can be commenced.

A study was planned to evaluate the practicability of combining the two preservation methods.

Canine kidneys were subjected to 30 minutes' warm ischaemia and then stored in ice for up to 6 hours. After ice storage the kidneys were perfused continuously for 24 hours with oxygenated plasma-protein fraction at 6° C. Preserved kidneys were replaced as autografts and the contralateral kidneys were removed. Results were assessed by postoperative serum creatinine levels. Three kidneys out of 4 functioned immediately after 3 hours' ice storage and 21 hours' perfusion.

Eight kidneys were preserved for 6 hours in ice and then perfused for 18 hours. In 3 dogs immediate contralateral nephrectomy resulted in death. The other 5 kidneys functioned immediately.

Changes in perfusion pressure, kidney weight, and perfusate lactic dehydrogenase of the 4 failures were compared with the 8 successes. It was not possible to predict which kidneys would not function immediately. Histological examination suggested that 3 of the 4 failures would probably have survived if contralateral nephrectomy had been delayed.

Combined methods of storage are therefore possible, but with ischaemically injured kidneys the duration of simple ice storage is critical; when this period exceeds 6 hours return of function will be delayed.

JOHNSON, R. W. G., MORLEY, A., SWINNEY, J., and TAYLOR, R. M. R. (1971), *Br. J. Surg.*, **58**, 299.

37. Liver Storage: 12-hour Preservation of the Pig Liver: H. SPILG, ROSEMARY HICKMAN, C. J. UYS, S. J. SAUNDERS, and J. TERBLANCHE, Cape Town, South Africa.

A prerequisite for a clinical liver-transplantation programme is a successful method of storage. Dog livers cannot be preserved beyond 2–3 hours by simple methods, and complex techniques are infrequently successful beyond 10 hours.

In this study simple hypothermia using various preserving solutions and the role of hyperbaric oxygen to store pig livers were investigated. Success of storage was assessed by orthotopic transplantation. Four basic preserving solutions were tested for varying periods at different temperatures: (1) a balanced salt solution, (2) plasma, (3) plasma with cell-membrane-stabilizing drugs, and (4) a solution similar in cation composition to intracellular fluid.

Consistently successful results following 6–8 hours' storage were obtained in 10 pigs using solution 2 (plasma) at 8–12° C. Reduction of temperature to 2–5° C., or the use of solutions 1, 3, or 4, failed to extend preservation beyond this period.

When hyperbaric oxygen at 3 A.T.A. was combined with simple hypothermic immersion storage in a plasma-preserving solution at 2–5° C, storage was successfully extended to 12 hours in 5 pigs.

The results of liver storage achieved by these simple methods should have wider clinical application than the currently used complex techniques.

38. Pig-liver Perfusion: A Comparison of Function with Porcine or Human Blood, with and without Hypothermia: J. WINCH, J. KOLTHAMMER, R. HAGUE, and R. WILLIAMS (J. G. Murray), King's College Hospital, London.

Before using pig-liver perfusion to treat a patient in hepatic failure the liver is cleared of porcine blood by flushing the portal vein with a cooled, balanced, electrolyte solution. Cooling is said to be essential for protection against ischaemia.

We present the results of 36 4-hour perfusions of isolated pig livers divided into four groups. Groups A and B were cooled to 7° C. during flushing and were subsequently rewarmed to 38° C. before perfusion on circuit (Winch, 1971). This rewarming took 30 minutes. Groups C and D were flushed with the same solution at 38° C. and placed in the circuit already warmed to 38° C. Groups A and C were perfused with fresh porcine blood, and groups B and D with fresh human blood. The efficiency of liver function in the four groups was compared by measuring bile volume and the rate at which a loading dose of bromsulphthalein was excreted into bile. Intravascular coagulation was assessed using the ^{125}I-fibrinogen test (Winch et al., 1971).

There was no difference between the four groups in the extent of intravascular coagulation occurring, but biochemical function was better when the liver was perfused with porcine blood. However, livers perfused with either porcine or human blood were less efficient if they had been cooled and rewarmed than if they had not been cooled at all. Therefore hypothermia is not only unnecessary but is harmful in the preparation of a pig liver for extracorporeal perfusion.

39. Estimation of Tissue Compartments in the Isolated Perfused Canine Liver: R. J. Nicholls (H. D. Ritchie), The London Hospital.

Inulin space, total tissue water, the erythrocyte mass, and albumin 'space' were measured simultaneously in the perfused canine liver using ^{14}C-inulin, ^{3}H$_2$O, ^{51}Cr-red cells, and ^{131}I-albumin as tracers.

Twenty experiments were performed. Perfusion flow rate (0·6 ml. per g. per minute) and P.C.V. (40) were kept at a standard value in each experiment; perfusate albumin concentration was varied deliberately from 1·2 to 5·0 g. per cent.

'Spaces' from the ratio of tissue to plasma radioactivity were estimated and expressed as ml. per g. wet liver per cent.

A lymph fistula was established. Lymph ^{131}I-albumin activity was 87 ± 6 per cent plasma ^{131}I-albumin activity.

The inulin compartment rose by 16·5 per cent per hour during the second hour of perfusion when lymph ^{14}C and ^{3}H activity had equilibrated with plasma. At 1 hour after the addition of the isotopes the inulin compartment was 25 ± 4·4 per cent. Total tissue water (75·7 ± 8·3 per cent at 1 hour) remained unchanged over the same time whilst intracellular flnid volume showed a steady fall.

A linear regression was obtained when the inulin compartment at 1 hour was plotted against the lymph/plasma-albumin ratio ($r = 0·88$) and the lymph/plasma-albumin difference ($r = 0·85$).

Lymph-flow was related to inulin compartment size. There was no correlation between inulin compartment and plasma-albumin, plasma-globulin, or portal pressure.

The technique provides a method of studying tissue compartments under dynamic conditions in isolated viscera.

40. In vivo Radio-isotope Assessment of Liver Regeneration in the Rat: S. J. Karran, K. G. Leach, and L. H. Blumgart, Department of Surgery, Cardiff.

Extensive liver resection is possible because the remnant will regenerate. This paper reports an investigation of the uptake of technetium sulphur colloid (T.S.C.) and selenomethionine (S.M.) by normal and regenerating liver, and scintiscanning to assess liver weight in the rat.

Scintiscans of the liver were obtained in 32 animals using the gamma-camera with a pin-hole collimator. In 17 of these, S.M. scans were less well defined than T.S.C. scans and were distorted by uptake in other organs. Despite concentration by different cellular systems (Croft, 1969) there was no difference in the areas of post-mortem liver scans ($P = 0·95$) nor in the distribution of these compounds.

Twenty-one sets of T.S.C. scans were obtained from 4 minutes to 44 days after partial hepatectomy. The mean lateral area (A_L) was compared with liver weight (W) ($r = 0·95$). The linear regression equation was $W = 0·026A_L - 0·48$.

In addition 2 animals were scanned sequentially up to 99 days after hepatectomy.

In no animal did liver weight increase after the tenth postoperative day, other than that accounted for by normal growth.

The technique offers an *in vivo* method of assessing liver regeneration in the rat and supports the recent use of T.S.C. scans in assessing liver size after partial hepatectomy in man (Blumgart et al., 1971).

41. Effect of Truncal (T.V.), Selective (S.V.), and Highly Selective Vagotomy (H.S.V.) in Man on Gastric Emptying of Food and Barium: A. R. Wilkinson and D. Johnston, Department of Surgery, University of Leeds.

The crucial questions after H.S.V. (Johnston and Wilkinson, 1970) concern gastric emptying and recurrent ulceration. To provide objective evidence about the first question the pattern of gastric emptying of a semi-solid meal of food and barium was studied by serial radiographs taken from 15 to 150 minutes after eating. Between radiographs the patients sat or walked about. Three criteria of gastric emptying were used: (1) when it started, (2) when it finished (stomach empty), and (3) when the head of the meal reached the caecum. Eleven pre-operative patients with duodenal ulcer and patients more than 1 year after T.V. + P. (pyloroplasty) (12), S.V. + P. (10), and H.S.V. (14) were studied.

Gastric emptying had started by 15 minutes in 63 per cent of D.U.s, in 100 per cent of T.V. + P.s, in 100 per cent of S.V. + P.s, and in 78 per cent of H.S.V.s. Emptying was complete by 90 minutes in 0 per cent of D.U.s, in 75 per cent of T.V. + P.s, in 60 per cent of S.V. + P.s, and in 14 per cent of H.S.V.s, and by 150 minutes in 54 per cent of D.U.s, in 92 per cent of T.V. + P.s, in 80 per cent of S.V. + P.s, and in 50 per cent of H.S.V.s. The head of the meal had reached the caecum by 45 minutes in 0 per cent of D.U.s, in 58 per cent of T.V. + P.s, in 50 per cent of S.V. + P.s, and in 14 per cent of H.S.V.s.

Gastric emptying after truncal and selective vagotomy, with pyloroplasty, is significantly ($P < 0·02$) faster than before operation. After H.S.V. gastric emptying is almost normal.

Johnston, D., and Wilkinson, A. R. (1970), *Br. J. Surg.*, **57**, 289.

42. Inhibitory Function of Gastric Antral, Hepatic, and Coeliac Fibres in Man: R. B. Smith, C. S. Humphrey, P. J. Lyndon, and D. Johnston, Department of Surgery, University of Leeds.

The gastric antral, hepatic, and coeliac branches of the vagus inhibit gastric secretion in the dog (Hart, 1968; Griffith, 1969). We wished to find out if they also did so in man. They are sacrificed in truncal vagotomy (T.V.) but preserved in highly selective vagotomy (H.S.V.).

Five groups of subjects were studied: 8 normal patients (N.), 6 preoperative patients with duodenal ulcer (D.U.), and patients more than 1 year after T.V. + P. (pyloroplasty) (29), selective, S.V. + P. (9), or H.S.V. (23). Each subject underwent two intramuscular injections of pentagastrin (P.G.T.) on separate days. One test was preceded by the intravenous administration of insulin, 0·2 U per kg., 2 hours earlier to stimulate vagal activity. The tests were done in random order. The insulin tests were positive in 60 per cent of the T.V. + P., S.V. + P., and H.S.V. patients.

Mean peak acid outputs ± 1 S.E. in mEq./hour, the first figure referring to P.G.T. alone, the second to P.G.T. after insulin, were: N., 33·3 ± 2·0 and 41·1 ± 2·9 ($P < 0·001$, potentiation 29·7 per cent); D.U., 41·6 ± 1·8 and 47·5 ± 2·9 ($P < 0·05$, potentiation 12·9 per cent); T.V. + P., 23·9 ± 2·31 and 24·2 ± 2·6 (not significant increase, 9·1 per cent); S.V. + P., 31·8 ± 6·9 and 33·2 ± 7·2 (not significant increase, 6 per cent); H.S.V., 19·8 ± 2·1 and 16·7 ± 1·6 ($P < 0·05$, inhibition 15·9 per cent).

The acid outputs in the three consecutive 5-minute periods (2–4) with P.G.T. after insulin, expressed as a percentage of the same period with P.G.T. alone, were: N., 193·8 ± 34·2 per cent; D.U., 129·3 ± 10·4 per cent; T.V. + P., 155·9 ± 53·2 per cent; S.V. + P., 106·24 ± 8·94 per cent; and H.S.V., 76·5 ± 11·4 per cent (inhibition).

Background vagal activity therefore led to a significant potentiation of the pentagastrin response in normal subjects and in patients with duodenal ulcer. In patients after H.S.V. insulin inhibited the pentagastrin response significantly.

This is the first evidence that the vagal fibres preserved in H.S.V. inhibit gastric secretion in man.

HART, W. (1968), *Arch. Klin. Chir.* **322**, 703.

43. The Effect of Vagotomy on the Inhibition of Gastric Secretion by Intraduodenal Fat: A. S. WARD (G. Slaney), Birmingham.

Fat in the duodenum inhibits gastric secretion in man. Johnston and Duthie (1969) suggested that inhibition by fat is dependent on a vagal reflex despite considerable animal evidence to the contrary. A study was undertaken to reassess the effect of intraduodenal fat on gastric secretion before and after total vagotomy.

Six patients with duodenal ulcer were tested before operation and a further 6 patients were tested 1 year after complete truncal vagotomy (proved by Hollander test). Two additional patients were examined both before and after operation. A suction tube was placed in the stomach and a perfusion tube in the distal duodenum. Gastric secretion was stimulated by an intravenous infusion of pentagastrin (6 μg. per kg. per hour), and after a secretory plateau had been reached 20 ml of Prosparol were instilled into the duodenum over 5 minutes. Gastric collection was then continued for a further hour.

Marked inhibition of gastric secretion occurred in all patients following duodenal infusion. The response was similar both before and after vagotomy. These results suggest that inhibition of gastric secretion by intraduodenal fat is mediated by a non-vagal mechanism in man as well as in animals. From this point of view there is little advantage in preserving the nerve-supply to the duodenum at vagotomy.

JOHNSTON, D., and DUTHIE, H. L. (1969), *Scand. J. Gastroent.*, **4**, 561.

44. The Correlation between the Rate of Gastric Emptying and Dumping and Diarrhoea after Truncal, Selective, and Highly Selective Vagotomy: C. S. HUMPHREY, A. R. WILKINSON, and D. JOHNSTON, Department of Surgery, University of Leeds.

A fluid test meal of hypertonic glucose (300 ml. 25 per cent) was used to investigate the relationship between gastric emptying and the side-effects of dumping and diarrhoea after truncal and selective vagotomy with pyloroplasty (T.V. + P., S.V. + P.) and highly selective vagotomy without drainage (H.S.V.). Phenol red was used as marker.

In the first 20 minutes 46 ± 8 per cent of the meal emptied in preoperative patients with duodenal ulcer, compared with 79 ± 6 per cent after T.V. + P., 62 ± 9 per cent after S.V. + P., and 52 ± 9 per cent after H.S.V. ($n = 12, \times 4$). T.V. + P. accelerated emptying significantly ($P < 0·02$), while H.S.V. and S.V. + P. did not.

After the meal, dumping and diarrhoea occurred significantly less frequently after H.S.V. than after T.V. + P. and S.V. + P.—dumping: 73 per cent of 15 T.V. + P.s, 80 per cent of 15 S.V. + P.s, and 47 per cent of 15 H.S.V.s ($P < 0·05$); diarrhoea: 66 per cent T.V. + P., 60 per cent S.V. + P., and 13 per cent H.S.V. ($P < 0·01$).

A significant correlation ($R = 0·84$, $P < 0·01$) was found between the rate of rise of blood-glucose concentration (mg. per cent per minute) and the proportion of the test meal emptied in 20 minutes. In the first 20 minutes the rate of rise of blood-glucose was 2·2 ± 0·2 in 15 D.U.s, 4·5 ± 0·4 in 15 T.V. + P.s, 3·7 ± 0·3 in 15 S.V. + P.s, and 3·0 ± 0·4 in 15 H.S.V.s.

A clinical study showed that 1 year after operation there was significantly less dumping ($P < 0·05$) and diarrhoea ($P < 0·01$) after H.S.V. than after T.V. + P. and S.V. + P.

The stomach is continent and emptying is still controlled after H.S.V.

45. The Gastro-oesophageal Junction in Duodenal Ulcer after Operation: P. THOMAS and R. EARLAM, The London Hospital.

Thirty-seven patients with duodenal ulcer were studied with oesophageal manometry preoperatively and then between 6 and 12 months later. Twenty-eight had vagotomy and either a pyloroplasty or gastro-enterostomy performed. Nine had a Polya partial gastrectomy with or without a vagotomy. Using non-perfused water-filled open tips (internal diameter 1·12 mm.) the mean maximum pressure above intragastric (barrier) was 9·8 ± 6·4 cm. H_2O, and the zone of elevated pressure (Z.E.P.) was 4·4 ± 1·1 cm. long. These are similar values to those obtained in a previous study on 70 patients with duodenal ulcer (Earlam, 1971). The barrier was unchanged following vagotomy and drainage but was reduced significantly after partial gastrectomy (3·2 ± 2·5 cm. H_2O, $P < 0·05$). Z.E.P. was shortened in both groups (3·5 ± 1·0 cm. and 2·9 ± 0·8 cm., $P < 0·05$). These parameters were also significantly different when measured by balloon. The mean intragastric pressure (open tip only) was increased in both groups postoperatively from 17·9 ± 5·0 to 22·6 ± 4·7 cm. H_2O ($P < 0·05$).

These manometric findings suggest that the gastro-oesophageal sphincter is not impaired following vagotomy and drainage operations. By these techniques there is no increased incidence of hiatal hernia following either type of operation. The low pressures following a partial gastrectomy may be due to removal of the antrum which produces gastrin which is known to increase the sphincteric pressure.

EARLAM, R. J. (1971), *Br. J. Surg.*, **58**, 296.

46. Ischaemia as a Factor in the Aetiology of Stress Ulceration: J. E. L. SALES (G. W. Taylor), University of Colorado Medical Centre, Denver, U.S.A., and St. Bartholomew's Hospital, London.

Stress ulceration of the gastroduodenal mucosa is a recognized complication of trauma and haemorrhage. The reasons for the development of the ulceration are obscure but mucosal ischaemia due to alterations in splanchnic blood-flow has been suggested. This paper defines the relationship of ulceration to the distribution of blood-flow in the stomach wall.

Fifteen 10-kg. piglets were bled to a systolic blood-pressure of 40 mm. Hg by 40 per cent haemorrhage. Five animals were killed immediately, 5 after 2 hours' hypotension, and a further 5 after 2 hours' hypotension and retransfusion.

Blood-flow was measured by two series of 25-μ diameter microspheres labelled with either ^{141}Ce or ^{51}Cr. The excised stomach was divided into 1-cm. squares and assayed for isotope activity. Gastric blood-flow (G.B.F.) and flow per g. were calculated. Cardiac output and sphere measurement in the gastric venous blood were also quantitated.

G.B.F. decreased linearly with 40 per cent haemorrhage. There was no evidence of arteriovenous shunting. After 2 hours of shock G.B.F., previously evenly distributed, became uneven. Acute ulceration occurred at disproportionately ischaemic sites. Retransfusion restored an even distribution of flow. Areas of disproportionate ischaemia of the gastric mucosa follow prolonged post-haemorrhagic hypotension. Acute ulceration occurs principally at these sites.

47. Exocrine Secretory Responses of the Pancreas to Pentagastrin and to a Standard Meal in Dogs:

SAROJ GUPTA and J. B. ELDER (I. E. Gillespie), Department of Surgery, University of Manchester.

It is well established that pentagastrin stimulates the exocrine secretion of the pancreas and that doses maximal for acid are also maximal for pancreatic secretion (Emas et al., 1968). Little is known of the relationship between the response to pentagastrin and food-stimulated pancreatic secretion.

In 4 dogs with chronic pancreatic and gastric fistulae (G.F.) (Preshaw and Grossman, 1965) the following were studied: (1) acid dose–response curves to intravenous pentagastrin with the G.F. open; (2) protein and bicarbonated outputs from the pancreas over a 4-hour period to pentagastrin as a dose maximal for acid secretion in each animal with the G.F. both open and closed; and (3) the exocrine response of the pancreas to a standard 400-g. meat meal.

In response to pentagastrin, with the G.F. closed, the total 4-hour bicarbonate output ($21{\cdot}57 \pm 1{\cdot}87$ mEq.) was significantly greater than that with the G.F. open ($2{\cdot}42 \pm 0{\cdot}77$ mEq.; $P < 0{\cdot}001$), and not significantly different from that observed in response to a standard meat meal ($20{\cdot}6 \pm 3{\cdot}2$ mEq.; $P < 0{\cdot}4$).

Total 4-hour protein output to pentagastrin with the G.F. closed (2305 ± 250 mg.) was significantly greater than that with the G.F. open (1291 ± 258 mg.; $P < 0{\cdot}005$), and not significantly greater than that to a standard meal (1883 ± 222 mg.; $P < 0{\cdot}2$).

These results suggest that the exocrine response of the pancreas to food can be reproduced by pentagastrin infusion alone.

48. Bile-acid Absorption by Jejunum and Colon after Ileal Resection in the Rat:

P. M. PERRY, JUNE WHITE, and R. H. DOWLING (G. W. Taylor), Royal Postgraduate Medical School and St. Bartholomew's Hospital, London.

Although ileal resection causes bile-salt (B.S.) malabsorption, post-ile-ectomy jejunal B.S. concentrations are often normal. This could be due to increased hepatic B.S. synthesis and/or non-ileal B.S. reabsorption. Since the ability of the liver to increase B.S. synthesis is limited (Dowling et al., 1970) B.S. absorption in the ile-ectomized rat was studied in order to quantify jejunal and colonic contributions to the B.S. enterohepatic circulation and to look for any compensatory increase in B.S. absorption following resection.

B.S. absorption was measured using an *in vivo* recirculation perfusion system in bile-fistula ile-ectomized and sham-operated control rats. ^{14}C-cholate (5 mg., 0·1 μc. per rate) and taurocholate absorption were measured both by the fall in luminal B.S. concentration and by cumulative isotope excretion in the bile. Absorption of water and glucose, and net Na^+, K^+, and Cl^- movement were measured simultaneously.

Our results show that, per unit length, jejunal B.S. absorption was twice as efficient as that of the colon which did not compensate for the loss of the ileum in B.S., glucose, water, or electrolyte absorption. Jejunal cholate absorption increased significantly after resection (68 ± 15 μg. per cm. intestine per 3 hours) compared with the controls (50 ± 17 μg.; $t = 2{\cdot}85$, $P < 0{\cdot}02$). Significant increases were also found for glucose, water, and electrolyte absorption in the jejunal remnant after ile-ectomy.

It is concluded that the jejunum is more important than the colon both in normal B.S. absorption and in adaptive ability to increase absorption after ileal resection.

DOWLING, R. H., MACK, E., and SMALL, D. M. (1970), *J. clin. Invest.*, **49**, 232.

49. Hepatitis in a Renal Transplant Unit:

D. R. THOMAS, W. BOGIE, J. D. BLAINEY, B. H. B. ROBINSON, P. DAWSON-EDWARDS, and A. D. BARNES, Queen Elizabeth Hospital, Birmingham.

Hepatitis is a serious disease in dialysis and transplantation units and has resulted in morbidity and mortality of patients and staff. Since the discovery of hepatitis-associated antigen (H.A.A. or Australia antigen) it has been possible to study the disease more fully. This paper describes the incidence of clinical liver disease among the patients and staff of a renal unit. H.A.A. screening was introduced 4 years after 1 dialysis patient developed clinical hepatitis. This uncovered a high incidence of 'subclinical carriers' of H.A.A. who appeared to be infecting other patients, their relatives, and the staff of the unit. Retrospective analysis at that time showed that the H.A.A.-positive patients had never been jaundiced but had usually shown a raised transaminase between 3 and 6 months after starting dialysis. Prospectively, about 60 per cent of the new patients were becoming H.A.A.-positive between 3 and 6 months after starting dialysis.

Although none of the staff and relatives had died from hepatitis it was decided to try to rid the unit of infection. The majority of patients dialysed in the unit were selected as unsuitable for home dialysis for social or other reasons.

Therefore, the patients were submitted to cadaveric renal transplantation at the earliest opportunity. Six patients who were H.A.A.-positive and 6 patients who were also dialysed within the unit and who may have been infected were transplanted with 13 kidneys between June, 1970, and January, 1971, with the best-matched kidneys available. None of the patients is now on dialysis or attending the hospital; 5 have renal transplants that are functioning satisfactorily at 16–20 months, 2 patients died from uncontrollable rejection, 4 patients died from infection, and 1 died from a subarachnoid haemorrhage.

As a result of this policy there have been no new cases of hepatitis or H.A.A.-positive patients in the unit for the past 10 months and no cases among the staff or relatives of the patients.

50. Donor Kidney Selection for Transplantation—Relationships between Glomerular Structure, Vascular Supply, and Age:

M. SWORN and M. FOX, University of Sheffield.

Kidneys from 50 consecutive post-mortems were examined macroscopically and histologically to assess and to compare glomerular appearance, vascular changes, and renal artery circumference. Correlation was also made with previous history of hypertension. The aim of the investigation was to determine the age beyond which persons without obvious parenchymal disease should best not be considered as kidney donors. Out of the 100 kidneys examined, 82 were used for the study; 18 were excluded because of renal parenchymal disease. Glomeruli were graded as normal, obsolescent, and intermediate.

Significant correlations between age, renal artery circumference, and the percentage of completely normal glomeruli were found. The percentage agreements and selection proportions were determined by comparing the percentage of normal glomeruli cut-off points with 10-year period age steps. If greater than 60 per cent completely normal glomeruli and less than 80 years were taken as cut-off points, the percentage agreement was 90 per cent. If, however, 90 per cent or more completely normal glomeruli were required the percentage of such kidneys varied from 67 per cent at less than 50 years of age to 8 per cent for kidneys from subjects older than 70 years. There was no significant difference between the percentage of normal glomeruli in patients with previous diastolic blood-pressure above or below 100 mm. Hg in the range examined.

51. **Survival of Canine Renal Allografts after Antilymphocytic Serum and Bone-marrow Treatment:** D. T. CARIDIS, A. LIEOGEOIS, I. BARRETT, B. W. LYTLE, and A. P. MONACO, Harvard and Aberdeen.

The principle of augmenting antilymphocytic serum-induced suppression of allograft immunity by infusion of specific donor bone-marrow cells was studied.

Adult dogs received rabbit anti-dog lymphocytic serum (R.A.D.L.S.) in doses of 1 ml. per kg. or 2 ml. per kg. from days -7 to $+7$ relative to bilateral nephrectomy and renal allotransplantation from unmatched non-litter-mate mongrel donors. Half of each group of R.A.D.L.S.-treated animals received intravenous donor bone-marrow ($2–4 \times 10^8$ nucleated cells per kg.) on day $+10$.

The mean survival time for the untreated controls was 10 days. In the 1 ml. per kg.-R.A.D.L.S. group bone-marrow-infused dogs survived for 14–33 days and the non-infused dogs survived for 14–24 days. In the 2 ml. per kg.-R.A.D.L.S. group non-infused dogs survived for 14–31 days while the bone-marrow-treated dogs showed a significant prolongation of survival (20–78 days). No overt graft-versus-host reaction was observed clinically.

It is possible that the results are caused by increased antigenic challenge (bone-marrow infusion) producing transient host-versus-graft activity which may in turn lead to the establishment of an enhancement phenomenon resulting in augmented survival.

52. **The Use of Radioactive Fibrinogen for detecting Rejection of Human Renal Transplant:** E. D. YEBOAH, R. SHACKMAN, and G. D. CHISHOLM, Royal Postgraduate Medical School, London.

The use of ^{125}I-labelled human fibrinogen in the detection of kidney transplant rejection has been reported (Salaman, 1970). The present study concerns 33 patients after kidney transplantation.

Radioactive ^{125}I-labelled human fibrinogen was given and the radioactivity of the transplant measured with an external scintillation counter. In 7 patients with no clinical or biochemical evidence of rejection there was no increase in radioactivity. In 14 patients with clinical and biochemical evidence of acute rejection there was an increased transplant radioactivity; in 3 of these the increased radioactivity preceded clinical evidence of rejection.

False positives were observed in cases with extravasation of urine, perirenal haematoma, and malacoplakia, and during arvin therapy.

The method is a useful aid for the early diagnosis of acute rejection but false positives may be found. It is not useful in cases of chronic rejection.

SALAMAN, J. R. (1970), *Br. med. J.*, **2**, 517.

53. **A Study of Renal Allograft Rejection in the Rat using ^{125}I-fibrinogen:** J. R. SALAMAN, Cardiff.

^{125}I-fibrinogen localizes in human renal transplants during periods of rejection (Salaman, 1970). Experiments were carried out in rats and the phenomenon was studied more closely and possible sources of error were defined.

Kidneys were transplanted from AGUS- to PVG/C-strain rats as rejection occurs rapidly with this combination (8·7 days). The recipient's left kidney was retained as a control, and after 3 days ^{125}I-labelled rat fibrinogen was injected intravenously. The kidneys were excised on the seventh day and their radioactivities were compared. Isografted rats and rats with renal ischaemia, ureteric obstruction, and renal vein thrombosis were also studied.

Renal Allografts (10 rats): The renal allografts took up radioactivity and by 7 days were up to three times more radioactive than the control kidneys.

Renal Isografts (10 rats): No differences were observed between the normal and the grafted kidneys.

Renal Ischaemia (10 rats): The kidneys were rendered ischaemic for 40 minutes and were no more radioactive than the controls.

Ureteric Obstruction (11 rats): The radioactivity of the hydronephrotic kidney was not significantly increased.

Renal Vein Thrombosis (8 rats): The thrombosed kidneys became highly radioactive after ligation of the renal vein.

^{125}I-fibrinogen is deposited in rejecting kidney transplants. Renal vein thrombosis may give similar results and this should be recognized when using ^{125}I-fibrinogen as a test for rejection.

SALAMAN, J. R. (1970), *Br. med. J.*, **2**, 201.

54. **An in vivo Antilymphocytic Serum (ALS) Efficacy Test:** A. A. VAN DEN BROEK and CH. R. H. WILDEVUUR, Groningen, Holland.

Although ALS is widely used to prevent or suppress graft rejection there is no general agreement as to its efficacy. This efficacy is tested mainly by its ability to modify graft rejection, which can be influenced by various other factors such as different degrees of histocompatibility (Keuning and van den Broek, 1968).

As ALS primarily interferes with thymus-derived lymphocytes, ALS treatment in thymectomized dogs should give complete depletion of lymphocytes in the thymus-dependent areas of lymph-nodes.

Experiments were performed to test the efficacy of samples of ALS in thymectomized dogs treated with a prescribed effective ALS dosage. Immunosuppression was tested by means of skin-grafting. The histology of the lymph-nodes was studied after the last ALS injection.

Samples of ALS giving complete depletion in the thymus-dependent areas of lymph-nodes correlated with prolongation of skin-graft survival up to 30 days. Samples of ALS giving incomplete depletion of the thymus-dependent areas correlated with unmodified graft rejection in 10–20 days.

It was concluded that the histology of lymph-nodes in thymectomized dogs after ALS treatment is a reliable *in vivo* test for the immunosuppressive potency of the ALS used.

KEUNING, F. J., and VAN DEN BROEK, A. A. (1968), *Exp. Hem.*, **17**, 4.

55. Human Tumour Xenografts: J. E. Castro and D. N. H. Hamilton, Clinical Research Centre, Harrow.

As a model for the investigation of human tumours, *in vivo* maintenance in xenogeneic hosts allows study of tumour growth in a near-normal environment and it allows the toxicity of therapeutic agents to be assessed without the disadvantages of excessive stromal overgrowth or infection as may occur *in vitro*.

Samples of different types of human tumours obtained at operation were implanted into CBA mice which had undergone adult thymectomy, lethal irradiation (900–1000 r), and reconstitution with syngeneic bone-marrow (Davies et al., 1969). Tumour fragments were implanted beneath the kidney capsule or subcutaneously and they were examined histologically.

Two weeks after implantation 60 per cent of the tumours were viable and results showed certain tumours, particularly colonic ones, to be easier to grow. Some tumours were maintained for 2 months or more but none metastasized.

Histological examination of viable grafts showed good correlation with the original cytology and there were typical appearances in dead specimens of a sparse cellular infiltrate and fibrosis.

Davies, A. J. S., Carter, R. L., Leuchars, E, and Wallis, V. (1969), *Immunology*, **17**, 111.

56. A Histological Technique for assaying the Efficacy of Methods designed to reduce Allograft Rejection: P. A. Hamilton Stewart and J. Swinney, Postgraduate School of Studies, Bradford, and Department of Surgery, University of Newcastle upon Tyne.

Rejection of allografts is associated with a marked lymphocytic infiltration. The effect of immunosuppression on lymphocytic infiltrate was studied in rats.

A disk, 3 × 1 mm., was taken from the decapsulated donor kidney with a skin-biopsy punch.

Incision and elevation of the recipient renal capsule allowed the slice to be placed with its decapsulated surface in contact with the anterior surface of the renal cortex of the recipient.

Microscopy of 10-day autografts and isografts showed the tubules of the graft touching those of the recipient kidney but with negligible evidence of cellular infiltration.

In contrast, allografts transplanted under controlled immunogenic conditions across a strong histocompatibility barrier displayed a marked band of lymphocytes and a few plasma cells with some fibroblasts in the junctional zone of the graft.

Using an eye-piece graticule 'blind' lymphocyte counting was performed in the same five junctional areas in each of 100 grafts.

No difference was detected between autografts and isografts ($P = 0{\cdot}3$).

A highly significant difference was observed between autografts and allografts ($P < 0{\cdot}001$) and between azathioprine- and prednisolone-treated allografts compared with controls ($P < 0{\cdot}001$).

If lymphocytic infiltration is a measure of host immunological reaction, then this is a sensitive method for the evaluation of immunosuppressive drugs and differences in genotype.

57. A New Atraumatic Isotope-labelling Technique for the Assessment of Digital Cutaneous Blood-flow: M. J. Fox and J. C. Milliken (W. G. Fegan), Department of Vascular Surgery, Sir Patrick Dun's Hospital, Dublin.

A technique has been devised in which digits of the hands or feet may be selectively, uniformly, and atraumatically labelled in a specially designed inexpensive irradiation chamber with ^{133}Xe gas. A direct estimate of the local cutaneous blood-flow can be made from the observed clearance curves (Sejrsen, 1968).

In order to demonstrate the flow-dependence of the clearance curves 10 normal volunteers were subjected to tourniquet tests during the initial clearance period. Clearance virtually ceased when the circulation was arrested and release of the tourniquet was followed by enhanced clearance due to resultant reactive hyperaemia.

Fingers of 5 normal volunteers were investigated at weekly intervals for 4 weeks. There was a close correlation between clearance half-times in individual subjects. The toes of 5 normal volunteers were examined similarly with consistent results.

Four patients with primary Raynaud's disease and 10 patients with peripheral atherosclerosis were examined. In each case there was an increased clearance half-time value compared with that in normal subjects. One patient with erythrocyanosis frigida was assessed before and after lumbar sympathectomy. A 50 per cent reduction in half-time was observed postoperatively.

This technique has the advantage of being simple, non-intrusive, safe for both the patient and the examiner, and readily reproducible.

Sejrsen, P. J. (1968), *Appl. Physiol.*, **24**, 570.

58. Raynaud's Disease and Cooling of the Fingers: I. A. Miller and D. N. Walder, Department of Surgery, University of Newcastle upon Tyne.

It is generally believed that following cooling of the fingers arteriovenous anastomoses in the terminal pulp and nail-bed dilate and the subsequent increase in blood-flow results in a rise of pulp temperature (Lewis, 1930); simultaneously the capillary flow at the base of the finger nail is reduced (Grant and Bland, 1931).

It seemed possible that the symptoms of Raynaud's disease might be due to a disturbance of this mechanism. In order to test this hypothesis estimations of (1) total finger blood-flow by venous occlusion plethysmography, (2) capillary blood-flow by a radio-isotope clearance technique, and (3) finger-tip temperature by a thermocouple were made before and after cooling of a digit in 8 normal subjects and in 10 patients with Raynaud's disease.

In the normal subjects there was no significant difference between the total finger blood-flow (15·91 ± 7·039 ml. per 100 g. per minute) and the capillary blood-flow (17·6 ± 11·09 ml. per 100 g. per minute) ($P > 0{\cdot}2$) before cooling, thus suggesting that the arteriovenous anastomoses were closed. After cooling the finger there was a highly significant difference between the total finger blood-flow (26·28 ± 9·467 ml. per 100 g. per minute) and the capillary flow (8·77 ± 8·105 ml. per 100 g. per minute) ($P < 0{\cdot}001$), indicating that the arteriovenous anastomoses were open.

In the patients with Raynaud's disease the findings were similar, that is, there was no significant difference between the total finger blood-flow (12·62 ± 7·136 ml. per minute) and the capillary blood-flow (13·8 ± 8·378 ml. per 100 g. per minute) ($P > 0{\cdot}2$) before cooling, but after cooling there was a highly significant difference between the total finger blood-flow (20·08 ± 11·137 ml. per 100 g. per minute) and the capillary blood-flow (4·91 ± 4·299 ml. per 100 g. per minute) ($P < 0{\cdot}001$). Thus in Raynaud's disease there is no alteration in the normal interrelationship of blood-flow through the arteriovenous anastomoses and capillaries so that the fault must lie in the vasculature proximal to the arteriovenous anastomoses.

Grant, R. T., and Bland, E. F. (1931), *Heart*, **15**, 385.
Lewis, T. (1930), *Ibid.*, **15**, 177.

59. Animal Experiments on the Effect of Various Haemostyptic Drugs: H. E. Koehnlein and U. Mergard, Freiburg, Germany.

An attempt was made to find a reproducible test to compare the effect of six systemically and four locally administered haemostyptic drugs.

A standardized liver section was performed in 300 rats. Bleeding time and blood-loss were measured exactly. The same test was performed on healthy animals and on animals who had received 0·2 ml. CCl_4 and 0·2 ml. of olive oil per 100 g. 24 hours before the operation. The following drugs were tested: (1) epsilon-amino-caproic acid (17·14 mg. per 100 g.) i.v. 15 minutes before liver section; (2) Anvitoff (0·0073 ml. per 100 g.) i.v. 60 minutes before operation; (3) vitamin K (0·06 ml. per 100 g.) i.v. 3 hours before operation; (4) Tachostyptan (0·04 ml. per 100 g.) i.v. directly before operation; (5) Epsilon-Tachostyptan (0·04 ml. per 100g.) i.v. 10 minutes before operation; (6) reptilase (0·003 ml. per 100 g.) i.v. 10 minutes before operations; locally: Clauden powder, collagen powder, Tabotamp gauze, and Topostasin.

Locally applied collagen was superior to all other haemostyptic drugs in both experiments. The bleeding stopped immediately in every animal. Blood-loss and bleeding time were not measurable. From the intravenously administered drugs reptilase showed the best effect: blood-loss was 24 mg. as compared with 65 mg. in the controls; bleeding time was 2·6 minutes versus 4·4 minutes. Consequently collagen powder has been used in 25 patients with very good effect.

60. Preliminary Studies on the Effect of Adrenergic Blockade on Haemorrhage-induced Changes in Blood Coagulability and Fibrinolysis: M. H. Irving and Christine Hawkey, St. Bartholomew's Hospital and Nuffield Institute of Comparative Medicine, London.

Haemorrhage and both accidental and operative trauma cause an increase in the coagulability and fibrinolytic activity of the blood. Venous thrombosis and disseminated intravascular coagulation are manifestations of the increased coagulability.

The exact mechanisms which stimulate hypercoagulability and fibrinolysis in such circumstances are not known, but intravenous adrenaline infusion has been shown to activate both systems. This observation is of significance, for adrenaline and noradrenaline levels in the blood attain high values in haemorrhagic shock.

Four groups of 3 sheep each were subjected to 3 hours' haemorrhagic shock by the elevated reservoir technique. One group acted as a control, while the other groups were premedicated with phenoxybenzamine (B), propranolol (C), and phenoxybenzamine and propranolol in combination (D). Measurements of platelet count, cephalin clotting time, fibrinogen, factor V, and fibrinolytic activity were made at regular intervals throughout the period of haemorrhagic shock.

Marked changes in the activity of all the measured indices were found in the control and alpha-blocked (phenoxybenzamine) animals but did not occur in the beta-blocked (propranolol) group. The results in the animals with the combined blockade were equivocal.

The results suggest that haemorrhage-induced hypercoagulability and fibrinolysis are mediated through the beta-activity of endogenously released catecholamines.

61. The Effect of Pyridinol Carbamate Treatment on the Platelet Response to ADP in Patients with Peripheral Atherosclerosis: R. C. Cotton, K. Bloor, and G. Archibald, Royal Infirmary, Manchester, and I.C.I. Research Laboratories, Macclesfield.

It is claimed that treatment with pyridinol carbamate results in an improvement of blood-flow in the affected limbs in patients with peripheral atherosclerosis (Shimamoto et al., 1970). It is suggested that this effect is produced by inhibiting processes involved in the continuing development of the atheromatous/thrombotic lesions.

The platelet response to ADP was investigated in patients with peripheral atherosclerosis using the platelet-aggregation filtration pressure (P.A.F.P.) method (Dhall and Matheson, 1969). The mean P.A.F.P. in 21 patients (mean age 56·9 ± 1·7 years) was 95·3 ± 6·6 mm. Hg. In 14 healthy male subjects of similar age the P.A.F.P. was 55·5 ± 5·2 mm. Hg and in 11 younger normal males (mean age 24·2 ± 0·9 years) the P.A.F.P. was 50·2 ± 1·0 mm. Hg. The difference between the means in each of these groups was significant (*P* < 0·001).

In an open trial 13 of the patients were treated with pyridinol carbamate for 4 months. The mean P.A.F.P. in these patients was reduced from 91·5 ± 9·5 to 69·5 ± 4·8 mm. Hg by the sixth week of treatment and this effect on the platelets persisted for the rest of the period of treatment.

It is concluded that pyridinol carbamate reduces the sensitivity of the platelets to ADP to normal levels in these patients. This effect is probably an indirect one.

Dhall, D. P., and Matheson, N. A. (1969), *Cardiovasc. Res.*, **3**, 155.

62. Use of the Scanning Electron Microscope in studying the Effect of Implanted Emboli on Canine Arteries: John D. Hamer, Department of Surgery, Queen Elizabeth Hospital, Birmingham.

Limb salvage following arterial embolectomy is most satisfactory when operation is performed soon after embolism (Thompson et al., 1970). There appears to be a critical period after embolism during which embolectomy is frequently followed by rethrombosis.

This investigation was carried out to search for morphological changes in the surface ultrastructure of canine arteries exposed to implanted emboli, and to investigate the association of such changes with rethrombosis after embolectomy. The significance of post-embolectomy blood-flow rate was also examined.

Nine dogs in three equal groups were investigated. Electrostatically induced venous thrombus was implanted into the carotid and femoral arteries on one side, each contralateral artery acting as a control, and embolectomy was performed 7 days later. Blood-flow restriction was imposed in groups II and III by 30 per cent and 50 per cent respectively, whereas in group I flow was unrestricted.

Seven days later all vessels were inspected and it was found that three out of six vessels in group I had rethrombosed against one control. In group II four out of six vessels had rethrombosed, and in group III all six arteries had rethrombosed.

Scanning electron microscopy has revealed characteristic surface changes in vessels exposed to emboli for 7 days. These changes are reversible in the presence of sustained arterial patency. Although platelet adhesion to endothelial cells has been described after physical trauma (Sheppard and French, 1970) this phenomenon was not observed in this investigation.

63. A Further Trial comparing Dextran 70 with Warfarin in the Prophylaxis of Postoperative Venous Thrombosis: A. I. Davidson, M. E. A. Brunt, and N. A. Matheson, Aberdeen.

Dextran 70 (Macrodex) has been reported to afford significantly better protection against postoperative venous thrombosis in gynaecological patients than Warfarin begun 36 hours after operation. In the Warfarin group, however, half of the patients developing venous thrombosis did so before the commencement of the anticoagulant. The efficacy of dextran 70 (500 ml. during operation; 250 ml. daily on the first 3 days after operation) was therefore compared with that of Warfarin begun at least 36 hours before operation (30 mg. followed by additional doses to maintain the Quick one-stage prothrombin time at 2 to 2·5 times the control level) in 60 patients undergoing pelvic floor repair and randomly allocated to either treatment. Venous thrombosis was diagnosed by ^{125}I-fibrinogen uptake which was positive in 4 of the 30 patients on Warfarin and in 3 of the 30 patients on Macrodex. The efficacy of Warfarin was improved by its earlier administration, but in these patients Macrodex appeared to be at least equally effective.

There was no significant difference in the volume of operative blood-loss measured by haemoglobin extraction in the two groups of patients.

64. Fibrinolysis after Operation and its Relationship to Deep-vein Thrombosis: I. C. Gordon-Smith, J. A. Hickman, and L. P. Le Quesne, The Middlesex Hospital, London.

Studies of postoperative fibrinolytic activity using conventional lysis-time methods are influenced by the rise in fibrinogen concentration following operation. Fibrinolytic activity in patients undergoing major surgery was re-examined by a technique employing ^{125}I-fibrinogen; this gives a quantitative measurement of systemic fibrinolytic activity independent of the plasma-fibrinogen concentration (Hickman, 1971).

So far 45 patients have been studied before operation, immediately afterwards, and daily for a further 7 days. In 85 per cent of the patients fibrinolytic activity was increased immediately following operation ($P < 0{\cdot}001$). There was no evidence of sustained inhibition, or fibrinolytic 'shutdown', in the postoperative period. Indeed, compared with mean preoperative levels fibrinolytic activity tended to increase from the second postoperative day and this was significant by the sixth day ($P < 0{\cdot}01$).

These results do not confirm the pattern of postoperative fibrinolytic activity previously described (Brown et al., 1971), probably because the lysis-time methods employed in those studies were influenced by the postoperative rise in plasma-fibrinogen concentration.

Patients with deep-vein thrombosis, diagnosed by the ^{125}I-fibrinogen technique, exhibited lower fibrinolytic activity during the first postoperative day than patients with no thrombosis ($P < 0{\cdot}05$).

65. Congenital Stenosis of the Gut: An Experimental Study in the Chick Embryo: R. J. Earlam, The London Hospital.

Ischaemia associated with a volvulus or obstruction in an umbilical hernia has been postulated as a cause of congenital intestinal atresia and stenosis (Louw, 1959), but there is only one supportive experiment, in which puppies were operated upon *in utero* (Barnard, 1956), and that is for atresia alone.

In the present study the blood-supply to a segment of the chick-embryo gut early in its development was divided when a normal large umbilical hernia containing gut was still present. Fertile incubated eggs were opened between the ninth and seventeenth days (normal incubation period 21 days). After dividing the covering layers a loop of bowel was carefully lifted out and the mesenteric vessels supplying it were cut. The gut was replaced and the layers so arranged as to prevent leakage of amniotic fluid.

One hundred and six technically successful attempts were made to open the eggs and lift up a loop of bowel without causing a haemorrhage or immediate death, but only 20 survived longer than 24 hours; 5 had their mesenteric vessels divided and 15 acted as controls without interruption of the blood-supply. An area of stenosis was found in 3 of these 5 which were killed within 6 days after the operation. This supports the idea that ischaemia can cause stenosis of the gut before birth.

66. Water and Electrolyte Transfer by Colonic Mucosa studied in vitro: E. Q. Archampong, J. Harris, and C. G. Clark, Department of Surgery, University College Hospital, London.

A technique is described for studying the ability of isolated colonic mucosa to transport water and electrolytes. The mucosa was placed between two Perspex chambers and bathed with modified oxygenated Tyrode solution. Polyethylene glycol was used as a marker and isotopes of sodium, potassium, and chloride were added to the chamber bathing the luminal aspect of the mucosa. The potential difference of the membrane was continuously recorded and a short-circuit device was added to measure the current required to bring the mucosa to electrical neutrality, thereby providing another measure of sodium transport.

In seven experiments with mucosa from colon obtained from cancer patients (controls) it was found that water was absorbed at a rate of 0·001 ml. per minute per cm.^{2} and sodium at 0·170 μEq. per minute per cm.^{2} Potassium was secreted at a rate of 0·020 μEq. per minute per cm.^{2} A negative potential difference was maintained and the short-circuit current was 0·116 μEq. per minute per cm.^{2} In parallel experiments with identical mucosa Salazopyrin significantly increased the absorption of water to 0·002 ml. per minute per cm.^{2} and that of sodium to 0·314 μEq. per minute per cm.^{2} with no change in potassium excretion. Azathioprine had no apparent effect in this system.

In inflammatory bowel disease eight studies show gross alteration in mucosal function which can be restored to more normal patterns by Salazopyrin or Azathioprine depending on the nature of the disease.

67. The Response of the Dog Colon to Ischaemia: J. W. L. Robinson, C. Rausis, and V. Mirkovitch, Lausanne, Switzerland.

The blood-supply to loops of dog colon was interrupted for 1, 2, or 3 hours by clamping the mesenteric and marginal arteries as well as the intestine. The mucosal active transport of sodium was abolished after 1 hour's ischaemia with a reduction in Na$^+$-K$^+$-ATPase in mucosal homogenates. After 2 and 3 hours' ischaemia there was a large increase in the passive permeability of the colonic wall with no active transport and only very low values of Na$^+$-K$^+$-ATPase. One hour's ischaemia provoked only minor changes in histology and microcirculation, but after 2 hours considerable desquamation of the surface cells was observed with venous thrombosis. After 3 hours, heavy oedema and haemorrhagic infiltration without microperfusion of the crypts were seen.

The recovery of the colon from 3 hours' ischaemia was uncertain, both functionally and morphologically, but there was a close correlation between the histological picture, the sodium transport capacity, and the Na^+-K^+-ATPase levels of the experimental loops. One of 4 animals recovered after 1 week, and the majority had recovered after 3 or 4 weeks even though 1 out of 4 dogs had a completely non-functional loop 4 weeks after the ischaemia. Recovery followed a pattern that may be more or less protracted in time. The mucosal regeneration was rapid since no loop with discrete zones of regeneration surrounded by cryptless tissue was observed. The submucosal tissues were greatly thickened and the loop was shortened in length.

68. The Relationship of Colonic Symptoms to the Muscular Abnormality of Diverticular Disease: L. E. Hughes, Department of Surgery, Cardiff.

An increased interest in abnormal muscular activity in diverticular disease has led to the proposal of sigmoid myotomy as a rational therapeutic measure, particularly when 'functional' symptoms predominate. This approach presupposes that such symptoms (abdominal pain, severe constipation, or diarrhoea) are associated closely with diverticular muscle patterns. This paper describes a study of the relationship of diverticulosis and diverticular muscle patterns with colonic symptoms.

Fifty patients undergoing colonic investigation were studied in a prospective fashion. Patients in whom a clear pathological cause for their symptoms could be demonstrated were excluded. The series was otherwise consecutive. Muscular patterns were determined by the silicone-foam-enema technique (Hughes, 1970). Accessory radiological, surgical, pathological, and autopsy studies were carried out to confirm the validity of this technique. The presence of diverticula was determined by combined studies of barium and silicone enema. Symptoms were recorded prior to silicone-enema examination.

Results showed that there is no significant correlation between the presence of diverticula or diverticular muscle patterns and any individual functional symptom. When all three functional symptoms were grouped together there was a negative correlation which just reached the 5 per cent significance level.

It is concluded that caution should be exercised in the use of therapeutic measures that presume a causal relationship between 'functional' symptoms and diverticular disease.

69. An Animal Model to study Diverticular Disease: I. Hodgson (B. N. Brooke), St. George's Hospital, London.

Painter (1962) and Arfwidsson (1964) have demonstrated colonic pressure changes in diverticular disorders. In order to pursue this further an animal model was devised using rabbits.

Adult New Zealand White rabbits were given gas induction and chloralose anaesthetics and were then maintained on oxygen after placing fluid-filled open-tipped narrow-bore polythene tubes in the colon through a caecostomy. After a resting period of 30 minutes colonic activity was induced using a dose of 0·05 mg. per kg. prostigmine and the resulting intracolonic pressure changes were measured for 30 minutes.

The rabbits were placed on a free diet of white bread, butter, milk, and sugar supplemented by vitamins. After 4 months on this diet the rabbits had put on weight, had become constipated, their general condition had deteriorated, and their colon had contracted. Repeat pressure measurements using the same dose of prostigmine showed the mean colonic motility index (C.M.I.) to be five times greater than the pre-dietary mean C.M.I.

Furthermore, after prostigmine scattered intertaenial temporary diverticula, similar to those demonstrated by Painter (1962) in humans, appeared. They were wide-necked, hemispherical, 0·5 cm. in diameter, blue-black in colour, and regularly appeared to be superimposed on the haustra at the same spot during contraction.

70. Colomyotomy and Intraluminal Pressures studied in the Rabbit: T. Balfour, V. Giannakos, and A. N. Smith, Edinburgh.

Twenty rabbits were submitted to colomyotomy of the Reilly type under anaesthesia (Reilly, 1966). The intracolonic pressures were studied manometrically. There was an initial fall to minimal pressures on stimulation by cholinergic agents, with a return to 50 per cent of normal in 2 months and completely in 3 months. Closure of the myotomy site by resuturing the outer muscle-coat was followed by the return of the pressure responses in 3–4 weeks.

The response of the myotomy site to distension was examined by inflating a standard excised segment; comparisons were made with normal loops and after an anastomosis. The pressures required to rupture an anastomosis were low initially. For the myotomy, pressures at or even above those required to rupture normal intestine were required.

It is concluded that the effects of myotomy in the rabbit as in man (Smith et al., 1971) are temporary. Protection of the intact myotomy site by resuture is unnecessary since the resistance to rupture is high. The fact that resuture of bowel is followed by very early return of pressure suggests that myotomy may lower pressure by widening the lumen more than by division of muscle.

71. DL-A and Isolated Pancreas Allograft: J. de Gruyl, L. Verschoor, H. M. Vriesendorp, P. Horchner, D. L. Westbroek, and H. A. M. Hulsmans, Rotterdam, The Netherlands.

The technical and functional possibilities of an isolated pancreas transplantation without adjacent duodenum was studied in the dog (Lillehei et al., 1970), and the influence of DL-A histocompatibility on isolated pancreas allograft survival was examined (Vriesendorp et al., 1971). Three groups of dogs were studied: total exocrine duct ligation was carried out on 12 dogs; autotransplantation of the isolated pancreas was performed in 17; and allotransplantation of the isolated pancreas without immunosuppressive therapy was carried out in 10 non-identical litter-mate beagles and in 10 identical litter-mate beagles.

After duct ligation only in 3 dogs some exocrine pancreas function was found, as measured by faecal α-chymotrypsine and trypsin. At a second laparotomy in these dogs some normal pancreatic tissue was found. Endocrine function of the pancreas with ligated ducts showed a decrease, as measured by the glucose-tolerance test and serum insulin, but prediabetic or diabetic levels were not reached. During the follow-up period of 2 years a restoration of function was observed. Autotransplantation in the dog had a high technical failure rate because of the triple pancreas vascularization. Some surviving dogs showed up to 3 years' normal endocrine function. The mean survival time of the non-treated non-identical group was 12 days. The mean survival time of the identical group was 40 days. The intravenous glucose-tolerance test was an impractical parameter of rejection, because it is only when the pancreas is totally necrotic that this test is abnormal.

DL-A identity showed a strong influence on non-treated isolated pancreas allograft survival.

LILLEHEI, R. C., SIMMONS, R. L., NAJARIAN, J. S., WEIL, R., UCHIDA, H., RUIZ, J. O., KJELLSTRAND, C. M., and GOETZ, F. C. (1970), *Ann. Surg.*, **172**, 405.

72. Transplantation of the Endocrine Pancreas in Guinea-pigs: J. FERGUSON and R. J. SCOTHORNE (I. D. A. Johnston), Department of Anatomy, University of Newcastle upon Tyne.

A number of reports have described transplantation of the whole pancreas by vascular anastomosis (Reemtsma et al., 1964). More recently Lillehei et al. (1971) have reviewed the current status of clinical allotransplantation of the pancreas, as a combined pancreaticoduodenal graft.

The fate of pancreatic islets isolated from all exocrine pancreas by the method of Hellerström (1964) and implanted into the testis or omentum was studied. Grafts were recovered at intervals and studied microscopically in sections stained with Gomori's aldehyde fuchsin.

Intratesticular isografts between Duncan Hartley guinea-pigs from a closed colony survived for periods of up to 90 days without any evidence of lymphocytic infiltration.

Intratesticular allografts (outbred to Duncan Hartley guinea pigs) were recovered at intervals of up to 11 weeks and showed varying degrees of lymphocytic infiltration. A minority of rejected grafts was found, the earliest at 20 days after transplantation.

Intra-omental allografts were all alive when recovered at intervals from 10 days to 11 weeks.

Intratesticular islet-cell allografts in hosts sensitized by a previous skin-graft from the same donor were rejected in an accelerated fashion, all being dead by 8 days.

This study shows the feasibility of transplanting isolated endocrine pancreatic islets in guinea-pigs. Evidence is presented which suggests that the extended survival of islets in the testis may be related to a block in the afferent side of the 'immunological reflex arc'.

73. Quantitative Studies of Bone Transplantation—The Role of the Allograft Barrier: V. M. GOLDBERG and E. M. LANCE (A. Cox), New York.

The healing of full-thickness iliac bone-grafts over a 3-month interval was studied in young adult New Zealand White rabbits, focusing on the rates of revascularization and new bone formation. The former was measured by determining the distribution of ^{51}Cr-labelled erythrocytes (Albert et al., 1958), while the latter was estimated from the uptake of ^{85}Sr (Bauer and Ray, 1958).

Revascularization of autografts proceeded rapidly for 4 weeks, peaked at 6 weeks, and was followed by a slow decline. New bone formation was maximal at 3 weeks and remained at a high plateau thereafter. The revascularization of allografts in untreated animals did not show an initial rise and remained significantly lower than autografts after the second week of observation ($P<0\cdot01$). New bone formation in allografts was comparatively slow for the first 6 weeks ($P<0\cdot001$) and rose slowly thereafter. By contrast the curves for both revascularization and new bone formation in allografts of animals treated with azathioprine were virtually superimposable on those for autografts.

These studies document and quantify the barrier imposed on bone-implant acceptance by antigenic differences and demonstrate the removal of this barrier with immunosuppressive treatment.

74. Transplantation of the Porcine Pancreas—Observations on the Metabolism of Glucose and Insulin: R. A. SELLS, M. BRAMLEY, P. MILLARD, and R. Y. CALNE, Cambridge and Liverpool.

Pancreatic transplantation in the pig has not hitherto been reported in detail. This paper describes the technique and the biochemical effects of orthotopic and heterotopic pancreaticoduodenal allografts following recipient pancreatectomy.

Nineteen pancreatic allografts were transplanted. The 12 pigs studied survived for a mean of 25 days (range 11–50 days). No immunosuppression was used.

Pancreatectomy without grafting was performed in 4 animals.

Control intravenous glucose-tolerance tests were carried out on 16 fasting, anaesthetized, normal pigs.

With orthotopic transplants (6 pigs) glucose tolerance was found to be similar to the normal control group and rejection of the pancreas was noted at post-mortem examination.

In the heterotopic transplants (6 pigs) a rapid fall in blood-sugar in response to a glucose load was noted, with greatly increased (ten times normal) rise in insulin level ($P<0\cdot005$).

Six animals with combined liver, kidney, and pancreatic transplants survived for more than 1 day, and 3 were studied at 5, 15, and 20 days. Glucose tolerance was normal. Little evidence of pancreatic rejection was found at post-mortem examination.

Orthotopic transplants secreting insulin into the portal vein result in normal peripheral blood-glucose and insulin levels.

Heterotopic grafts draining into a systemic vein produce hypoglycaemia and hyperinsulinaemia.

Pancreatic rejection occurs in the pig and may be modified by simultaneous transplantation of the liver and the kidney.

75. Hand Function—A Practical Method of Assessment: R. A. DICKSON and J. S. CALNAN, Royal Postgraduate Medical School, London.

Quantitative assessment of hand function is based largely on the measurement of grip strength using the pneumatic dynamometer (Wright, 1959). There is no method of measuring the contribution of individual digits to hand function which is so important to both patient and hand surgeon when only one digit is affected by disease. An instrument, the cybernometer, was developed for this purpose (Dickson et al., 1972).

Forty normal hands and 20 rheumatoid hands were studied using the cybernometer and the pneumatic dynamometer. The grip strength, individual digital flexion force, and pinch force (three recordings of each) were measured in random order. Fatigue was not observed.

In the normal hands the index and middle fingers were significantly stronger than the ring and little fingers ($P<0\cdot05$). The fingers of the dominant hand were significantly stronger than their non-dominant counterparts ($P<0\cdot05$). The force of pinch was approximately twice that of flexion. The grip strengths of both normal and rheumatoid hands bore no relation to the forces of their individual digits, weaknesses in rheumatoid fingers not being reflected in a diminution in grip strength.

We therefore question the value of grip strength measurements in the assessment of hand function and present the cybernometer as a more specific and accurate instrument.

WRIGHT, V. (1959), *Clin. Sci.*, **18**, 17.

76. Force and Cortical Thickness—A Relationship in the Individual Digits of the Hand: R. A. DICKSON, J. S. M. BEALES, A PETRIE, and J. S. CALNAN, Royal Postgraduate Medical School, London.

The relationship between total hand function and the cortical thickness of the hand bones has been described (Virtama et al., 1968). However, the relationship between the forces of individual digits and the dimensions of their small bones has never been reported. Such an investigation has been carried out in the hands of 15 normal adult males.

The flexion forces and pinch forces of the digits of both hands were measured using the cybernometer. Radiographs of the hands were obtained under standard conditions and the dimensions of the metacarpals and proximal phalanges were measured. From these parameters the area index was calculated (Exton-Smith et al., 1969). Correlation coefficients of flexion force and pinch force with area index were determined.

There was a significant trend at the 1 per cent level for the correlation coefficients to be positive for the metacarpal area index with pinch force. A similar trend at the 5 per cent level was observed for the proximal phalanx area index with pinch force. Flexion force and area index did not appear to be related.

SHORT NOTES OF RARE OR OBSCURE CASES

GASTRIC NECROSIS: A RARE COMPLICATION OF CHLORAL HYDRATE INTOXICATION

BY I. D. A. VELLAR, J. P. RICHARDSON, J. C. DOYLE, AND M. KEATING
DEPARTMENTS OF SURGERY, MEDICINE, AND CARDIO-THORACIC SURGERY, ST. VINCENT'S HOSPITAL, MELBOURNE

SUMMARY

A rare complication of chloral hydrate intoxication is described. Added to the initial acute cardiorespiratory and central nervous system depression, subsequent gastric necrosis and perforation provided a difficult problem in management. A satisfactory outcome was finally achieved using the Roux-en-Y technique to by-pass the stricture at the oesophagogastric anastomosis.

THE popularity of chloral hydrate as a hypnotic agent has waxed and waned over the years. First synthesized by Liebig in 1832 it proved to be an excellent hypnotic drug. It became less widely used as a result of numerous deaths from overdosage. The introduction of the barbiturates to clinical medicine by Fischer and Von Mering in 1903 (Goodman and Gilman, 1965) hastened the decline in popularity of the drug. Although chloral hydrate is a well-known irritant of the skin and mucous membranes and the effects of acute intoxication have been well documented, there have been no reports of actual necrosis of the stomach wall following its ingestion. We present this case to highlight the management of this very rare complication of chloral hydrate poisoning.

CASE REPORT

F. A., a 25-year old female, was admitted to St. Vincent's Hospital, Melbourne, on 29 Nov., 1969. The patient had suffered from depression in the past and on the day before admission she had ingested 200 ml. of syrup of chloral. This contained 20 g. of chloral hydrate. She was found unconscious and was admitted to the local hospital. Examination then showed a deeply unconscious areflexic woman with a blood-pressure of 70 mm. Hg systolic. She required intubation and assisted ventilation and was then transferred to St. Vincent's Hospital.

On admission, some 24 hours after the ingestion of the chloral hydrate, the patient was hypothermic (rectal temperature 35° C.), deeply unconscious, and areflexic, with a blood-pressure of 80 mm. Hg and a pulse-rate of 90 per minute. Widespread crepitations were heard over both lungs and it was assumed that the patient had vomited and had inhaled the vomit. A radiograph of the chest confirmed the diagnosis of widespread pulmonary oedema. Blood-gas analysis on admission showed a Po_2 of 110 mm. Hg, Pco_2 of 100 mm. Hg, and *p*H of 6·95.

The patient was treated with mannitol, frusemide, steroids, and antibiotics. The assisted ventilation was continued, and 24 hours after admission the Pco_2 had fallen to 35 mm. Hg, the rectal temperature had risen to 37·5° C., and the conscious state had improved. Three days after admission a tracheotomy was performed. The patient had become intolerant of the endotracheal tube but still required assisted ventilation to control the pulmonary oedema. The next day abdominal distension was noted. A plain radiograph revealed a large amount of gas beneath the diaphragm and a laparotomy was performed. A severe generalized peritonitis was found. The peritoneal cavity contained 2 litres of bile-stained fluid. Mobilization of the stomach then revealed that the entire fundus had necrosed. Bile was welling out through the ragged opening in the upper stomach. Owing to the difficulty encountered in the abdominal dissection and the possibility of oesophageal involvement the left chest was entered after excision of the eighth rib. The diaphragm was incised and the necrotic perforation was visualized. The perforation extended right up to the oesophagogastric junction and its edges consisted of bile-stained slough. The adjacent stomach was thick-walled and oedematous. The necrotic stomach was excised by performing an upper gastrectomy (*Fig.* 1). The cut end of the oesophagus bled freely and the mucosa appeared normal. The cut end of the stomach was oversewn and invaginated and the oesophagus was anastomosed to the posterior wall of the gastric remnant. A pyloroplasty was also performed.

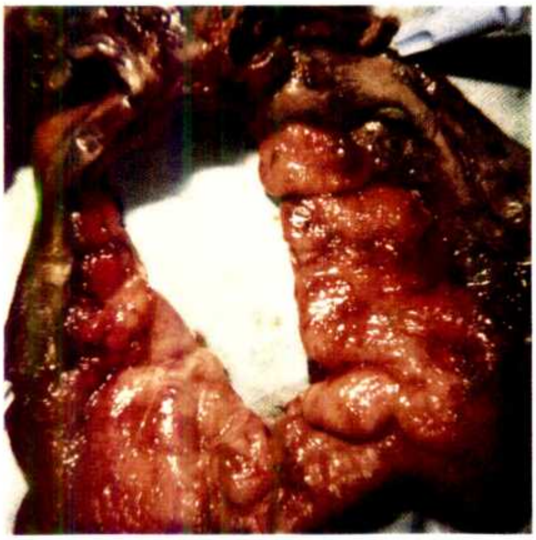

FIG. 1.—Resected stomach showing necrotic edge.

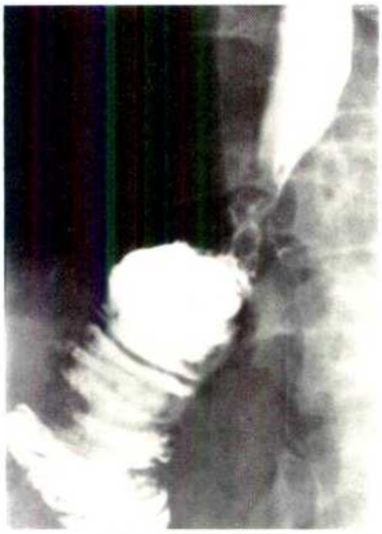

FIG. 3.—Patent oesophagojejunal anastomosis.

The patient's immediate recovery from this procedure was satisfactory and by the second postoperative day she was fully conscious. She became very confused on the third postoperative day and removed the nasogastric tube and the abdominal and thoracic drain tubes. On the fifth postoperative day dehiscence of the abdominal incision required resuturing. No leaks were apparent at this time. However, on the eighth postoperative day bile-stained fluid commenced to discharge from the thoracic wound. A Gastrografin swallow confirmed the presence of a leak from the oesophagogastric anastomosis. A further laparotomy was performed and this showed leakage from the anterior aspect of the oesophagogastric anastomosis and also leakage from the pyloroplasty. The pyloroplasty was oversewn, a large drain was replaced down to the oesophagogastric anastomosis (which was extremely friable and would not hold sutures), and finally a tube jejunostomy was fashioned using a Foley catheter.

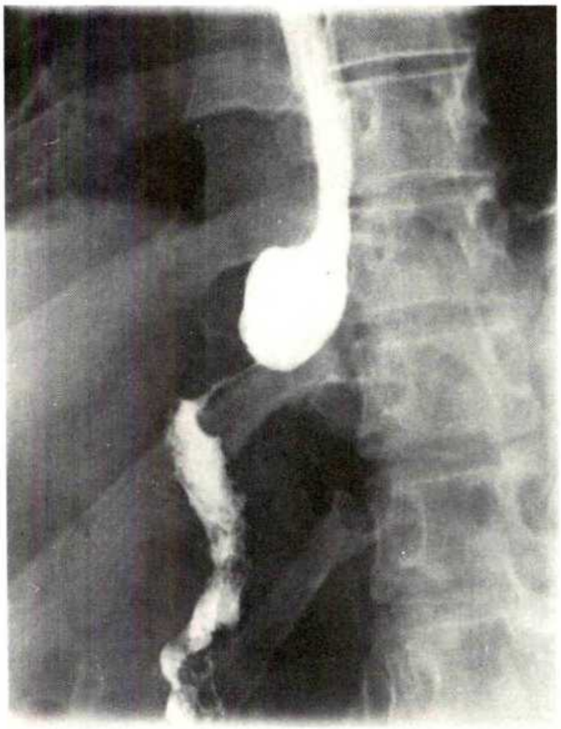

FIG. 2.—Stricture at the oesophagogastric anastomosis.

A stormy postoperative course followed. Over the next 3 weeks the patient showed a continuing pyrexia of 39°–40° C. Three massive haemorrhages from the upper gastro-intestinal tract required a total of 10 litres of blood to be infused. The thoracotomy wound became infected and partially broke down. Eventually the infection at the left lung base resolved and the drainage of gastro-intestinal fluid from the abdominal drain lessened and then stopped. A further Gastrografin swallow now showed no leak from the oesophagogastric anastomosis and the patient gradually recommenced oral feedings. The tube jejunostomy was functioning satisfactorily and the patient commenced to put on weight. However, 2 weeks later she complained of dysphagia. A tight stricture at the level of the oesophagogastric anastomosis was demonstrated (*Fig.* 2). This was confirmed by oesophagoscopy. It proved impossible to dilate the stricture. At this stage the patient was stabilized on jejunostomy feedings and was discharged home 3 months after her original admission.

One month later the patient was readmitted for definitive surgery to the stricture. She was depressed and was unable to swallow her saliva but her nutritional state was good. A barium swallow showed complete obstruction at the level of the oesophagogastric anastomosis. The thoracotomy wound had almost healed except for a number of superficial sinuses. It was proposed to by-pass the stricture using a Roux loop. As the left pleural cavity had previously been infected it was necessary to approach the lower oesophagus from the right side.

An exploratory laparotomy was performed. There were surprisingly few adhesions in the peritoneal cavity except beneath the left side of the diaphragm. The stomach remnant was shrunken and indurated. It was an easy matter to fashion a Roux loop, and then the patient was turned on her left side and a right thoracotomy was performed through the eighth interspace. The lower oesophagus was mobilized and transected just above the diaphragm. The distal end of the oesophagus was oversewn. The jejunum was led in front of the colon and the left lobe of the liver and then through a hole in the diaphragm and finally was anastomosed end to end to the oesophagus. The Roux-en-Y loop was completed by an end-to-side anastomosis of proximal to distal jejunum within the abdomen.

The postoperative course on this occasion was satisfactory and a Gastrografin swallow 7 days later revealed an intact anastomosis (*Fig.* 3). Three weeks later an oesophagoscopy was performed and this confirmed a widely patent anastomosis between the oesophagus and the jejunum. The patient was discharged swallowing well 1 month after the operation.

DISCUSSION

Acute intoxication by chloral hydrate is manifested by cardiovascular, respiratory, and central nervous system depression. Clinically, hypotension and various cardiac arrhythmias may occur (Gleich, Mongan, and Vaules, 1967). Chloral hydrate apparently accelerates the breakdown of coumarin derivatives. This action may lead to inadvertent overdosage of the anticoagulant when the administration of chloral hydrate is discontinued (Cucinell, Odessky, Weiss, and Dayton, 1966). The local irritant effect of chloral hydrate is well known. The nausea and vomiting which may follow its ingestion are undoubtedly due to its irritant effect on the gastric mucosa. There have only been 2 reports incriminating chloral hydrate intoxication with damage to the gastro-intestinal tract. One case (Gleich and others, 1967) presented as an oesophageal stenosis after the ingestion of 18 g. of chloral hydrate. This responded satisfactorily to dilatation. The second case (Feller, 1929) died after ingesting 150 g. of chloral hydrate. At autopsy the gastric mucosa showed widespread necrosis. Full-thickness necrosis of the stomach wall following the ingestion of a potentially lethal amount of chloral hydrate has not previously been reported.

The case presented here provided continuing difficulty in management. The initial respiratory failure, hypotension, hypothermia, and pulmonary oedema in a deeply unconscious patient merged into the management of massive gastric necrosis with generalized peritonitis. The catastrophe resulting from the suture-line leaks may have been precipitated in part by the presence of even more extensive gastric damage than was realized at the time of operation. It is possible that this may have impaired healing at the anastomosis, thus contributing to the leaks from the pyloroplasty and oesophagogastric suture lines (Gray and Holmes, 1948). The formation of a feeding jejunostomy proved to be of vital importance in maintaining nutrition as the patient eventually developed complete obstruction at the oesophagogastric junction. Fortuitously, the line of jejunal transection in fashioning the Roux loop coincided exactly with the site of the jejunostomy. Though the approach through the right chest added somewhat to the technical difficulties, a satisfactory by-pass of the stricture was achieved using the Roux technique. This was confirmed radiologically, at oesophagoscopy, and by the ability of the patient to swallow solids without difficulty.

Acknowledgement.—We wish to thank Professor Bennett for permission to report this case.

A CASE OF XANTHOGRANULOMATOUS PYELONEPHRITIS

By CLIVE BARTRAM and DAVID JAGELMAN

WESTMINSTER HOSPITAL, LONDON

SUMMARY

A patient with a non-functioning kidney was investigated. Although the arteriographic findings suggested an inflammatory process, a malignant lesion could not be excluded. The appearance of the kidney at operation suggested malignancy but histological examination following nephro-ureterectomy showed xanthogranulomatous pyelonephritis. This is an uncommon reaction to severe renal infection and is often associated with upper renal tract obstruction. The clinical and radiological findings of this condition are reviewed.

The case which is presented here illustrates the difficulty of diagnosing an unusual condition in a non-functioning kidney. Radiologically the presence of a neoplasm could not be excluded, and at operation the appearances of the renal mass suggested an invasive malignant process. The infective nature of the lesion was only revealed histologically on paraffin section, a frozen section at the time of operation being inconclusive.

CASE REPORT

A 47-year-old woman presented with a 2-year history of left loin pain and recurrent urinary infection. On clinical examination she was mildly anaemic and had a palpable left-sided renal mass.

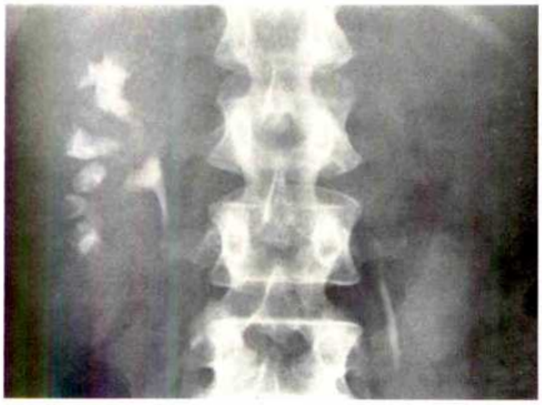

FIG. 1.—Post-micturation intravenous pyelogram, showing a non-functioning left kidney but with contrast present in the left upper ureter.

Investigations showed the following: haemoglobin, 11·1 g. per 100 ml.; W.B.C., 10,300 per c.mm.; E.S.R., 54 mm. per hour (Wintrobe); and a midstream specimen of urine contained a lactose-fermenting coliform. Culture for *Mycobacterium tuberculosis* was negative. An intravenous pyelogram showed a normal right kidney and a non-functioning left kidney. However, on the full-length post-micturition film (*Fig.* 1) some contrast was seen in the upper part of the left ureter. A micturating cystogram confirmed left vesico-ureteric reflux, and the left renal pelvis was dilated. However, both the micturating cystogram and a left retrograde pyelogram examination failed to define the calices adequately. A selective left renal arteriogram was performed via a right femoral catheterization. The capillary phase (*Fig.* 2 A) showed a large capsular artery, a thinned cortex with areas of increased capillary density, and stretching of the vessels in the region of the dilated pelvis. The nephrographic phase (*Fig.* 2 B) confirmed the presence of only a small amount of functioning tissue of irregular density and some opacification of the pelvis. It was thought that the left kidney was extensively damaged and hydronephrotic as a result of reflux and repeated infections. Although there was no definite neoplastic circulation, the presence of an abnormal capillary circulation raised the possibility of malignant change.

The left kidney was explored via a left paramedian incision. The renal substance was irregular and was whitish yellow in appearance. It was firmly adherent to the surrounding structures, invading the transverse mesocolon, and there was an associated perinephric abscess. The features suggested a neoplasm but a frozen section was inconclusive. A left nephro-ureterectomy was performed (*Fig.* 3) and the patient made an uneventful recovery.

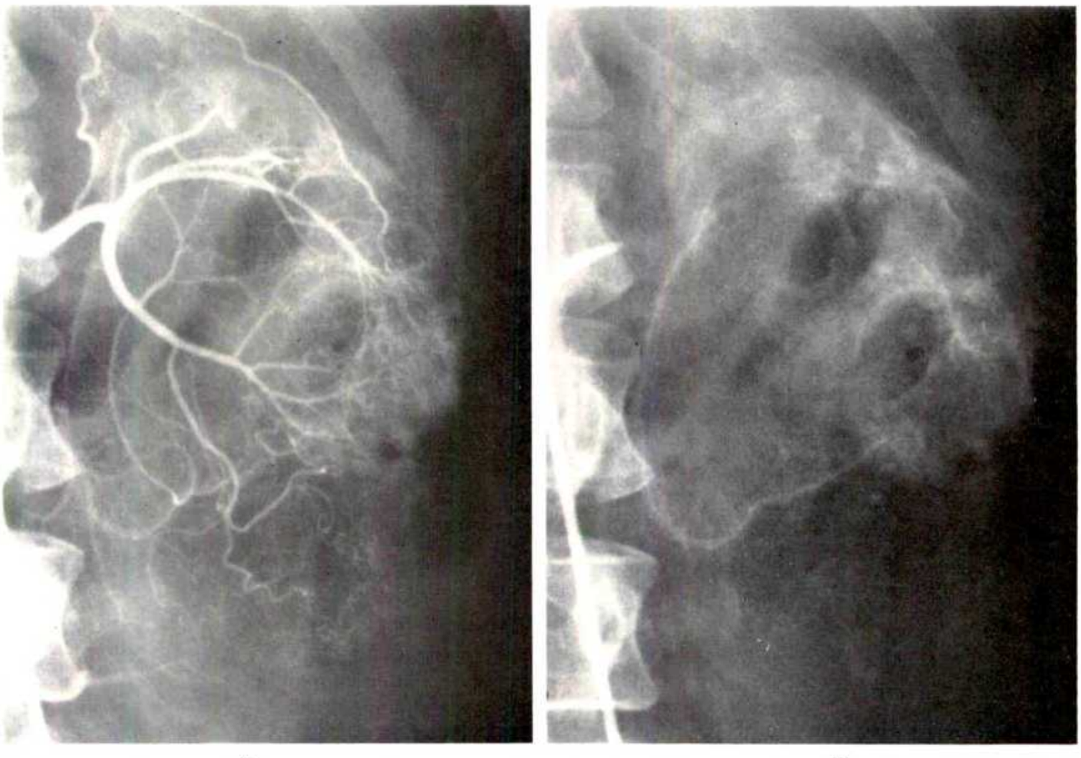

FIG. 2.—Selective left renal arteriogram. A, The capillary phase showing reduced renal tissue, irregular capillary density, and stretching of the vessels around the pelvis. B, The nephrographic phase confirms the irregular density of the cortex and shows opacification of the pelvis.

Pathological examination of the specimen revealed a grossly distorted kidney with severe hydronephrosis and pyelonephrosis. On the cut surface there were numerous yellow nodules, some of which extended into the perinephric fat. Histologically, there was severe pyelonephritis with focal areas of granulomatous reaction with giant cells and macrophages containing foamy cytoplasm. No acid-fast bacilli were seen. These features were regarded as compatible with a diagnosis of xanthogranulomatous pyelonephritis.

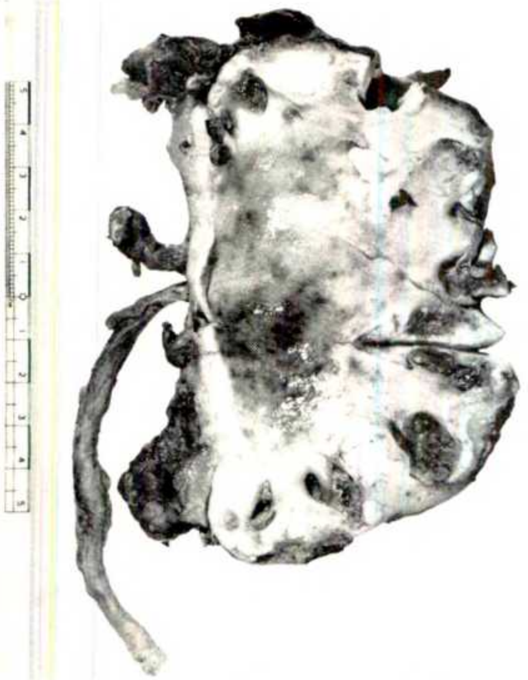

FIG. 3.—The left nephrectomy specimen. Note the presence of nodules and extensive renal damage.

DISCUSSION

Xanthogranulomatous pyelonephritis was first described by Schlagenhaufer in 1916. It is an uncommon reaction to severe renal infection, probably occurring in about 3 per cent of such cases (Elliott, Johnson, and Balfour, 1968), involvement being on one side only. Clinically, the following features are often present: recurrent urinary-tract infection, loin pain, a tender palpable renal mass, low-grade fever, mild anaemia, and bacteriuria (Hooper, Kempson, and Schlegel, 1962; Friedenberg and Spjut, 1963; Rios-Dalenz and Peacock, 1966).

The usual finding on intravenous pyelography is that the kidney is non-functioning owing to calculus or pelvi-ureteric obstruction, and when the kidney is visualized it is often enlarged. Xanthogranulomatous pyelonephritis does not appear to occur in the small shrunken kidney. The cortex is irregular and filling defects are present; these may also be seen in the pelvis. The pelvi-ureteric junction is often irregular. The loss of perinephric fat may suggest a perinephric abscess. The defects seen on pyelography raise the possibility of renal carcinoma, and quiescent renal tuberculosis should be considered in the differential diagnosis.

Few case reports have included arteriographic findings. Salmon and Koehler (1967), however, demonstrated that xanthogranulomatous pyelonephritis is vascular, and the arteriographic differences between an inflammatory and a malignant process are summarized in *Table I*.

Unfortunately the use of epinephrine will not help to distinguish the lesion, for, as was demonstrated by Kahn and Wise (1967), the renal arteries in the affected area fail to show the normal vasconstriction. The arteriographic findings, therefore, may be able to suggest that the lesion is inflammatory but verification must await histological examination. The microscopic features, as described by Heptinstal (1966), are of giant cells and macrophages containing a foamy cytoplasm.

Table I.—SUMMARY OF THE ARTERIOGRAPHIC FEATURES THAT DIFFERENTIATE AN INFLAMMATORY PROCESS FROM A MALIGNANT PROCESS

Inflammatory Process	*Malignant Process*
Stretching of vessels over lesion	Arteries of irregular calibre
Minimal irregularity of arteries	Early filling of abnormal circulation
Dense capillary blush in affected areas during normal capillary phase	Rapid filling of large irregular veins
Veins fill at normal rate	Pooling of contrast
No contrast pooling	Feeding arteries may be present
Large capsular artery if perirenal involvement

A CASE OF CARCINOMA OF THE COLON IN ASSOCIATION WITH NEUROFIBROMATOSIS

By D. H. R. JENKINS* and W. GILL
DEPARTMENT OF CLINICAL SURGERY, UNIVERSITY OF EDINBURGH

SUMMARY

A case is presented of neurofibromatosis of the large bowel associated with a primary adenocarcinoma of the colon. This is believed to be the first report of such an association.

NEUROFIBROMATOSIS occurs once in every 2500–3000 live births (Lukash and Johnson, 1969). The disease was first described in 1882 by von Recklinghausen and may involve the skin, bladder, blood-vessels, bones, stomach, ileum, colon, and tongue (Russel, 1965). The severity of the cutaneous lesions bears no relationship to the presence of disease in other tissues (Leader Article, *Br. med. J.*, 1966), and the condition may be associated with mental deficiency, endocrinal somatic retardation, and phaeochromocytoma. Visceral neurofibromatosis is infrequent, and a study of 1399 examples of benign neoplasms of the small intestine revealed only 14 cases of neurofibromatosis (River, Silverstein, and Tope, 1956). These authors commented on the restricted involvement of the intestine when the disease was present.

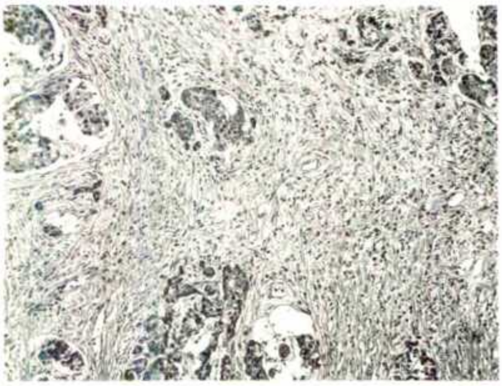

FIG. 1.—Clumps of adenocarcinoma intimately mixed with neurofibromatous tissue. H. and E. (× 66.)

Involvement of the large bowel by neurofibromatous tissue is rare (Weston, 1963) and usually becomes apparent only with malignant change of the abnormal tissue, which may occur in 10–15 per cent of cases (Hosoi, 1931; Crowe, Schull, and Keel, 1956) and results in sarcoma.

The case described here is that of an adenocarcinoma growing within neurofibromatous tissue in the colon. We have been unable to find any record of this association in the literature.

CASE REPORT

A 49-year-old unemployed labourer suffering from cardiac asthma presented as a surgical emergency to the Royal Infirmary of Edinburgh. The patient complained of constant, severe, generalized abdominal pain and appeared markedly dehydrated. One month prior to admission he had experienced intermittent, central abdominal pain of a colicky nature which had been relieved by the passage of flatus and diarrhoea. The diarrhoea had persisted and the faeces had occasionally been black in colour.

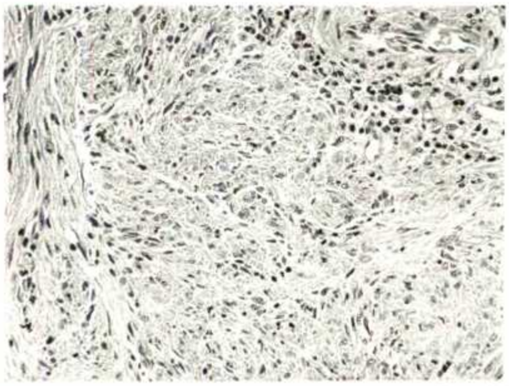

FIG. 2.—Photomicrograph of a representative polyp. H. and E. (× 100.)

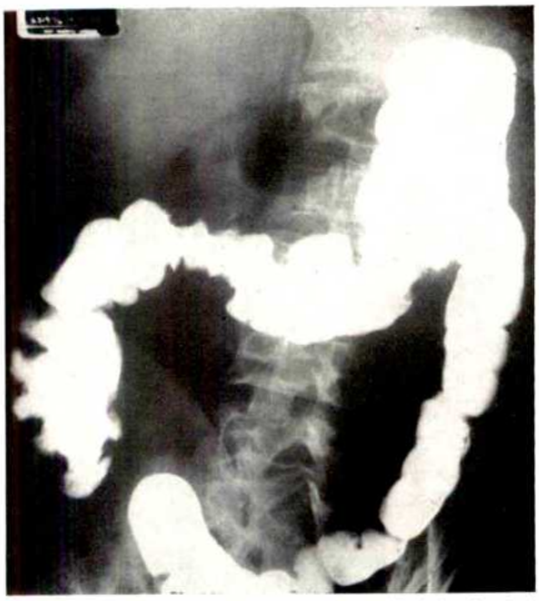

FIG. 3.—Barium-enema film demonstrating multiple intraluminal nodules in the ascending colon.

Now, now, now, what's going on
down here?

To be precise, sir, unnecessary bleeding. That's why we're "topping him up" – he's lost a litre or more[1,2].

Transfusion is costly and not without risk. By using EPSIKAPRON, post-prostatectomy blood loss can be cut by 80 per cent or more[3,4]. Moreover, ". . . blood transfusions can be avoided and draining catheters kept patent without difficulty and removed earlier, which makes the post-operative course smoother and shorter"[4].

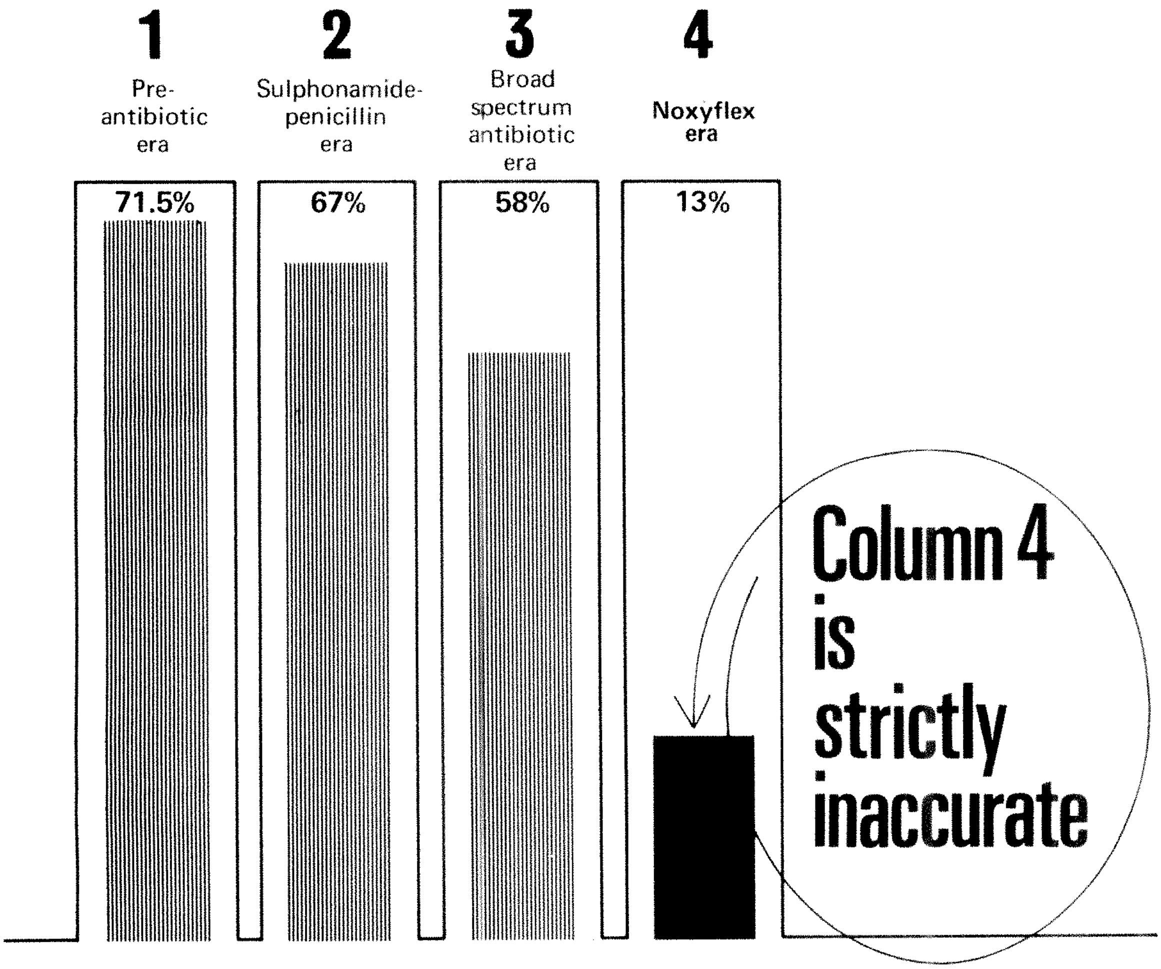
The graph below compares mortality rates due to faecal peritonitis, era by era.
It is not pedantically accurate because its sources differ. But the point is fairly made.



Why inaccurate? Because column 4 refers to 23 cases of faecal peritonitis which were treated successfully with Noxyflex. But the *3 deaths which occurred were due to causes other than peritonitis - as post-mortem revealed. **The mortality rate due to peritonitis can therefore be regarded as zero.**

* The whole graph, and the causes of the deaths referred to are the subject of the new Noxyflex folder "Why three deaths?" You will receive at least one copy!

When bacterial contamination of the peritoneum is diagnosed or suspected: Noxyflex

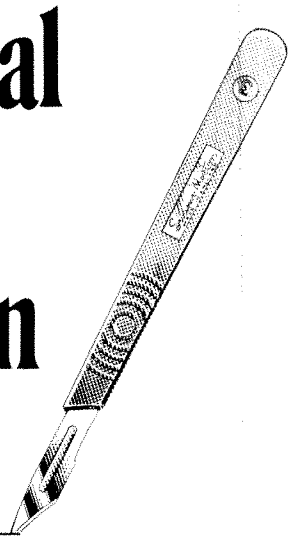
Swann-Morton surgical blades have an edge over the others



Swann-Morton of Sheffield are one of the largest manufacturers of surgical blades in the world. The Company achieved this leading position through the unvarying high quality of its products.

Swann-Morton blades are manufactured of the finest tempered surgical steel, precision-ground to give edges of the high degree of sharpness essential for the most delicate surgery. Swann-Morton blades are safe, stable and economical. They are sterilized by gamma radiation, packed in quick-peel foil envelopes and colour-coded for easy recognition. They can also be kept indefinitely under any conditions of storage and climate.

Here are details of the Swann-Morton range of products:
Sterilized stainless steel blades
Sterilized carbon steel blades
Standard carbon steel blades
Sterile disposable scalpels
Sterile disposable stitch cutters
Surgical handles
Autoclavable plastic surgical handles

With the **HANAULUX GLASS FIBRE OPTIC LAMP**

The Glass Fibre Optic Satellite Lamp gives concentrated illumination for cavities and other areas requiring additional light, and because the light emitted is absolutely cold (being free from infra-red) the sterilizable flexible light-head can be adjusted by the surgeon and the possible drying of a wound is obviated.

Of particular value in neurosurgery, ENT and gynaecology, this lamp has maximum manoeuvrability and remains firmly in any adjusted position. The light-head can, in fact, be moved down to table top level.

This Hanaulux Glass Fibre Optic Lamp can be satellite-mounted on the main operating lamp, or installed as a separate wall or ceiling unit.

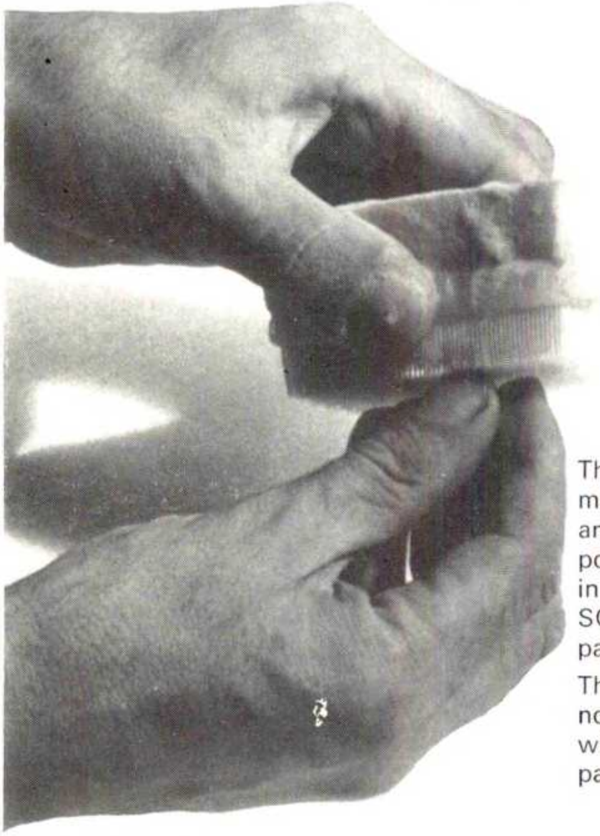
DESERET® E-Z SCRUB

surgical scrub brush and sponge with its own 3% Hexachlorophene detergent cream instant suds and nail cleaner



The patented E–Z (say Easy) SCRUB is the modern way to scrub up in the theatre, gentle and consistently effective, combining both disposable brush and detergent cream-filled sponge in individually wrapped and sterile pack. E–Z SCRUBS are also ideal for high risk emergency packs.

The pH 5.5 detergent cream is hypoallergenic and non-irritating. The E–Z SCRUB is available also with a complexed iodine microbicide, both packed in 25 pack dispenser.

Matburn Built-in Equipment for the Operation Theatre

There is a growing tendency in theatre design towards the use of built-in equipment systems in order to clear the theatre floor of trailing wires and tubes, suction and electrosurgery units and similar equipment.

To meet the needs of fixed services systems, a superb range of Matburn equipment has been evolved, representing many years of experience in this specialised field.

Matburn Fixed Services Systems are designed for installation in both new and existing hospitals; the technical advice of a team of skilled engineers is available at all stages of projects.

The illustration, reproduced by kind permission of the South East Metropolitan Regional Board, shows a fixed services table with mobile base installed in the Abnormal Delivery Theatre of the Greenwich District Hospital, London.

ESCHMANN

Eschmann Bros. & Walsh Limited,

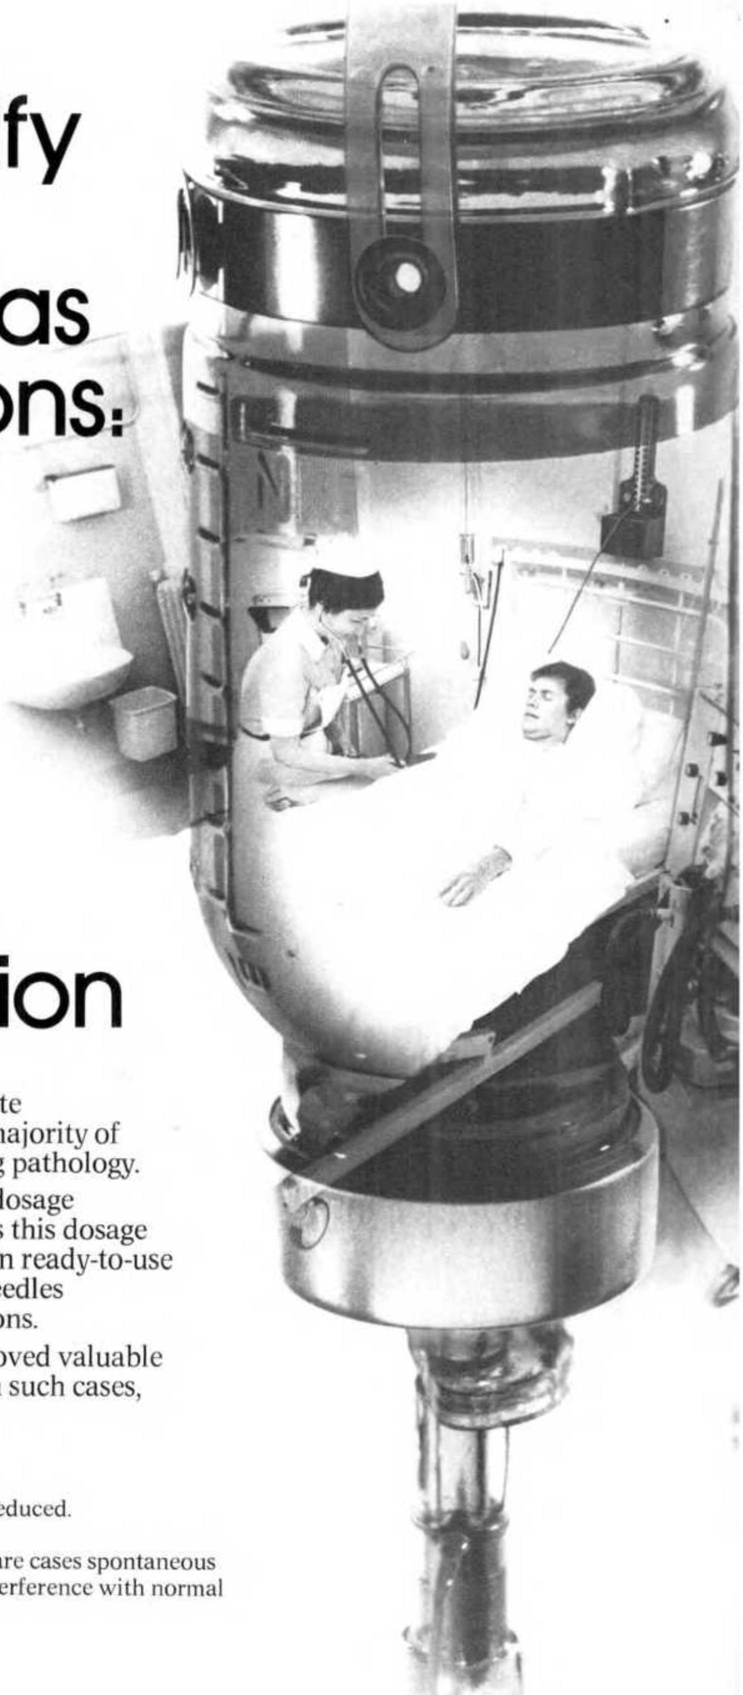
Sussex, England BN4 5EB.



Now, to simplify treatment of pseudomonas chest infections:

Pyopen infusion

In the published papers, Pyopen's success rate in chest infections is 65% even though the majority of the patients described had severe underlying pathology.

The best results have been achieved with a dosage of 20-30G. I.V. daily. Pyopen infusion makes this dosage simpler to administer by providing Pyopen in ready-to-use infusion bottles with diluent and transfer needles for the easier preparation of infusion solutions.

Pyopen is, of course, a penicillin, and has proved valuable in patients with known renal impairment: in such cases, however, dosage should be reduced.

Adult dosage: 20-30G. I.V. daily.
In patients with renal impairment dosage should be reduced.
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen

Further information is available on request.
Pyopen* (carbenicillin sodium B.P.) is a British product originated by
Beecham Research Laboratories, Brentford, England. *regd.

The patient claimed a loss in weight of 12 kg. over this period.

On examination the patient had generalized cutaneous neurofibromatosis and café-au-lait spots. His abdomen was acutely tender in all areas, with apparent rebound tenderness. No palpable intra-abdominal masses were present and a rectal examination was unhelpful, although the test for faecal occult blood was positive. The white blood-count was 10,100; haemoglobin, 9·8 g. per cent; blood-urea, 39 mg. per cent, and the serum amylase and electrolytes were normal. Plain radiographs of the abdomen indicated obstruction of the small bowel and the ascending colon, although clinically the abdomen was not distended.

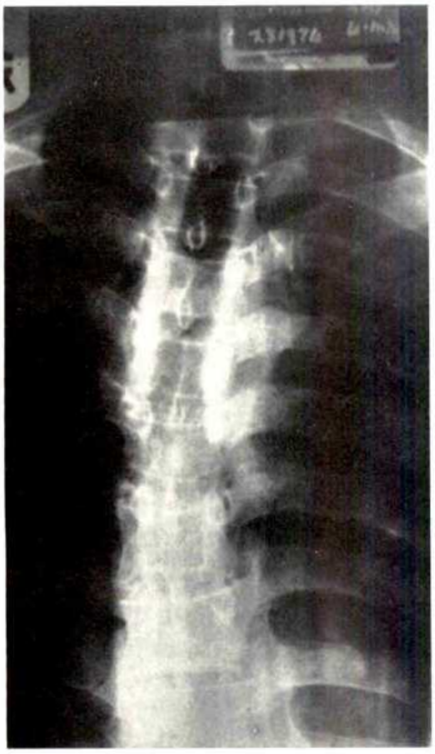


FIG. 4.—Collapsed 5th thoracic vertebra.

At laparotomy a stenosing annular neoplasm of the transverse colon was present, with regional lymph-node involvement. The transverse colon was unusually long and pendulous, and the entire colon contained numerous yellowish-white intramural nodules of a rubbery consistency which were situated so that no line of resection free from involvement could be found. A limited transverse colectomy was performed, transecting colon which was involved by the neurofibromatosis. The end-to-end anastomosis was carried out with difficulty owing to the irregular thickness of the bowel wall containing the intramural nodules.

A small anastomotic leak developed on the sixth postoperative day but had closed spontaneously 5 days later. Thereafter the patient made an uneventful recovery.

Macroscopic examination of the surgical specimen showed that the ulcerating annular neoplasm had fully penetrated the colonic wall and was surrounded by polypoidal masses in the adjacent bowel. Histological examination demonstrated an adenocarcinoma with massive involvement of the lymph-nodes. The carcinomatous tissue was intimately mixed with neurofibromatous tissue (*Fig.* 1) and the adjacent polyps showed the microscopic features of neurofibromata (*Fig.* 2).

A barium-enema examination 2 weeks after the resection displayed multiple intraluminal nodules, varying in size and distributed predominantly in the ascending and residual transverse colon (*Fig.* 3). A skeletal survey at this time revealed thoracic scoliosis in association with a collapsed fifth thoracic vertebra (*Fig.* 4).

DISCUSSION

Neurofibromatosis is a hereditary condition dependent on a dominant gene. Fifty per cent of cases have affected relations (Lukash and Johnson, 1969). The identity of our patient's parents and siblings is unknown, but his children appear to be unaffected. Kyphoscoliosis is the most common osseous abnormality reported, and it occurs in approximately 10 per cent of all patients with neurofibromatosis (Meszaros, Guzzo, and Schorsch, 1966). The scoliosis and vertebral collapse which were present in our patient may indicate replacement of the vertebral body by neurofibromatous tissue or it may be due to secondary spread from the carcinoma.

Levy and Khatib (1960) in their report of a case of von Recklinghausen's disease with asymptomatic involvement of the small and large intestines suggest that visceral involvement is more common than is normally supposed. They suggest that thorough radiological examination of the chest and the gastro-intestinal tract in all cases of von Recklinghausen's disease and prompt surgical excision of the affected bowel should be carried out. Lukash, Morgan, Sennett, and Neilson (1966) support the suggestion of Levy and Khatib (1960) on the incidence of gastro-intestinal involvement and favour local excision as the treatment of choice. Zbinden (1951), in contrast, recommends a conservative policy of observation.

This prognosis of the patient presented here is especially poor in view of the double pathology, the extensive lymphatic metastases, and the vertebral erosion of unknown aetiology. In the presence of sarcomatous degeneration most authors favour resection and continuing supervision of the residual involved bowel. The controversial aspect of this case is in the management of the remaining neurofibromatous bowel.

A CASE OF INTRALUMINAL DIVERTICULUM OF THE DUODENUM

BY HUGH P. GUERRIER AND MAURICE J. TURNER
NEWTON ABBOT HOSPITAL, DEVON

SUMMARY

The rare anomaly of intraluminal duodenal diverticulum is illustrated by a case history. Twenty-three earlier cases are quoted. In the discussion attention is drawn to the varied clinical presentation which may occur, including the possibilities of intestinal haemorrhage and subacute obstruction. The importance of radiology in making a pre-operative diagnosis is stressed. Theories of possible causation are briefly reviewed.

DIVERTICULA of the duodenum are common enough to be seen almost daily by the practising radiologist. Taking the form of protrusions of the duodenal wall and often lying within the curve of the second part, they occur frequently in the periampullary region. These diverticula are regarded as being usually of little clinical significance. Very rare, by contrast, is the intraluminal diverticulum, only 23 reports of which have been found in the literature. Seventeen cases including the 1 reported here have been confirmed at operation. The remaining cases showed such characteristic radiographic appearances that a confident diagnosis was made (although in 1 patient in this group who later came to operation no diverticulum was found; Heilbrun and Boyden, 1964).

An intraluminal diverticulum is a pouch lying inside the lumen of the duodenum and attached by its neck to the duodenal wall. The opening of the pouch communicates with the duodenal lumen. In the published cases the sex incidence was equal, and the average age at the time of diagnosis was 35 years, the youngest patient being 11 and the oldest 59. Only 1 case has been reported in a child.

The lesion, although rare, is worthy of notice because it can cause serious abdominal symptoms, in particular, intestinal haemorrhage and subacute obstruction. Haematemesis or melaena occurred in 5 of the 24 cases and in 3 patients was associated with severe anaemia (Hb 5·6 g. per cent or less). Another patient suffered from haemorrhagic diarrhoea. Symptoms suggesting repeated attacks of subacute obstruction were reported in 5 of the cases, including our patient. In the majority of instances there were symptoms of mild, chronic, or intermittent dyspepsia, often dating from childhood.

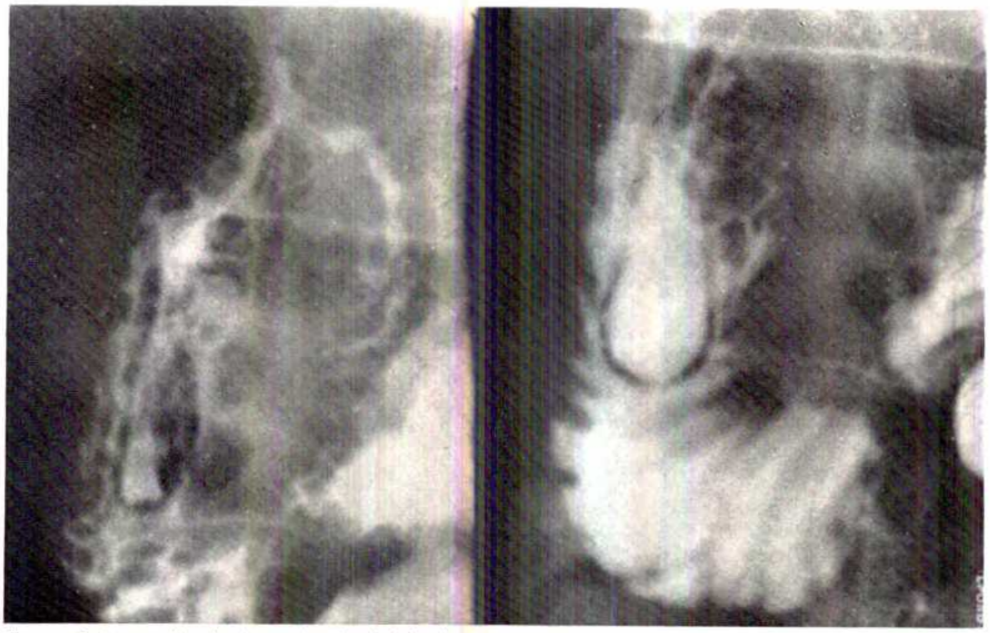

FIG. 1.—Barium studies showing an intraluminal duodenal diverticulum (A) almost empty and (B) distended with barium.

CASE REPORT

A carpenter, aged 41 years, complained of 3-weekly bouts of epigastric pain and vomiting over the previous 12 months, usually occurring about half an hour after a heavy meal. The pain was relieved by vomiting, after which he felt quite well again. He reported a loss of weight of 6·3 kg. Bowel function was regular and there had been no haematemesis or melaena. The patient had

had an appendicectomy 12 years previously but denied any digestive troubles in childhood.

Physical examination was entirely negative.

RADIOLOGICAL FINDINGS.—Barium meal showed a normal oesophagus and stomach, but in the second part of the duodenum barium was held up intermittently in the form of a pouch inside the lumen (*Fig.* 1 B). This pouch varied in shape and size with peristaltic movements. At times it was so small as to be scarcely visible (*Fig.* 1 A). At other times it measured 4 cm. in length and 1·5 cm. in width.

The appearances were interpreted as being caused by an intraluminal diverticulum attached fairly high up on the internal wall of the second part of the duodenum. From this point the diverticulum reached distally as far as the third part of the duodenum when distended. On the radiographic films the shadow of the barium was bounded by a thin radiolucent line which was taken to represent the membranous wall of the diverticulum.

There was some degree of dilatation of the first part of the duodenum, suggesting that intermittent obstruction of the second or third parts had taken place.

OPERATION.—Laparotomy was performed through a midline incision. Considerable peristalsis was seen in the region of the pylorus and the first and second parts of the duodenum, but no other abnormality was visible at this stage. The first and second parts of the duodenum were fully mobilized. A small portion of aberrant pancreatic tissue was found in close association with the second part of the duodenum, but this did not amount to a true annular pancreas nor was the abnormality sufficient to be considered a likely cause of obstruction. The second part of the duodenum was then opened and an intramural diverticulum or pouch was found on the posterior wall. The point of attachment was comfortably clear of the ampulla of Vater. The diverticulum was mobilized, everted, and excised, and a running suture was placed through the excised mucosal edges into the duodenum, which was closed in two layers. The abdomen was closed with a Redivac drain.

The patient made an uninterrupted recovery and 2 years later he is symptom-free and eating very well.

DISCUSSION

Table I shows the details of the 24 reported cases of intraluminal duodenal diverticulum. There seems no reason to doubt that the majority are of congenital origin, and one theory is that the diverticulum is produced by peristaltic pressure on the upper surface of a perforate congenital diaphragm of the duodenum. Several descriptions accord well with this theory (Silcock, 1885; Nelson, 1947; Meyer and Edgren, 1956; Coors and Mitchum, 1962; Curtis, Simpson, and Lowdon, 1965). In other cases, however, the pouch is attached only to a small part of the circumference of the gut and other theories have been proposed, such as partial reduplication of the duodenum or a pulsion effect upon a prominent mucosal fold. The fact that different structural forms of diverticula are found at operation suggests that more than one mode of formation is responsible. The case of Wenz (1963) is of particular interest in that two separate intraluminal diverticula were found in the same patient.

There are other associations which may be relevant. One case of intraluminal duodenal diverticulum occurred in a Mongol and there is known to be a relatively high incidence of duodenal stenosis and atresia in Mongols (Curtis and others, 1965). The association of a congenital duodenal septum with an annular pancreas is well known (Harper, 1967), and in 3 of the 24 cases of intraluminal diverticulum, including the case reported here, the presence of a partial degree of annular pancreas or other pancreatic anomaly has been observed (Coors and Mitchum, 1962; Petty and Mousley, 1966). In the case of Buisseret and Van Den Eynde (1962) an associated malrotation of the gut with the common mesentery was recorded.

Table I.—SUMMARY OF THE DETAILS OF 24 RECORDED CASES (12 MALES AND 12 FEMALES)* OF INTRALUMINAL DUODENAL DIVERTICULUM

SIGNS AND SYMPTOMS		RADIOLOGICAL FINDINGS		OPERATION (17 Cases)	
Details	No. of Cases	Details	No. of Cases	Details	No. of Cases
Pain; usually epigastric and intermittent	17	Intraluminal pouch	21	Site of pouch near ampulla of Vater	12
Vomiting	6	Changing size of pouch during examination	13	Histology: pouch formed of mucous and submucous tissues with muscularis mucosae	12
Bleeding; usually melaena	6			Inflamed pouch	1
Symptoms since childhood	5			Ulcerated pouch	2
Diarrhoea	3			Foreign body in pouch	
Physical signs: tender epigastrium only	5				

* Age—average: 35 years; youngest 11 years; oldest 59 years.

In several patients foreign bodies have been found in the diverticula, such as a penny (Meyer and Edgren, 1956) and food debris (Wiot and Spiro, 1963). Ulceration of the diverticulum was found in 2 cases who had presented with melaena (Zatzkin, Macy, and Kveton, 1959; Kessler and Witmer, 1964).

It is noteworthy that in the great majority of cases who had operations the site of attachment of the diverticulum was found to be near the ampulla of Vater, showing the need for special operative care to avoid damage to the biliary or pancreatic ducts, a complication which has been reported in 1 instance (Wiot and Spiro, 1963). The 5 other recorded cases had no special features (Kinzer, 1949; Köhler, 1960; Hirsch and Mal, 1962; Laudan and Norton, 1963; Newman and Nathan, 1968).

AN UNUSUAL DISLOCATION OF THE HIP

BY R. F. BROWN[*] AND F. A. SIMMONDS
ROWLEY BRISTOW ORTHOPAEDIC HOSPITAL, PYRFORD, WOKING, SURREY

ANTERIOR dislocations of the hip-joint are classified into pubic, perineal, and obturator types, and of these the last is the most common. We wish to report a case of an obturator dislocation which differs from the usual type, where the head of the femur rests in the obturator foramen, in that the head passed almost completely through the foramen and became locked in this position.

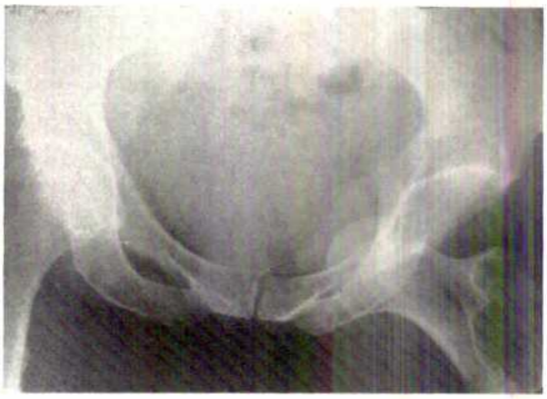

FIG. 1.—Radiograph showing an obturator dislocation of the hip with the head of the femur protruding almost completely through the obturator foramen.

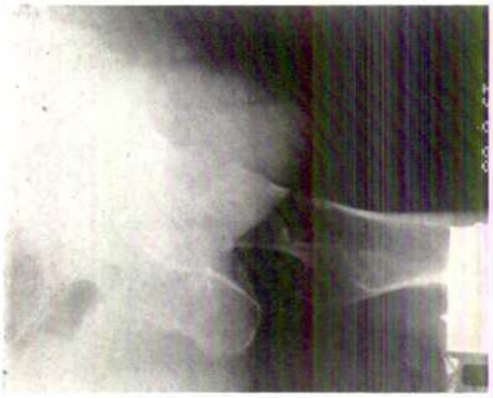
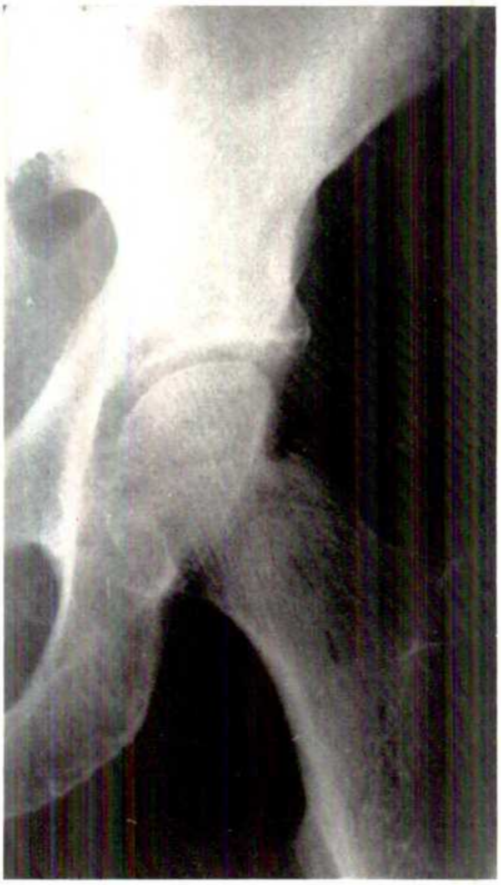


A



B

FIG. 2.—Radiographs showing the dislocation to be reduced. A notch is present on the anterosuperior aspect of the head of the femur. A, Lateral view. B, Anteroposterior view.

CASE REPORT

Mrs. K., aged 57 years, had been a front-seat passenger in a car which had overturned while travelling at about 30 m.p.h. On admission to hospital she was unable to remember the accident clearly owing to a minor head injury, but she did complain of pain in the region of the left hip. There was no previous history of hip trouble. On examination the patient was obese and there was no obvious swelling in the region of the left hip. The left thigh was held fixed in a position of 30 degrees of abduction, slight flexion, and in mid-rotation. The region was moderately tender but careful palpation failed to reveal the head of the femur in the perineum, in the groin, or in the buttock. All pulses in the leg were present and there was no nerve damage. There was neither active nor passive movement at the hip-joint.

---

[*] Present address: Royal Hospital, West Street, Sheffield 1.

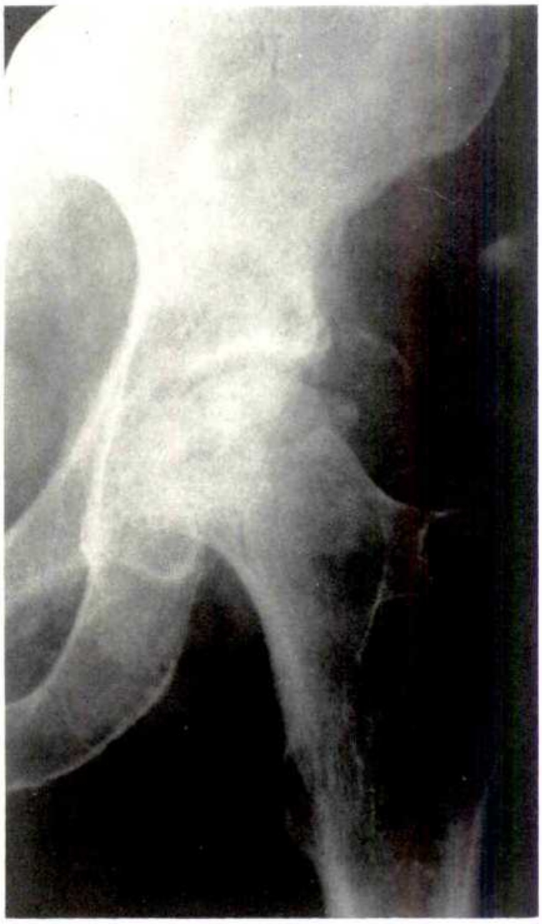


FIG. 3.—Radiograph showing avascular necrosis of the head of the femur.

Radiographs (*Fig.* 1) showed an obturator dislocation of the hip with the head of the femur protruding almost completely through the obturator foramen. The lateral radiograph confirmed that the dislocation was not of the pubic type, but the quality was too poor to reproduce.

Under a general anaesthetic the head of the femur was found to be firmly locked in the dislocated position. Longitudinal traction was applied and an attempt was made to lever the head back into the acetabulum using the operator's knee in the adductor region as a fulcrum. This appeared to fail but it must have disengaged the head, because, while breath was being regained, a simple rotation of the leg was performed and the hip reduced.

Radiographs at this stage (*Fig.* 2) showed the dislocation to be reduced and revealed a notch on the anterosuperior aspect of the head of the femur, which, in retrospect, had also been present in the previous radiographs (*Fig.* 1). Skeletal traction was applied and maintained for 3 weeks, and after a further week's bed-rest with the leg free the patient was allowed to walk, taking partial weight on the leg. She was discharged 7 weeks after injury walking with the aid of elbow crutches.

Subsequently the head of the femur developed avascular necrosis and disintegrated (*Fig.* 3). Eighteen months following injury a McKee–Farrar prosthesis was inserted (*Fig.* 4). The notch shown on the early radiographs could not be identified with certainty at operation owing to the deterioration of the femoral head. Two months after the operation the patient was pain-free and walking with aid of the one stick.

DISCUSSION

A search of the literature has not revealed a case in which the greater part of the head of the femur has passed through the obturator foramen or one in which the head has become immediately impacted in the foramen. There are, however, reports by Cooper (1823) and Watkins (1923) of unreduced dislocations being held by new bone formation, but in none of these did the head pass through the foramen.

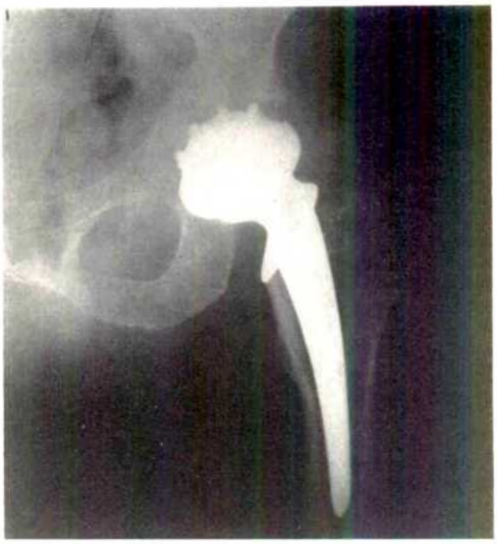

FIG. 4.—Radiograph showing a McKee-Farrar prosthesis in position and the relatively circular obturator foramen.

In the male pelvis the obturator foramen is too small for the head of the femur to pass through, but in 1 out of 25 female pelves examined by one of us (R. F. B.) the foramen was almost able to accommodate the head.

The likely mechanism in the present case is that the hip dislocated into the obturator position by forced abduction of the thigh. As the head passed into the relatively circular obturator foramen the sharp anterolateral margin of the foramen indented the anterosuperior aspect of the head, effectively locking it in the dislocated position. Unfortunately, the exact method of reduction is not known as it occurred semi-accidentally, but it is almost certain that the head was disimpacted and partially reduced by traction and a lateral force on the upper thigh.

The avascular necrosis which occurred in the present case was not surprising as 8·8 per cent of the anterior dislocations reported by Brav (1962) developed this complication.

The report by Thompson and Epstein (1951) indicates that one-quarter of hip dislocations occurs in females and about 5 per cent are of the obturator type. The fact that the event described here appears to be possible only in obturator dislocations in females, and then only once in 25 instances, explains its rarity.

REVIEWS AND NOTICES OF BOOKS

Current Concepts in the Management of Leukemia and Lymphoma. Edited by J. E. ULTMANN, M. L. GRIEM, W. H. KUSTEN, and R. W. WISSLER. 9½ × 6½ in. Pp. 198 + xiv. Illustrated. 1971. London: William Heinemann. £6·70.

THERE can be little doubt that lymphoma and leukaemia are subjects in which we require far more information as regards treatment.

This volume presents the proceedings of the Fourth Biennial Cancer Teaching Symposium held at the University of Chicago in March, 1970. At this symposium over 450 physicians and scientists took part in the discussions.

Every aspect of the lymphoma and leukaemia problem is considered in the various papers. The value of cytoxan, oncovin, and prednisone are considered at length as to their use in the treatment of acute leukaemia.

At the present time it seems that Hodgkin's disease and Burkitt's lymphoma are to a great extent curable, but there seems little improvement after treatment in the chronic leukaemias.

This is a useful monograph and it will make a strong appeal to all cancer research workers who are working in this all too difficult field.

This book is No. 36 in the series of 'Recent Results in Cancer Research'.

Clinical Anatomy. By HAROLD ELLIS, M.A., M.Ch., D.M., F.R.C.S., London. Fifth edition. 8½ × 5¼ in. Pp. 389 + xiv. Illustrated. 1971. Oxford: Blackwell Scientific Publications. £2·50.

THIS is a book which is most important for the medical student of today, for it highlights those features of anatomy which are of clinical importance. It is right and proper that a practical surgeon should write such a book because he can stress those areas or parts of anatomy which are of real importance to a doctor. Professor Ellis approaches anatomy as an anatomist, as an examiner in anatomy for the Primary Fellowship of the Royal College of Surgeons, and lastly as a lecturer. The popularity of this book can be seen by the fact that five editions have appeared in just over ten years, and one edition was reprinted. These facts speak for themselves.

One of the important features of this book is the excellence of the illustrations. Most of the line illustrations are original and quite simple, but very informative.

In our opinion this new edition will continue to enjoy the popularity it deserves.

The price of the book is moderate and well within the budget of the student.

Mechanical Devices for Cardiopulmonary Assistance. Edited by R. H. BARTLETT, M.D., California, P. A. DRINKER, Ph.D., Boston, and P. M. GALLETTI, M.D., Ph.D., Providence. 9⅖ × 6⅗ in. Pp. 195 + xv. Illustrated. 1971. Basel: S. Kargar. £7·20.

THIS volume is No. 6 in the series of 'Advances in Cardiology'. It contains the proceedings of a symposium on this subject held in Boston, Mass., in March, 1970, under the auspices of the Association for the Advancement of Medical Instrumentation.

The great advances which have been made during the past twenty years in extracorporeal circulation has to be seen to be believed. These advances have been due to the co-operation between surgeons, physiologists, and bio-engineering research workers. In this volume the numerous contributors have set forth in a fascinating way the various uses of silicone-membrane technology. The cardiac surgeon and the cardiac transplant surgeon can now take their time during operations, for there is now no time limit to extracorporeal circulation.

This book contains a vast amount of valuable information concerning gas and particulate embolism, and thrombosis in extracorporeal circuits, all of which are central to further development.

A first-class production on a very important subject.

Oral Pathology. By DONALD A. KERR, B.S., D.D.S., M.S., and MAJOR M. ASH, jun., B.S., D.D.S., M.S., Ann Arbor. Third edition. 9 × 6 in. Pp. 310 + xv, with 165 illustrations. 1971. London: Henry Kimpton. £1·40.

THIS book is an introduction to general and oral pathology for the dental hygienist. It covers this important subject in a lucid and practical way. The illustrations are of a high standard, especially the photomicrographs.

The chapters on developmental disturbances, neoplasia, nutritional disturbances, dental caries, and endocrine diseases are particularly good.

This is the third edition in ten years and this fact speaks for the popularity of the book.

Diseases of the Urinary Tract. Specially Commissioned articles from the *British Medical Journal.* 8½ × 5½ in. Pp. 122. Illustrated. 1971. London: British Medical Association. £1.

THIS paperback contains articles on the diseases of the urinary tract which appeared in the *British Medical Journal* in the year 1970. These articles, all written by experts in their own particular field, are concise and practical and the illustrations are excellent.

Articles on chronic renal failure, the nephrotic syndrome, and cancer of the prostate are the best in the book.

Students and practitioners who wish to bring themselves up to date on modern practice in this field will find this a readable account of the important aspects of the speciality.

The price of the book is cheap and within the purse of any student.

Diseases of the Ear, Nose and Throat. Vols. 1–4. Edited by JOHN BALLANTYNE, F.R.C.S., D.L.O., London, and JOHN GROVES, M.B., B.S., F.R.C.S., London. Third edition. 9½ × 6¼ in. Pp. 2109. Illustrated. 1971. London: The Butterworth Group. £32.

THIS comprehensive four-volume work constitutes the third edition of Scott-Brown's original textbook, which was originally published in 1952.

Volume 1 of some 450 pages is devoted to basic sciences and contains some excellent chapters on the anatomy of the ear, nose, and throat, with a considerable number of original illustrations. Professor David Slome contributes an outstanding account of the physiology of the nose and paranasal sinuses, the mouth and oesophagus, as well as the physiology of the larynx and tracheobronchial tree. The mechanism of normal speech is described in a very practical way by D. B. Fry.

The illustrations throughout the volume are of a very high order and there are ten coloured plates which enhance the value of the book considerably.

A very up-to-date bibliography is given at the end of the book.

Volume 2 contains 670 pages and deals extensively with the ear. The numerous contributors from many centres in England have covered the subject of diseases of the ear in a most comprehensive manner.

Congenital conditions of the ear, infections of the middle ear, facial paralysis, otosclerosis, and acoustic neuroma are some of the best chapters in this volume.

Volume 3 deals with every aspect of diseases of the nose. The outstanding contribution to this volume is by G. H. Bateman, who writes on trans-sphenoidal hypophysectomy. This is an excellent account of the operation.

Volume 4 is devoted to diseases of the throat; it is divided into two parts: Part 1 deals with the diseases of the mouth, pharynx, and oesophagus, while Part 2 is concerned with diseases of the larynx and tracheobronchial tree.

Perhaps the most interesting part of this volume is that dealing with the diseases of the larynx, which is most comprehensive and very well illustrated.

This large work is a credit to British medicine and as a reference work it could not be bettered. Surgeons specializing in diseases of the ear, nose, and throat will certainly want to possess this important work. Postgraduates preparing for the Fellowship of the Royal Colleges in E.N.T. will find everything they need in these volumes.

Outline of Orthopaedics. By J. CRAWFORD ADAMS, M.D., M.S., F.R.C.S., London. Seventh edition. 8½ × 5½ in. Pp. 475 + vii. Illustrated. 1971. Edinburgh: Churchill Livingstone. £2·25.

THE seventh edition of this well-known book has been carefully revised, and in parts rewritten.

Seven editions of a book in fifteen years is good going by any standards, especially when most of the editions were reprinted. This well-written, concise book with clear-cut illustrations is ideal for students and the price is most moderate.

A First Notebook of Head Injury. By KENNETH G. JAMIESON, M.D., M.S. (Melb.), F.R.A.C.S., F.A.C.S., Brisbane. Second edition. 8½ × 5½ in. Pp. 148 + xii. Illustrated. 1971. London: The Butterworth Group. £1·60.

THIS useful paperback contains a wealth of information regarding head injuries. Trauma to the skull and its contents is still on the increase and most of it comes from road accidents.

This book is ideal for the student as it is arranged in notebook form for easy reference.

The numerous line drawings are clear and help the reader to understand the text.

This new second edition gives an account of injury and tumours of the temporal lobes.

The author, with his matured clinical acumen, gives a systematic account of the mechanisms, pathology, clinical picture, and differential diagnosis of the commonly encountered complications of head injury.

An excellent notebook for the student and cheap as well.

Intensive Care of the Surgical Patient. Edited by MARSHALL D. GOLDIN, M.D., M.S., Chicago. 8¾ × 5¾ in. Pp. 500 + xii. Illustrated. 1971. Chicago: Year Book Medical Publishers. $17.95.

WITH the ever-increasing field of modern surgery, particularly in cardiovascular and thoracic surgery, it is inevitable that hospitals should have an intensive care unit. Also the increase in road-traffic accidents, resulting very often in extensive multiple injuries, all require intensive care, especially burn cases. This book covers the whole field of intensive care, and it is made up of articles by 42 contributors from various surgical centres in America. The field is a wide one, from postanaesthetic management to transplantation of organs.

The various methods of electronic monitoring are well described. Tracheostomy is described in some detail; it seems to be a common operation in the treatment of extensive road-traffic accidents. The chapter on postoperative haemorrhage is very practical and informative. Parenteral intubation, drugs useful in the treatment of shock, pediatric cardiac surgery, and peripheral vascular surgery are some of the best chapters in this book.

This is a book which should be available in every intensive care unit in our hospitals.

Today's Drugs. Vol. 2. Specially commissioned articles from the *British Medical Journal.* 8½ × 5½ in. Pp. 204. 1971. London: British Medical Association. £1.

THIS is a useful second volume dealing with today's drugs. It is concerned with hormones and oral contraceptives, cardiovascular agents, and drugs acting on the gastro-intestinal tract.

All clinicians will find this a useful desk book for quick reference.

Scoliosis and Growth. Edited by P. A. ZORAB, M.D., M.R.C.P. 9½ × 7½ in. Pp. 154 + xi. Illustrated. 1971. Edinburgh: Churchill Livingstone. £4.

THIS book contains the proceedings of a Third Symposium held at the Institute of Diseases of the Chest, Brompton Hospital, London, on 13 November, 1970.

Scoliosis is an interesting condition of the spine and it is surely gratifying that the Institute of Diseases of the Chest has arranged three symposia dealing with scoliosis; the first was in July, 1965, the second in December, 1967, and the third in November, 1970.

This third symposium deals with some very interesting aspects of scoliosis, and the various contributors come from near and far. Such problems as growth and scoliosis, causation of idiopathic scoliosis, skeletal growth in Morquio's disease, growth of the spinal articular processes, and the effects of early fusion on spine growth are discussed in great detail.

There is an excellent account by Lynne Reid of lung growth. The bronchial tree is developed by the sixteenth week of intra-uterine life. The alveoli, as is commonly understood, develop after birth, increasing in number until the age of 8 years and in size until growth of the chest wall is finished.

This is an interesting and stimulating book, full of useful information not obtainable from any other source. Anyone interested in spinal curvature, such as orthopaedic surgeons, pathologists, and physiotherapists, will find a mine of information within its pages.

Special Topics in Stereotaxis, Epilepsy, Disorders of Behaviour, and Autonomic Balance. Edited by W. UMBACH, Berlin. 9 × 6 in. Pp. 182. Illustrated. 1971. Stuttgart. Hippokrates Verlag. DM.36.

THIS paperback contains the papers which were presented at a Berlin Symposium in 1970 by notable physicians and scientists from four countries.

The very latest results concerning stereotaxic stimulation and coagulation in cases of special central disturbances are discussed in detail and illustrated with clinical photographs and line drawings showing the exact spot in the brain which undergoes coagulation.

The types of cases which have been investigated are drug-resistant epilepsy, behavioural disturbances, aggressiveness, and those suffering from unbearable extreme pain.

The various methods and techniques for the electrocoagulations are described in a very practical way.

Although this excellent book is published in Germany, the publishers should be congratulated for bringing out this English edition, for it will be found of real value to all neurologists, physiologists, and psychiatrists.

Methods of Ossiculoplasty. By JAMES R. TABOR, M.D., F.A.C.S. 8¾ × 5¾ in. Pp. 88 + ix. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $6.75.

THIS monograph is devoted to the indications for, the operation of, and the results following ossiculoplasty. The author records the clinical results regarding 271 consecutive ossiculoplasties.

This book covers the whole subject of ossiculoplasty in a very complete manner and numerous drawings illustrate the technique of the operation.

Specific ossicular reconstructions are described and the results are tabulated in detail. A discussion of statistical comparisons is presented. Advantages and disadvantages of different statistical approaches are discussed as they are related to the results in the different patient populations of the surgical groups.

Regeneration of Liver and Kidney. By NANCY L. R. BUCHER, M.D., and RONALD A. MALT, M.D., Boston. 8⅛ × 5⅝ in. Pp. 277 + xiv. Illustrated. 1971. Edinburgh: Churchill Livingstone. £6.

IN this age of organ transplantation this is an important and useful book, and is indispensable to cancer research workers studying the regulation of cell growth and disorders in whole organs.

The authors have published much of the material in this volume in articles appearing in the *New England Journal of Medicine*, but it is obvious that clinicians and research workers prefer all these facts segregated in one book. Intensified probing into the process of tissue restoration and repair assumes new priority as modern techniques and surgical skills succeed in arresting impairment and in prolonged survival. The regeneration process of the liver and kidney offers an ideal opportunity for examining the transition of tissue from an essentially static condition to active growth. These two organs have 'expanding' cell populations; partial ablation of tissue mass readily induces a regulated growth which ceases when the deficit has been restored.

This book will be a 'must' for cancer research workers, physiologists, and pathologists.

The Craft of Surgery. Vols. 1–3. Edited by PHILIP COOPER, M.D., New York. Second edition. 10 × 7 in. Pp. 1997. Illustrated. 1971. Edinburgh: Churchill Livingstone. £31·50.

THIS comprehensive three-volume work covers the whole field of modern surgery. Although the vast majority of the numerous contributors come from various surgical centres in the United States of America, a few come from Australia and three from England, namely Norman Tanner, John Goligher, and the late Alan Hunt.

The first of these large volumes deals with a wide field, including the head and neck, the skin, the breast, and the thorax including the oesophagus.

George Crile, jun., contributes an excellent account of benign tumours of the thyroid. Articles on achalasia and oesophageal hiatal hernia are excellent.

As one would expect, the various chapters on the surgery of the thorax are comprehensive and include articles on transplantation of the heart and myocardial revascularization. Cardiovascular injuries are covered in a very practical manner; and the many illustrations depicting the various operative techniques are good.

Volume 2 is concerned with the vascular system, the abdomen, and the female genitalia.

Every type of aneurysm is considered in some detail, and various forms of arterial grafting are well described and illustrated. The many forms of shunts are described. The large section dealing with the abdomen is probably the best in the book.

Norman Tanner contributes a very interesting and practical chapter on the use of drains in the peritoneal cavity and the abdominal wall. John Goligher is at his best in his chapter on synchronous combined abdominoperineal excision of the rectum. Milton Porten presents the surgery of hypoglycaemia in a modern setting.

Volume 3 deals with the extremities and urological and pediatric surgery. Neurological surgery and general orthopaedics complete the volume.

William Littler presents the surgery of the hand in a most interesting and practical way. Amputations receive the attention they deserve in this traumatic age.

Renal transplantation is well described and illustrated.

Head injury, which is on the increase in most parts of the world, is dealt with in a very practical manner.

The modern treatment of rheumatoid arthritis by surgery is a great advance in surgical technique.

One of the features of this large work is the excellence of the illustrations; they certainly enhance the value of the written word.

As a work of reference this production could not be bettered, and young surgeons everywhere should obtain a copy for their benefit.

The Illness of Trauma. By GARBETT PIPKIN, M.D., and VICTOR BUHLER, M.D., Kansas. 9 × 6 in. Pp. 167 + ix. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $12.75.

THIS book is concerned with the treatment of trauma as seen in America today. Every facet of the diagnosis and treatment of severe injury has been covered. Intensive care can be overdone, as can be seen in *Fig.* 41 on p. 91 :

the multimonitoring system is really too much, the patient appears to have a needle in every vein and a tube in every orifice.

There is a series of care studies which makes interesting reading. Fat embolism in the lungs, kidneys, and brain is a cause of death which we do not see so frequently over here.

It seems that the authors' wish is to alert the clinicians to the cause of the injured patient's morbidity by a study of the clinical indices.

Atlas for Surgical Repair of Cleft Lip, Cleft Palate, and Noncleft Velopharyngeal Incompetence. By Richard B. Yules, M.D., Boston. 11 × 8½ in. Pp. 200 + vii. Illustrated. 1971. Springfield, Ill.: Charles C. Thomas. $24.

This profusely illustrated atlas presents all the common surgical procedures which are in use today for the correction of cleft lip and cleft palate, both primary and secondary deformities. The illustrations are line drawings and they have been ably executed. We agree with the author when he states that there is no 'correct surgical procedure' for any given defect. This book deals with general patient management, the time of operation, a selection of operative techniques, and a description of the surgical technique itself.

All those postgraduate surgeons who want to specialize in plastic repair of the lip and palate will find this book useful.

Chest Injuries. Physiologic Principles and Emergency Management. By Emil A. Naclerio, M.D., F.A.C.S., F.C.C.P., F.A.C.C., New York. 10 × 6¾ in. Pp. 383 + xiv. Illustrated. 1971. New York: Grune & Stratton Inc. $28.50.

In this age of trauma the chest is often injured in road accidents, by gunshot wounds, or by stabbings. In the United States of America accidents are the leading cause of death up to the age of 37 years. This in itself is ample justification for the publication of this book.

The author gives a very practical account of first aid for thoracic injuries and this is illustrated by some sixteen coloured plates by Frank H. Netter. These plates are quite a feature of the book and enhance the value of the volume.

Every aspect of chest injury is amply covered, from tracheostomy to hernia of the lung. The numerous line drawings, the majority of which are original, are a feature of this book.

Thoracic cage injuries and wounds of the pleura and heart all receive good coverage.

There is an excellent bibliography at the end of the book.

This is a book which can be recommended to students, nurses, and resident medical officers. Physiotherapists will find much to interest them in this very practical volume.

Occult Traumatic Lesions of the Cervical Vertebrae. By Martin S. Abel, M.D., Palo Alto. Pp. 148 + viii. Illustrated. 1971. St. Louis: Warren H. Green Inc. $12.50.

This is an interesting monograph written by a radiologist who has spent many years in improving X-ray technique concerning the cervical spine.

The author has made use of many cadaver experiments and microscopical studies of old injuries. These studies over many years have demonstrated in a convincing way that the lateral processes of C.1 and C.2 are commonly fractured in relatively minor extension and flexing injuries.

The X-ray pictures of these fractures are of a very high standard and are very convincing.

The author considers that occult injuries are a significant, and probably the leading, cause of hypertrophic changes limited to the smaller joints of the cervical region of the vertebral column. Similar changes have been found in young adult spastics which point to injury during delivery.

This monograph will serve as a useful reference volume on a particular condition which is not well understood.

Gynaecology. Essentials of Clinical Practice. By Thomas H. Green, jun., M.D., Massachusetts. Second edition. 9⅛ × 6 in. Pp. 511 + xii. Illustrated. 1971. Edinburgh: Churchill Livingstone. £4·50.

The first edition of this paperback was published just over five years ago and the second edition has just been published, and it shows evidence of a thorough revision.

The line drawings throughout the book are clear and instructive.

The chapters on endometriosis and conception control are particularly good.

This is a book for students and its price is moderate and well within the purse of the average student.

Cleft Lip and Palate. Surgical, Dental and Speech Aspects. Edited by William C. Grabb, M.D., Ann Arbor; Sheldon W. Rosenstein, D.D.S., Chicago; and Kenneth R. Bzoch, Ph.D., Gainesville. 10 × 7 in. Pp. 916 + xxxiii. Illustrated. 1971. Edinburgh: Churchill Livingstone. £21.

This is the most comprehensive work on cleft lip and palate that has so far been published.

The exhaustive text, the work of 71 authorities in the fields of surgery, dentistry, and speech, is divided into five parts: Part 1 is concerned with general aspects which include anatomy, embryology, and classification of cleft lip and palate.

Part 2 deals with the surgical aspects of cleft lip and palate; Part 3 is devoted to maxillary orthopaedics and bone-grafting in cleft palate; Part 4 is concerned with the dental aspects of cleft lip and palate; while Part 5 deals with speech and hearing, including communicative disorders related to cleft lip and palate.

As one would expect in a work edited by American surgeons and dentists, the vast majority of the contributors come from American centres, but there are some from England, Canada, Sweden, and Switzerland.

In a comprehensive work such as this, with a multiplicity of operative techniques, good illustrations are essential. The reader is not disappointed, for throughout the volume excellent drawings illustrate the text. The pre- and postoperative clinical pictures are quite a feature of this volume.

At the end of each chapter there is a list of references dealing with the subject-matter. There is also a very complete subject index at the end of the work.

This large and important work will be read by general and oral surgeons, plastic surgeons, dental surgeons, and speech therapists. It will also be the reference volume for students and residents in hospital.

An excellent production.

Klinische Sudeckprophylaxe und Therapie. By Jost L. Bircher, Basel. 9 × 6 in. Pp. 60 + viii. Illustrated. 1971. Berlin: Springer-Verlag. DM.24.

This monograph concerns the experimental production and treatment of Sudeck's atrophy. The author has managed consistently to produce lesions resembling Sudeck's atrophy in rabbits by injecting the area around one of the sciatic nerves with a phenol solution.

The author then continues to show that the exhibition of Tanderil, Hydergin, and Phenergan together are successful in reducing the pathological changes which he initially induced in the experimental rabbits. The clinical relationship of his findings are discussed. The book contains a very extensive bibliography of this very specialized subject.

Atlas of Transbronchial Biopsy. Early Diagnosis of Peripheral Pulmonary Carcinomas. By EITAKA TSUBOI, M.D., Tokyo. 11¾ × 8¼ in. Pp. 151 + viii. Illustrated. 1971. Stuttgart: Georg Thieme Verlag. DM.125.

THIS is one of the best, if not the best, medical book which has been produced in Japan since the Second World War.

Cancer of the lung is one of the commonest causes of death in most places in the world, but especially so in Japan.

Cytology is one of the modern adjuncts to diagnostic methods and is today a fully accepted diagnostic procedure.

Professor Tsuboi has cleverly devised some special curved curettes which can be used after bronchoscopy for obtaining small fragments of tissue from the bronchus. With the use of X-rays the curette can be pushed to the spot where an early carcinoma of the bronchus is suspected. In the hands of Professor Tsuboi transbronchial biopsy has become a very important diagnostic technique in the detection of pulmonary diseases.

In this large atlas there are some 215 illustrations, 35 of which are in colour. The illustrations of radiographs, operative techniques, pathological specimens, and photomicrographs are of a high order.

This book provides an exhaustive discussion of the method of transbronchial biopsy and describes its importance in the detection of lung cancer in Japan.

This atlas will have a wide appeal not only to chest physicians and surgeons but also to pathologists and research workers. It should find a place in every medical library.

Frontiers of Nuclear Medicine. Edited by WOLFGANG HORST, Zürich. 9¾ × 6½ in. Pp. 306 + xvi. Illustrated. 1971. Berlin: Springer-Verlag. DM.98.

THIS book is a collection of twenty-four separate papers dealing with various aspects of nuclear medicine and has been dedicated to the memory of George von Hevesy, who died in 1966. The subject-matter of the papers ranges from computer analysis of radioactive techniques to the use of various radio-isotopes in medical diagnosis. The majority of the papers are in English and all of them are extremely well illustrated. This volume undoubtedly gives a quick up-to-date review of the most recent advances in radio-isotope techniques, and should be welcomed by all those interested in this field of medicine. The printing and publication are of this publisher's usual high standard.

Encyclopedia of Urology. Edited by C. E. ALKEN, Hamburg; V. W. DIX, London; W. E. GOODWIN, Los Angeles; and E. WILDBOLZ, Bern. 9⅜ × 6½ in. Pp. 256 + x, with 132 illustrations. 1970. Berlin: Springer-Verlag. DM. 142.

FOUR subjects are covered in this volume. Renovascular surgery occupies 33 pages in a tidy account by Kaufman and Lupu. In renal hypertension the most useful tests are described and there is adequate detail of surgical treatment; shorter sections follow on aneurysms, embolism, and thrombosis.

Renal transplantation has the longest section of 74 pages and is the work of Donald Martin of California. This is an excellent account of the current position, which admittedly is not yet stabilized despite the advances made by the contributions of daring surgeons. The technique of transplantation is well described and illustrated and the practice of learning it in 100 canine operations must surely be worth while. The difficult problems of antigen identification and matching are made comprehensible.

The third section of 38 pages dealing with open surgery of the prostate is by Professor Gittes, also of California. Despite his assertion that transurethral prostatectomy has rightly become the method of choice in America, he is prepared to use open surgery for a prostate weighing more than 40 g. He does not favour the repair of the posterior wall of the urethra, yet it was the introduction of retrigonization by Harris which made prostatectomy with closure possible and paved the way to the success of the modern open operation; plain, not chromic, catgut should be used.

The last section on the neurogenic bladder in spinal cord injury comes from Burghele and Ichim of Bucharest and occupies 64 pages. It is the most thought-provoking section in the book. The authors recognize the lack of agreement between the anatomical and functional aspects of the problem and realize that the mechanism of reciprocal relaxation of the bladder-neck with contraction of the detrusor is not known. There are full accounts of the use of electrical stimulation in treatment.

The production of the book lives up to the high standard we have come to expect in this series, and we consider that it will become one of the most popular.

Traumatismes Ostéo-articulaires de la Main. Edited by R. VILAIN, Paris. 10½ × 8 in. Pp. 184 + viii, with 175 illustrations. 1971. Paris: Expansion Scientifique Française. 105F.

THIS latest publication by the study group of hand surgery deals with fractures and joint injuries. It is written in both English and French, one text above the other. This is an advantage for those who cannot read French, but the arrangement is a little confusing. When leafing through this extremely well-produced book, one is primarily struck by the far-reaching consequences that may follow on apparently trivial injuries. It is evident that the initial treatment is frequently decisive—as so often in traumatology—which has important implications for the organization of first-aid departments. The book opens with a minute account of the surgical anatomy of the hand, which admirably summarizes modern knowledge and stays conveniently close to the parts which follow. After this introduction the remainder of the book is about equally divided between primary treatment and treatment of the sequelae. Should the primary treatment not produce the desired results, one can then be guided by the later chapters, which deal with mal-union, non-union, and post-traumatic stiffness, from various point of view. The carpal bones are not included, with one notable exception for the scaphoid bone, non-union of which is covered at length. Perhaps somewhat out of place but nevertheless very interesting is an article on silicone-rubber implants for damaged joints of the hand, mainly tried so far in cases of arthritis. A most interesting publication at postgraduate level, which could serve as a supplement to any textbook on fractures and joint injuries, but rather to study than for reference. The anatomical introduction can be recommended to every surgeon and student of anatomy.

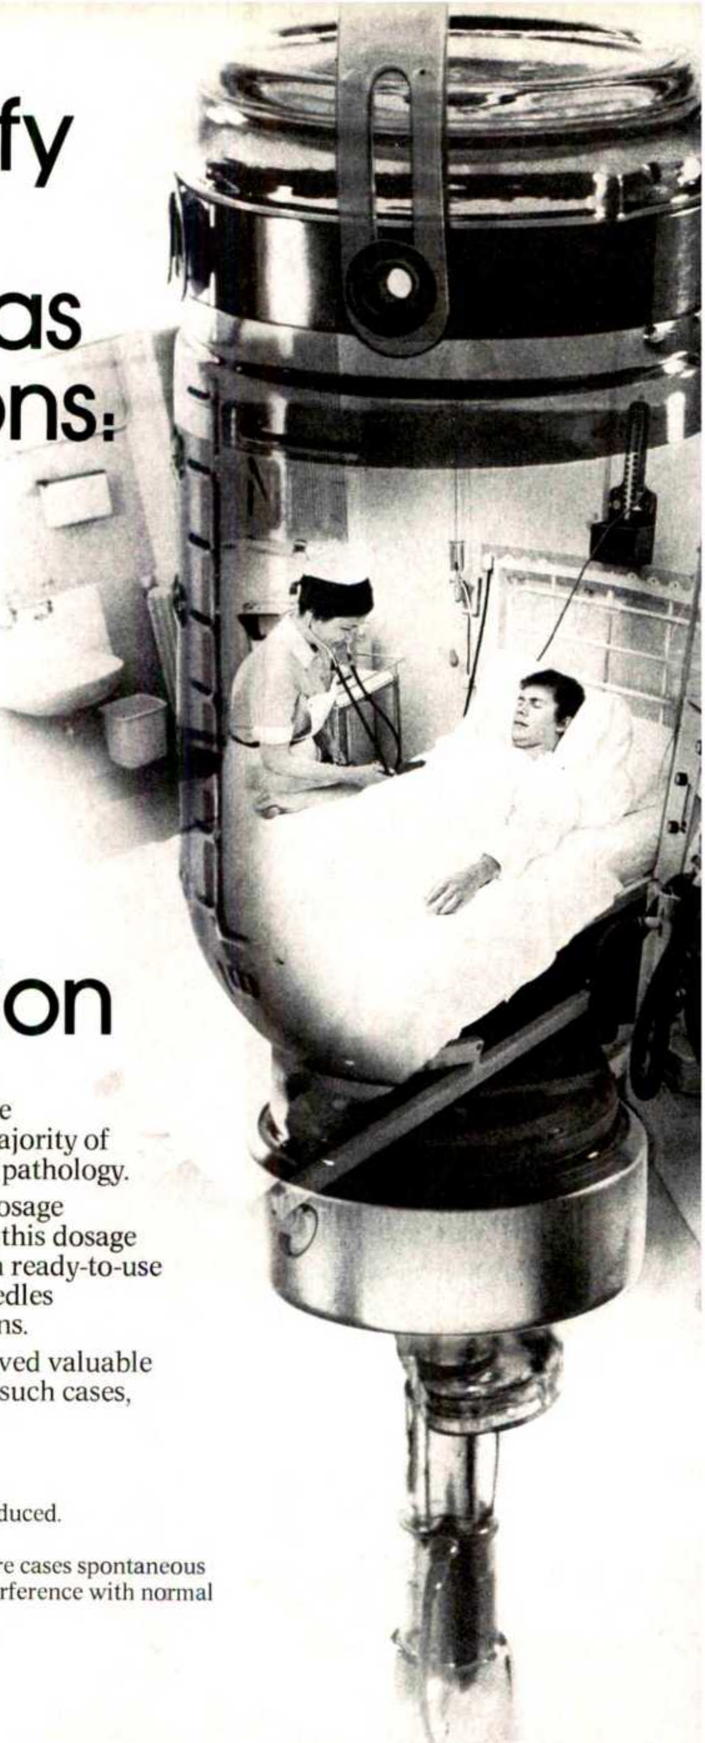
Now, to simplify treatment of pseudomonas chest infections.



Pyopen infusion

In the published papers, Pyopen's success rate in chest infections is 65% even though the majority of the patients described had severe underlying pathology.

The best results have been achieved with a dosage of 20-30G. I.V. daily. Pyopen infusion makes this dosage simpler to administer by providing Pyopen in ready-to-use infusion bottles with diluent and transfer needles for the easier preparation of infusion solutions.

Pyopen is, of course, a penicillin, and has proved valuable in patients with known renal impairment: in such cases, however, dosage should be reduced.

Adult dosage: 20-30G. I.V. daily.
In patients with renal impairment dosage should be reduced.
Contra-indications: Penicillin hypersensitivity.
Side-effects: As with other injectable penicillins. In rare cases spontaneous skin and mucous membrane haemorrhages due to interference with normal clotting mechanisms have been reported.

Pyopen

Further information is available on request.

EDITORIAL NOTICES

EDITORIAL COMMUNICATIONS should be addressed to the *Editorial Secretary, British Journal of Surgery, c/o John Wright & Sons Ltd., Bristol, BS8 1EX.*

Original Articles are invited, and should be sent, whenever possible, to a member of the Editorial Committee: they are accepted with the understanding that they are contributed to this Journal only, and that articles and their illustrations become the property of the Journal unless the authors state, before publication, that they reserve the right to themselves. Each article should be accompanied by an adequate summary, suitable for publication. Authors are asked to ensure that original illustrations are securely packed and adequately protected.

REPRINTS can be supplied at a reduced price if authors indicate their requirements at the time that proofs are returned. The following scale will be helpful as a guide to the cost; 50 copies are suggested as a minimum number.

NO. OF PAGES	NUMBER REQUIRED							
	50	100	150	200	250	300	400	500
2	£2·10	£2·80	£3·20	£3·80	£4·30	£4·80	£5·90	£6·90
4	2·70	3·90	4·60	5·40	6·16	6·90	8·40	9·90
6/8	4·50	5·80	7·10	8·30	9·60	10·80	13·40	15·90
10/12	7·20	9·80	11·70	13·70	15·70	17·70	21·80	25·40
14/16	8·70	11·10	13·50	15·90	18·30	20·70	25·50	30·30
18/20	11·40	15·10	18·20	21·30	24·50	27·70	33·90	39·00
COVERS	1·50	2·10	2·70	3·30	3·90	4·50	5·70	6·90

An additional charge will be made for reprints containing coloured illustrations, depending upon the amount of extra work involved.

BUSINESS COMMUNICATIONS should be addressed to *John Wright & Sons Ltd., British Journal of Surgery, Bristol, BS8 1EX.* Remittances should be made payable to *The British Journal of Surgery.*

BINDING.—Handsome Cloth Cases may be obtained for binding Vol. 58. Case 70p post free; Case and binding £2·75, post free. Cases are also available for some of the earlier volumes. Applications should be made to the Publishers, who will also undertake the binding if desired.

BACK NUMBERS.—The Publishers would be glad to purchase copies in good condition of Nos. 1, 3, and 8, Vol. 51; No. 9, Vol. 53; No. 10, Vol. 54; and Nos. 11 and 12, Vol. 55.

ADVERTISEMENTS.—All communications should be addressed to *H. S. Janes & Partners (Publications) Ltd., St. Martin's House,* 159 *Clapham High Street, London, S.W.4.*

INSTRUCTIONS TO AUTHORS

PREPARATION OF MS.—Papers should be submitted in typescript and the author should retain a carbon copy. Double spacing should be used throughout, except for quotations.

TABLES AND ILLUSTRATIONS.—Tables should be numbered in roman numerals and set out on sheets separate from the text. Illustrations, too, should be kept separate from the text and should be numbered consecutively in arabic numerals. Each figure should be referred to in the text, and the descriptive legends should be typewritten on a separate sheet of paper, and not put on the backs of the originals. Glossy photographs should be supplied unmounted and positive prints (not X-ray films or lantern slides), also unmounted, should be sent whenever possible. Drawings should be in a finished state suitable for reproduction. When *coloured illustrations* are submitted as colour prints they should be accompanied by the actual transparencies where possible. As coloured illustrations are very expensive to reproduce, the author may on occasion be asked to make a contribution towards the cost.

REFERENCES.—The arrangement is based on the Harvard System.

In this system the name of the author and the date of the publications are given in the text; the list of authors quoted is put at the end of the article in alphabetical order. Each reference in the list should give, in order, the author's name, initials, the year of publication (in brackets), the name of the journal, the volume (in heavy type arabic numerals), and the number of the first page of the paper. If the author cited has written more than one paper in the year, each should be distinguished by the letters a, b, and c, etc. For books, the place of publication should be stated and the publisher's name. The names of collaborating authors should be given in full on the first occasion, but in later citations the words "and others" should follow the first name. Abbreviations for journals should be those adopted in the "WORLD LIST OF SCIENTIFIC PERIODICALS" (1963).

Only in papers in which many and frequent references have to be made should the items be numbered; the numbers may then be inserted in the text without interrupting it with a list of names.

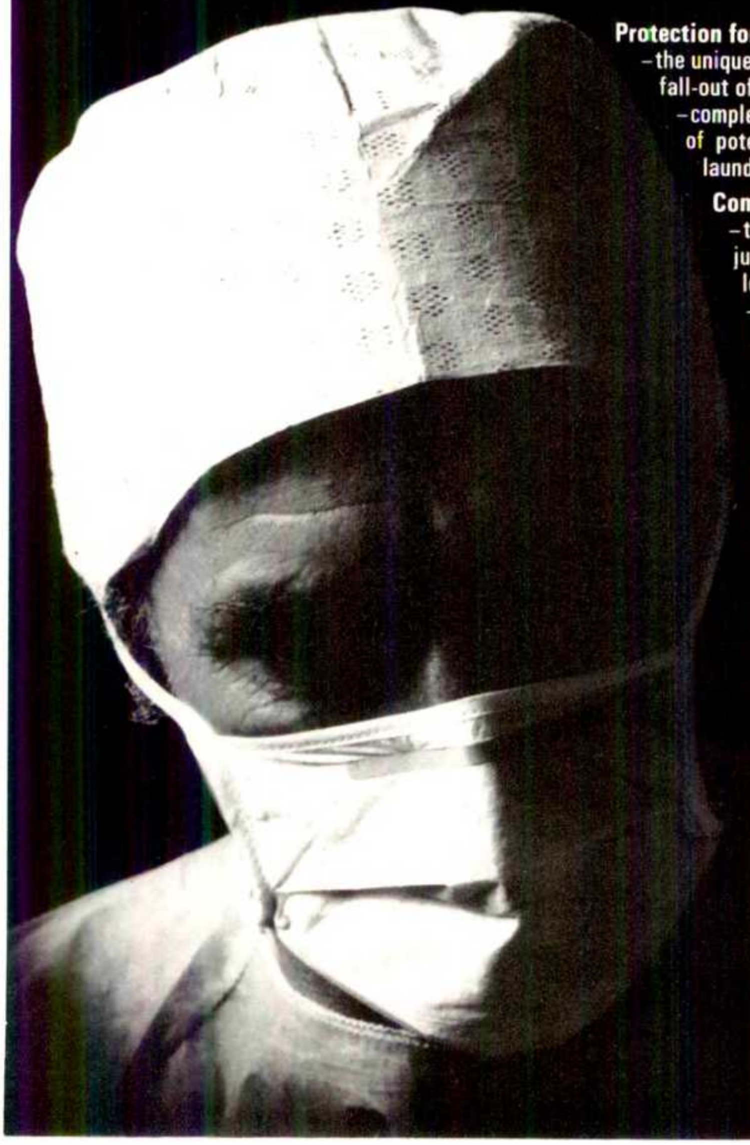
KEEP AHEAD IN PATIENT PROTECTION...

...AND KEEP AHEAD IN COMFORT

with **SURGINE*** Theatre Caps



Protection for Your Patient

- the unique fabric design prevents the passage and fall-out of hair debris.
- complete disposability prevents introduction of potentially infectious organisms into the laundry system.

Comfort for You

- the specially contoured crown and adjustable tie bands fit all but those with long hair.
- the soft non-woven fabric is light and cool to wear.

Convenience for Others

- saves valuable time by eliminating sorting, repairing and packing in service departments.
- saves cost and reliance on the laundry service.

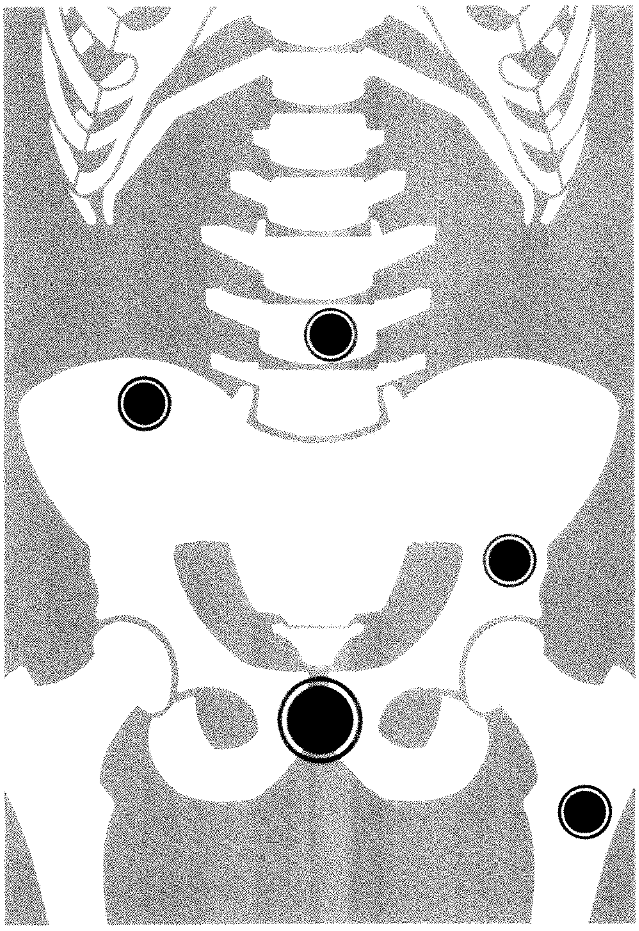
Honvan fosfestrol

Honvan is pharmacologically inert until dephosphorylated. It is selectively activated by tissues rich in acid phosphatase, notably the prostate, where it exerts a local cytotoxic action.

Regression of prostatic tumours and metastases is observed in most patients, including a majority of those unresponsive to standard oestrogen therapy.



a selective cytotoxic action
– in prostatic carcinoma

Response is rapid. **Honvan** is a practical alternative to surgery in acute urinary retention caused by prostatic carcinoma.

Gastric tolerance of **Honvan** is good and side effects comparatively rare.

Honvan is available for both intravenous and oral administration.

Full details are available on request from

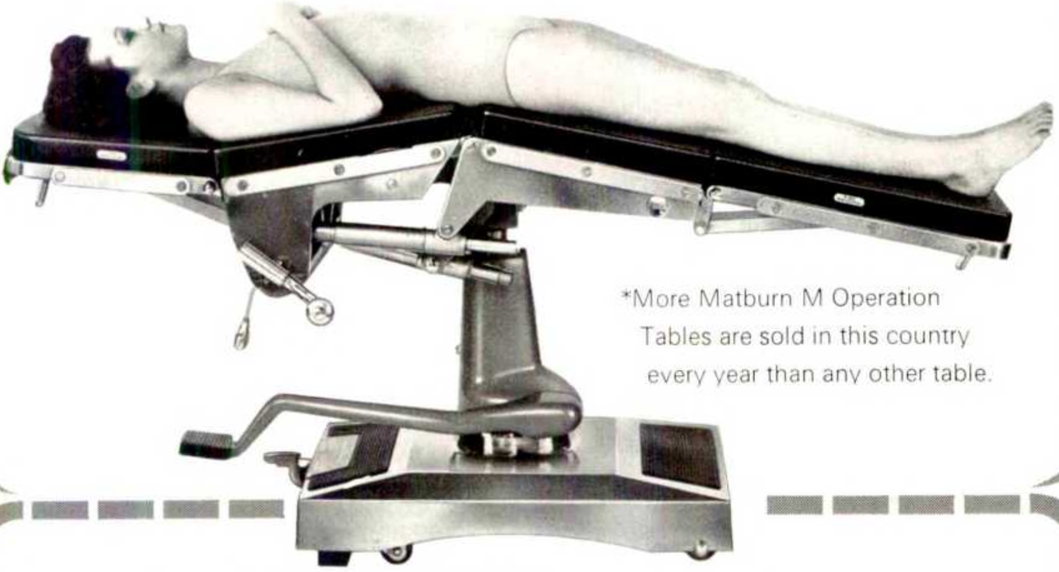
Matburn M

The supreme four section operation table...*

This is the supreme four-section operation table: grouped head-end control, the fullest range of positions and a series of over fifty accessories give the M the flexibility to meet the demands of any branch of surgery, and any procedure from routine examination under anaesthesia to advanced neurosurgical operations.

Built to the highest standards of engineering skill and precision, Matburn M combines absolute rigidity with easy mobility when required.



*More Matburn M Operation Tables are sold in this country every year than any other table.

ESCHMANN

Post-prostatectomy EPSIKAPRON® is better than post-prostatectomy bleeding*

**This observation has a high degree of clinical significance.*

Post-prostatectomy blood loss may be a litre or more[1,2]. Use of EPSIKAPRON can reduce this loss by 80-90%[3,4]. "The control of blood loss has proved to be not only statistically but also clinically significant"[2]. Blood transfusion, which is costly and not without risk, ". . . can be avoided and draining catheters kept patent without difficulty and removed earlier, which makes the post-operative course smoother and shorter"[3].

FOGARTY CATHETERS FOR ACUTE VASCULAR OCCLUSION

FOR: Venous Thrombectomy

Occlusion/Emergency Tamponade

Arterial Embolectomy

Dilation/Creation of Atrial Septal Defects in Infants

Double Lumen Balloon Catheter/Creation of Atrial Septal Defects in Infants

Biliary Balloon Probe/Exploration and Removal of Debris and Stones

Irrigation

Rugged Universal Hub Fits All Luer-Lok Type Syringes

BALLOON CATHETER CONCEPT

Each catheter has a specially constructed balloon at the distal tip (except Irrigation Catheter). In thrombectomy and embolectomy, when the catheter is introduced into a vein or artery, the instrument follows the path of least resistance and the tip threads itself past the thrombus or plaque. The balloon is then inflated with sterile fluid and the catheter withdrawn, bringing the clot with it. As an emergency tamponade, for dilation, or as a biliary probe, the balloon is similarly inflated.

GENERAL DESIGN FEATURES

1. Tips on the various types are specially designed for the particular procedure; all are soft and atraumatic.
2. Controlled symmetrical balloon geometry.
3. Secure balloon attachment by epoxied suture.
4. Length marked catheter bodies.

Explanation of Model Numbers in the following table: i.e.: 32-6F

Advantages

- Less patient trauma
- reduces operating time for tubal sterilizations
- facilities for ovarian biopsy and suction
- non-conducting plastic cannula provides an additional safety factor
- new "quick thread" insulated sheath gives improved cutting action
- simplified control mechanism for more precise use.

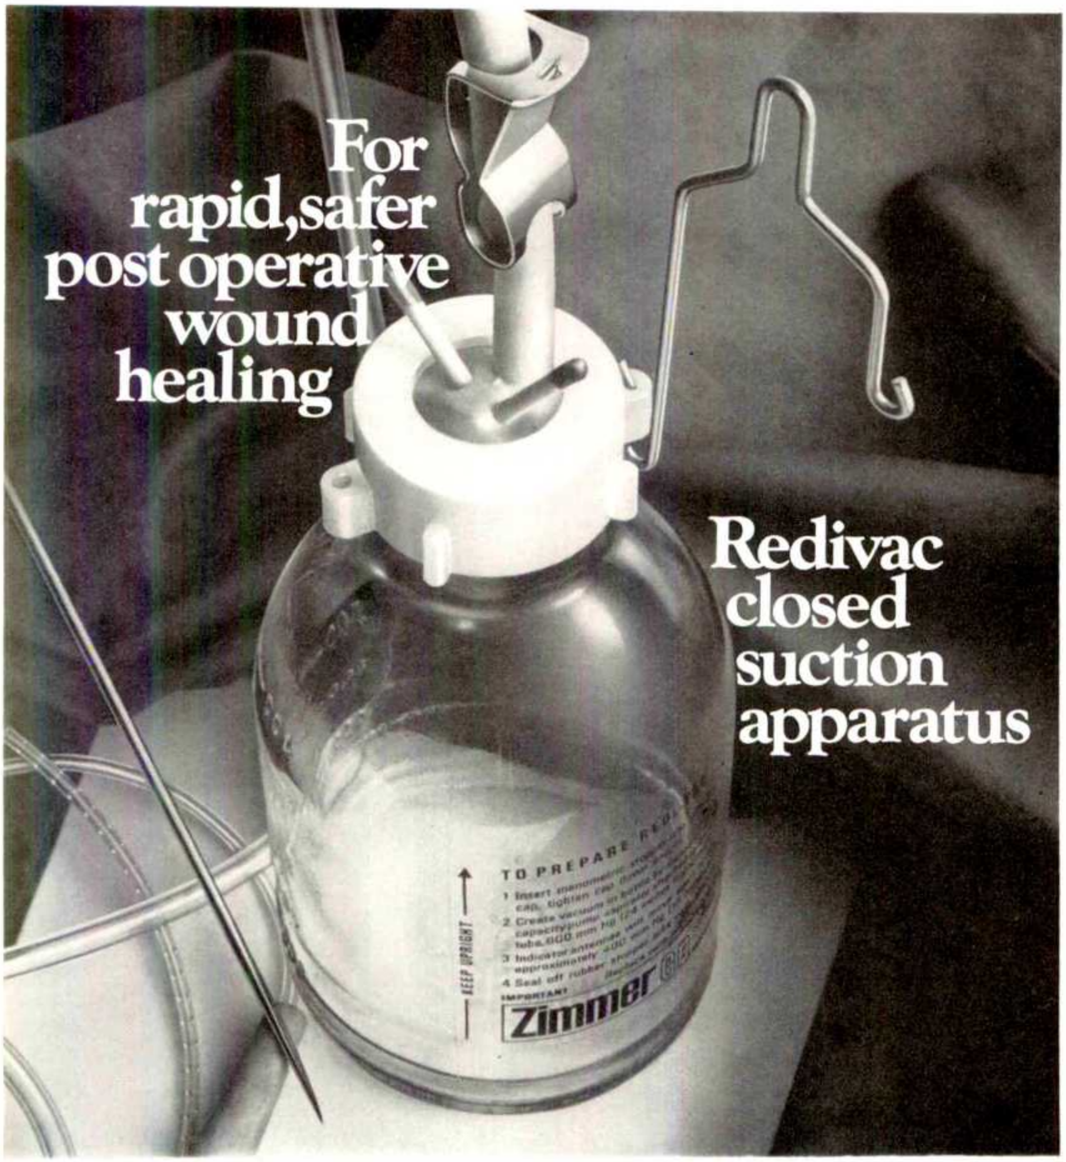
DOWNS SURGICAL GROUP



For rapid, safer post operative wound healing
Redivac closed suction apparatus
TO PREPARE
KEEP UPRIGHT
Zimmer

First intention wound healing after operation is prolonged by the accumulation of tissue fluids and blood at the site. This accumulation often encourages infection.

The problems associated with these traditional procedures are solved by Redivac Closed Suction Apparatus, which removes blood and tissue fluids and avoids the formation of haematoma.

The Redivac evacuator bottle supplies a negative pressure of 600 mm Hg. The drainage tube is laid in the wound and is passed through intact skin, some distance from the incision. It is then connected to the evacuator bottle and suction commenced.

The Redivac Closed Suction System is simple, inexpensive and comfortable for the patient. It is applicable in all deep surgical procedures. The Redivac Closed Suction System facilitates nursing and results in shorter hospitalisation of patients.

Take a cool look

With the HANAULUX GLASS FIBRE OPTIC LAMP

The Glass Fibre Optic Satellite Lamp gives concentrated illumination for cavities and other areas requiring additional light, and because the light emitted is absolutely cold (being free from infra-red) the sterilizable flexible light-head can be adjusted by the surgeon and the possible drying of a wound is obviated.

Of particular value in neurosurgery, ENT and gynaecology, this lamp has maximum manoeuvrability and remains firmly in any adjusted position. The light-head can, in fact, be moved down to table top level.

This Hanaulux Glass Fibre Optic Lamp can be satellite-mounted on the main operating lamp, or installed as a separate wall or ceiling unit.

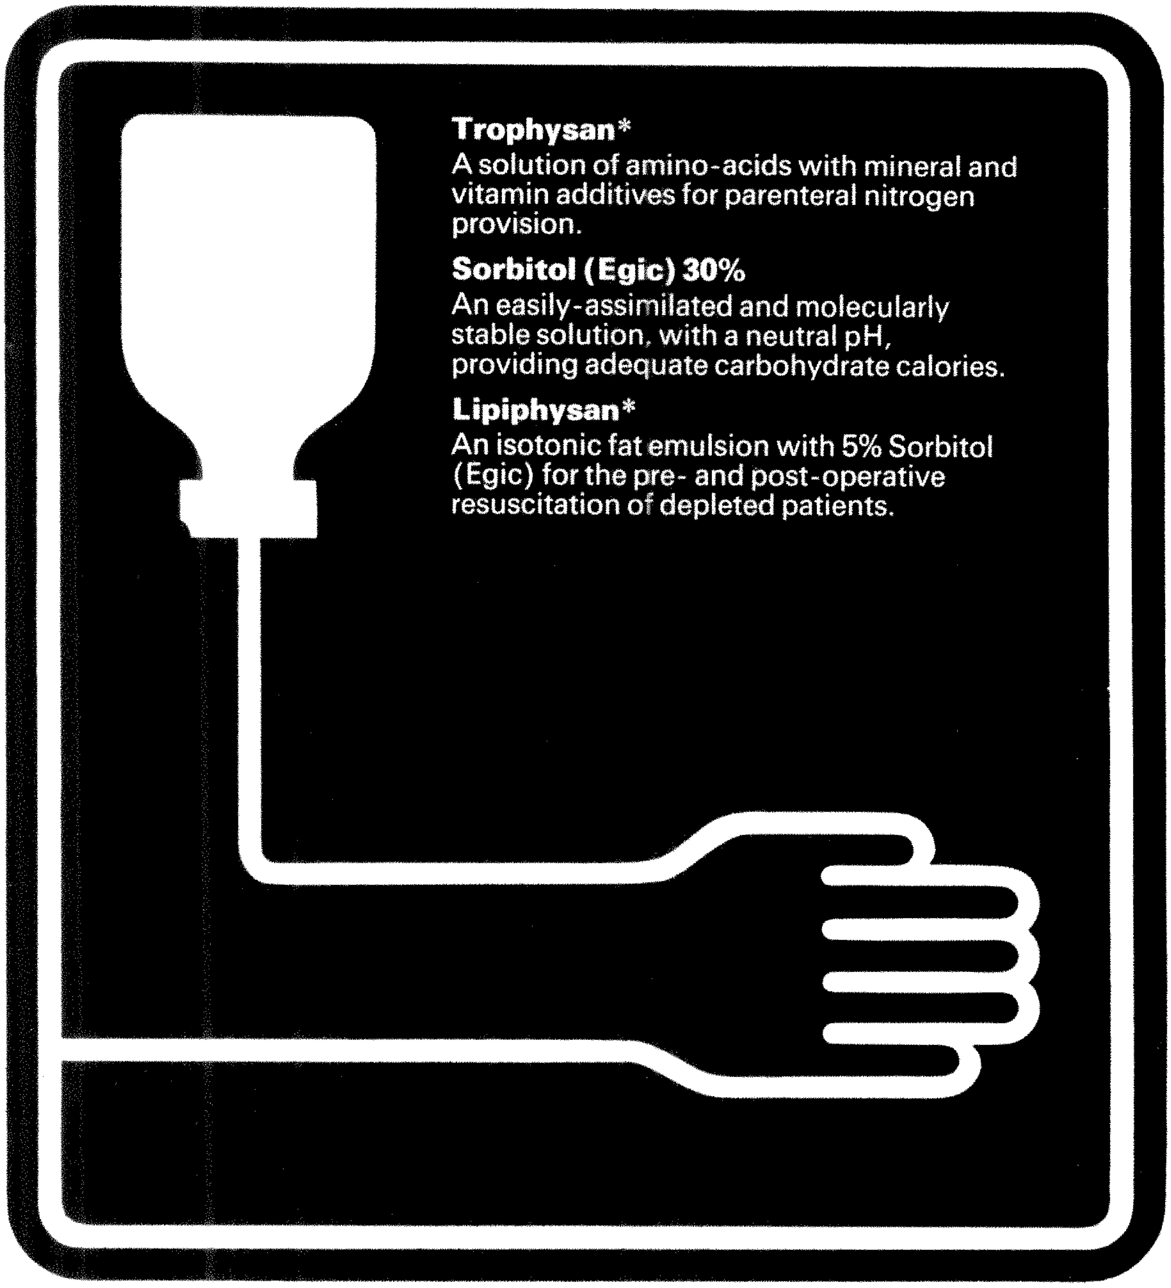
The problem of nutritional deficiency in surgery

In surgery of the GI tract the malnourished patient is a poor surgical risk. Pre-operative parenteral nutrition ensures adequate provision of nitrogen and calories and the correction of any electrolytic imbalance. This is best achieved by the use of SERVIER intravenous nutritional solutions.



Trophysan*
A solution of amino-acids with mineral and vitamin additives for parenteral nitrogen provision.

Sorbitol (Egic) 30%
An easily-assimilated and molecularly stable solution, with a neutral pH, providing adequate carbohydrate calories.

Lipiphysan*
An isotonic fat emulsion with 5% Sorbitol (Egic) for the pre- and post-operative resuscitation of depleted patients.

When nutritional deficiency is a problem, Servier has the solution.

PROGRESS IN THE PREVENTION OF POST-OPERATIVE DEEP VEIN THROMBOSIS

New British double-blind study confirms the prophylactic value of

LOMODEX® 70

“...is more effective, safer, and more readily applicable than the use of oral anti-coagulant therapy for the prevention of thromboembolic complications following major pelvic surgery.”

Lancet, 7751, i, 1972.

LOMODEX 70 (formerly Dextraven 70) has been shown to produce a highly significant reduction in the incidence of thrombosis when administered during surgery. The properties of LOMODEX 70 are such that, apart from its ability to maintain blood volume, it has been shown to have a significant effect on the changes of factors V, VIII & fibrinogen during the operative procedure.
Thus, the routine use of LOMODEX 70 during surgery represents a real step forward in the prevention of this all too common hazard with none of the problems associated with anti-coagulant therapy.

ORIGINAL PAPERS

THE SCOPE AND SAFETY OF SHORT-STAY SURGERY IN THE TREATMENT OF GROIN HERNIAE AND VARICOSE VEINS

A REPORT ON 705 CASES*

By F. S. A. DORAN, MARY WHITE, and M. DRURY

BROMSGROVE AND KIDDERMINSTER HOSPITALS, WORCESTERSHIRE

SUMMARY

Between 1948 and 1968 the number of surgical patients treated in England and Wales increased by 38·6 per cent. In 1968, 267,300 more surgical patients were admitted to hospital than in 1948. During the same period of time the increase in the number of beds was less than 1 per cent.

Faced with a steadily growing demand to treat patients suffering from cancer and other serious diseases it is difficult to find the beds and the operating time to treat patients with hernia and varicose veins. Even so the operations performed on patients suffering from these two complaints amount to nearly one-third of all the operations performed annually. There are 231 other operations in general surgery.

As a result the average time patients with ruptures and varicose veins languish on hospital waiting lists is up to 2 years, and often for longer than that.

At the present time in England and Wales the average time a patient stays in hospital after a herniorrhaphy or an operation for varicose veins is 10·5 days. This is an expensive waste of beds; 75 per cent of all patients can safely be sent home 48 hours after both these types of operation. The number of patients who develop an acute post-operative complication and cannot go home is only 5·4 per cent and the number who need readmission for a delayed complication is less than 1 per cent.

Being discharged home 48 hours after having their hernia repaired or their varicose veins operated on is popular both with the great majority of patients and also with their relatives. Moreover it is accepted by the general practitioners concerned. Proceeding in this way the time such patients have to wait for their operation is reduced to an average of 3–6 months.

It is important to realize, however, that short-stay surgery will increase the total number of operations performed each year. They are additional operations and, as such, need extra theatre time and extra theatre staff, otherwise they cannot be done.

The present series of 705 cases could not have been operated on if an additional theatre and staff had not been provided.

FACED with a steadily growing demand to treat patients suffering from cancer and other serious conditions most surgeons find it difficult to provide enough beds and theatre time to treat patients with hernia, varicose veins, piles, and subacute appendicitis. As a result such patients tend to languish on the waiting list for up to 2 years.

The facts are straightforward. In 1948 the number of general surgical patients admitted in England and Wales was 691,700. By 1968 the number had risen to 969,000, an increase of 267,300 and a growth of 38·6 per cent in 20 years. In the same 20 years the number of beds available only increased from 453,000 to 465,000, a growth of only 12,000 or 0·26 per cent (Lees, 1969).

It is likely that under the modern conditions of life in this country the numerical growth of patients seeking surgical treatment for ruptures, varicose veins, piles, and subacute appendicitis has increased more rapidly than it has for more dangerous conditions. This is suggested by the fact that at present there are 117,000 herniorrhaphies performed a year, 150,000 operations for varicose veins, 22,000 haemorrhoidectomies, and 25,000 operations for subacute appendicitis (Lees, 1969). These four conditions add up to one-third of all operations undertaken in general surgery. In addition to these four operations there are 231 other operations (Rob and Smith, 1956) and it takes them all to make up the rest of the annual total. Moreover, these four operations take half a million bed days and keep 10 per cent of all the available beds in continuous use.

---

* Based on a paper read at the Symposium on Short-stay Surgery organized by the Birmingham Regional Hospital Board and held at Dudley Road Hospital, Birmingham, on 22 Nov., 1969.

SHORT-STAY SURGERY

In the past surgeons believed that a wound would not heal strongly unless the patient was kept resting in bed for at least 14 days. To get a patient up sooner than that if he had had a groin hernia repaired was asking for a recurrence. During the last war the Army order was that after an inguinal herniorrhaphy the patient must stay in bed for 21 days (Farquharson, 1955).

The truth of this belief has now been challenged. Because of the high cost of hospital care in the United States of America patients have for some time been forced to leave the hospital early (Stallworthy, 1960). In Britain Farquharson (1955), owing to shortage of beds and operating sessions in Edinburgh, successfully repaired 485 inguinal herniae as out-patients, doing the operation under local anaesthesia in the out-patients' theatre. He argued, persuasively, that strict bed-rest in hospital was not essential to the secure healing of a surgical wound. However, he did not prove whether the herniorrhaphy healed as safely. His claim that the healing of the wound took place just as well at home as in hospital has been confirmed by Stephens and Dudley (1961), who treated 54 herniae and 112 varicose veins as out-patients, and by Williams (1969), who operated on 127 cases, of which 65 were ruptures, as out-patients.

Up to now it would appear that most surgeons do not find the policy of out-patient surgery for hernia and varicose veins attractive. Patients who have been operated on for either of these two conditions in England and Wales stay in hospital, on average, for 10·5 days (Lees, 1969). In 34 of the Birmingham Regional Board Hospitals the average time a patient is kept in hospital after a herniorrhaphy is 10·2 days, and after an operation for varicose veins 10·3 days.

It is evident that although surgeons in the main keep their patients in hospital for 10 days, they no longer believe that strict bed-rest is needed to obtain wound healing. All these patients are up and about in the ward. Farquharson (1955) has suggested that patients are kept in hospital because most surgeons are afraid that a complication developing at home would result in litigation. To minimize the risk of such complications Stephens and Dudley (1961) examined each patient and so did the anaesthetists. In addition to the physical examination the patient had a chest radiograph and, if indicated, an electrocardiogram and a forced expiratory volume test. No endotracheal tubes or relaxants were used and prompt recovery of consciousness was aimed at (Sutherland and Horsfall, 1961). The operations were done in the main theatre with strict aseptic precautions, not in the out-patients' theatre. At the beginning of practising short-stay surgery the patient was visited at home by a member of the hospital staff, but this was found to be unnecessary and the practice was discontinued.

Aldridge (1965), in an attempt to get the best of both worlds, carried out a trial on 136 patients admitted for herniorrhaphy. Instead of transferring them to a convalescent hospital 48 hours after the operation they were sent home at this time. The operations were all done under a general anaesthetic in the main theatre. Care at home was given by the district nurse with the backing of the patient's own doctor. Provided that the scheme was explained to the patient no objection was raised, and when asked afterwards all the patients said they liked it.

In 1968 an interesting trial was reported by Morris, Ward, and Handyside, in which 185 men, each with a unilateral inguinal hernia, were divided into two groups: one group was kept in hospital 5 or 6 days after the herniorrhaphy, the other group being discharged home after 24 hours. Complications developed in 43 patients or 23 per cent. Two-thirds of these complications were detected within 48 hours, the majority being apparent within 24 hours. Only 15 occurred on the third or subsequent postoperative day. Adding these facts to the patients' complaints about the immediate postoperative discomforts and the way that these were aggravated by an ambulance journey within 24 hours of the operation, the authors concluded that while it was unnecessary for the patients to be kept in hospital for 5 or 6 days they ought to stay there for 48 hours. This supports the period selected by Aldridge (1965).

The present report is concerned with 705 patients discharged home 48 hours after the operation.

GROIN HERNIAE

The evidence already published (Farquharson, 1955; Stephens and Dudley, 1961; Aldridge, 1965; Morris and others, 1968; Williams, 1969) leaves little serious doubt that after the repair of an inguinal or femoral hernia most patients can safely be discharged home in 48 hours. The material contained in this report confirms this opinion.

From the beginning of this short-stay scheme 345 patients with groin hernia attended the out-patients' department. Of this total, 266 or 77 per cent were accepted and only 79 were rejected and dealt with in the conventional manner. Of the 266 patients accepted, the great majority had an inguinal hernia.

No strict rule regarding age was enforced. The range was from 15 to 84 years, but the majority were between 30 and 59 years (*Fig.* 1). In most of the other reports it would seem that patients with double ruptures have not been accepted, and the Mansfield trial was undoubtedly restricted to men with a unilateral inguinal hernia (Morris and others, 1968). In the present series double ruptures have been accepted.

The operations performed on the 266 groin herniae were as follows:—

If the hernia was an oblique inguinal with a neck of 10 cm. in circumference or less a simple Lytle's repair of the deep ring was carried out, but frequently a rectus flap was added to protect the posterior wall of the inguinal canal or, alternatively, a nylon darn was used for the same purpose. The large oblique and the direct inguinal herniae were treated by either a Bloodgood-Keynes operation, an aponeurotic patch to the posterior wall of the canal, or a rectus flap sewn to Cooper's ligament. This last operation was used for all the femoral herniae. A certain number of the large oblique and the direct inguinal herniae was also treated with a nylon darn. The overall figures for each type of operation are set out in *Table I*.

Table I.—DETAILS OF THE OPERATIONS PERFORMED ON 266 GROIN HERNIAE

Operation	*No. of Cases*
Lytle's repair of the deep abdominal ring, with or without a rectus flap	125
Nylon darn operation	58
Bloodgood-Keynes	30
Aponeurotic flaps to repair the posterior wall of the canal	32
Rectus flap operation for femoral herniae	21
Total	266

Table II.—DETAILS OF THE OPERATIONS PERFORMED ON 244 PATIENTS WITH UNILATERAL VARICOSE VEINS

Operation	*No. of Cases*
Long saphenous strip	150
Short saphenous strip and dissection of popliteal fossa	36
Long saphenous strip and tie to leg perforating veins	36
Long and short saphenous strip	9
Long and short saphenous strip and tie to leg perforating veins	10
Tie to Hunter's canal perforating vein	3
Total	244

Table III.—DETAILS OF THE OPERATIONS PERFORMED ON 195 PATIENTS WITH BILATERAL VARICOSE VEINS

Operation	*No. of Cases*
Long saphenous strip	123
Short saphenous strip and dissection of popliteal fossa	4
Long saphenous strip and tie to leg perforating veins	30
Long and short saphenous strip	25
Long and short saphenous strip and tie to leg perforating veins	13
Total	195

Up to now no evidence has been published on the incidence of recurrence after herniorrhaphies managed as short-stay cases. This, as Morris and others (1968) said, is the 'acid test', and although they admit that their evidence is incomplete they took the optimistic view that early discharge did not increase the risk of a recurrence. We agree with this opinion. No obvious deterioration in the follow-up results of the 266 patients discharged home after 48 hours has been detected. The final answer to this question will have to wait until a properly conducted clinical trial arranged as a random series has been carried out. So far this has not been done. On the available evidence it is doubtful if a full clinical trial would be worth while.

VARICOSE VEINS

This report differs from all but one of its predecessors in that the majority of the patients—439 out of the total of 705—were cases of varicose veins. The series reported by Farquharson (1955), Aldridge (1965), and Morris and others (1968) were confined to patients with a hernia; no varicose veins were included. In the other series varicose veins were included. They amounted to 112 out of the 166 patients treated by Stephens and Dudley (1961), but there are only 5 patients with varicose veins in the list of 127 patients treated by Williams (1969).

As with the herniae, no strict rule with regard to age was enforced. The ages of the patients ranged from 14 to 71 years, but again most were between 30 and 59 years old (*Fig.* 1).

Another way in which the present series differs from its predecessors is that patients needing extensive below-knee operations have been included. Cases of this type were rejected by Stephens and Dudley (1961). The only patients we have excluded for surgical reasons have been those with an open varicose ulcer on the leg when they first attended the out-patients' department. Patients with perforating leg veins and varicose eczema were accepted provided that there was no ulceration. The proportion accepted was, as with the ruptures, 77 per cent or 439 out of a total of 570.

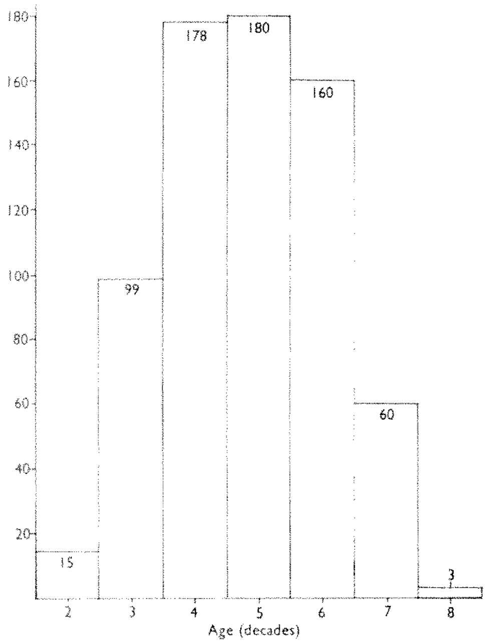

FIG. 1.—Age distribution of the 705 patients included in this series.

The extent of the operations carried out on these 439 patients with varicose veins is set out in *Tables II* and *III*. Some of the operations on the patients with bilateral varicose veins took over 2 hours to do, especially in those who were obese, or who had such tortuous saphenous veins that the stripper would not go up them swiftly. This was especially the case in those patients who had incompetence of the short as well as of the long saphenous vein, because they had to be turned over during the operation. Even if the incompetence was confined to one limb, having to turn the patient over and reapply paint and towels lengthened the time of the operation considerably.

Although clinical observation does not suggest that sending a patient home 48 hours after a herniorrhaphy increases the risk of a recurrence, the remote possibility that it does has not yet finally been excluded. With varicose veins, however, it is very difficult to invent any reason for suspecting that the final result of the operation is, in any way, damaged by this practice. It would seem, therefore, that after undergoing an operation for varicose veins, sometimes a prolonged and extensive one, it is quite safe to discharge a patient home after 48 hours.

IMMEDIATE POSTOPERATIVE COMPLICATIONS PREVENTING THE DISCHARGE OF THE PATIENT IN 48 HOURS

With regard to numbers, the occurrence of immediate postoperative complications is not a serious problem and does not threaten to undermine the short-stay system as a whole.

Out of the 705 patients in this report, only 38, or 5·4 per cent, were unfit to be discharged home 48 hours after operation. The reasons why these patients had to stay on in hospital are set out in *Table IV*. This shows that the most common cause has been acute chest infection with elevation of temperature. This corresponds with the findings of Morris and others (1968). Except for a few of these patients, the delay in their discharge home was only about 3 or 4 days.

Table IV.—THE IMMEDIATE POSTOPERATIVE COMPLICATIONS WHICH PREVENTED 38 PATIENTS FROM BEING DISCHARGED HOME IN 48 HOURS

Complication	*No. of Cases*
Upper respiratory infection	15
Extensive bruising and haematoma	5
Pain in the wound	4
Acute domestic collapse—relatives ill	4
Acute wound infection	2
Profuse bleeding at operation (varicose veins)	2
Prolonged postoperative apnoea	1
Prolonged operation (varicose veins)	1
Prolonged postoperative tachycardia	1
Persistent nausea and vomiting	1
Persistent abdominal discomfort	1
Violent drug reaction (massive urticaria)	1
Total	38

DELAYED POSTOPERATIVE COMPLICATIONS

The development of complications after the patient had been discharged home was not a serious problem numerically, occurring in 62 patients (9 per cent), of whom only 6 (0·9 per cent) had to be readmitted.

By far the most common complication was inflammation of the wound. It was more common in the patients who had been operated on for varicose veins than for a hernia, but even where there were multiple incisions on the limbs usually only one of the wounds was involved. In those patients who suffered an infection of the incision in the leg for perforating veins the portal of entry was often a small area of skin necrosis on one of the flaps.

In half of the infected cases the presence of sepsis was obvious between the seventh and the thirteenth postoperative days. In the remainder it did not show itself until the fourteenth to the twentieth days, and there was a small group in which the onset was delayed until the third or fourth week. Except for 3 cases who had to be readmitted, all the others were cleared up by out-patient treatment, but final wound healing sometimes took 4 weeks, and in a few it dragged on for 8 weeks, while one sinus took 4 months to dry up.

Often, in spite of obvious clinical signs of infection, some inflamed wounds did not discharge. The exudate cultured from those which did discharge contained *Staphylococcus pyogenes* in most instances. Quite a number of these exudates were reported as being sterile.

Of the 6 patients who were readmitted, 3, as mentioned above, had developed a septic wound. The other 3 patients comprised a woman who had a pulmonary embolus 8 days after a right long saphenous stripping, and 2 women who were found to have a deep-vein thrombosis in the left calf 6 days after returning home following long saphenous stripping. All were given a full course of anticoagulant therapy and made a satisfactory recovery.

GENERAL PRE- AND POSTOPERATIVE MANAGEMENT

On attending the out-patients' department for the first time, as well as clinically assessing the patient's general health and ordering a routine chest radiograph and haemoglobin estimation, each patient is questioned about his home conditions. It is obvious that the patient must have a satisfactory house to go to, which is reasonably equipped, and with a close relative willing to look after the patient. Usually a decision can be reached quickly and easily. If there is any doubt a telephone call to the patient's own doctor solves the problem one way or the other. Patients living alone, or in hostels, boarding houses, lodgings, etc., were always rejected for short-stay surgery.

In the West Midlands the general standard of housing is satisfactory. As witness to this is the fact that 77 per cent of all the patients who were sent to hospital with a hernia or with varicose veins have been treated as short-stay cases, and most of those who were rejected were turned down on surgical rather than on domestic grounds.

Fortunately nearly all of our patients live within a radius of 10 miles, but occasionally a patient living 20 miles away has been sent home in 48 hours if the domestic arrangements were good and the general practitioner was prepared to take a special interest.

Keeping the patient in for 48 hours before being discharged has the advantage that the ambulance journey is tolerated better and there is no need to administer perferozine to combat sickness on the return journey home as is necessary with 'day-surgery' (Dudley, 1961). Nevertheless, there have been numerous complaints about the discomfort of the ambulance journey home, particularly about the circuitous route taken in the discharge of other duties and of prolonged stops at other hospitals.

Once home the patient is instructed to go to bed for 2 days, except for essential purposes, and a letter is sent to the general practitioner before the patient leaves the hospital asking him to call on the patient. On the third day the patient is told to get up and move about the house. A normal diet is usually taken.

On the seventh postoperative day the patient is brought back to the out-patients' department by ambulance, examined, and half of the sutures are removed. Seven days later the ambulance brings the patient back again and the rest of the sutures are taken out. By then most patients are walking normally and their convalescence is well advanced. They are seen once or twice more, and if recovery is complete they are transferred to the follow-up system.

This, in outline, is how the present series has been conducted.

DISCUSSION

Provided that the patients are wisely selected, there remains no serious doubt that it is safe to send the majority of the patients home 48 hours after a herniorrhaphy or an operation for varicose veins.

However, it does not follow automatically that just because a thing can be done it ought to be done. It is only justifiable if it is to the patient's advantage, if it meets with the general practitioner's approval, and if it helps the hospital. To clarify this point a detailed survey was carried out on the last 200 patients who were treated as short-stay cases, and the general practitioners concerned were also questioned.

1. Patients and their Relatives.—The most important result of this survey is that 160 patients (80 per cent) liked the scheme unreservedly, 10 (5 per cent) liked it with reservations, and 26 (15 per cent) disliked it. The patients who disliked going home so soon after the operation gave a variety of reasons. One complained of 'feeling really ill' and another suffered with 'anxiety' and also said it was difficult to climb stairs. The rest of the patients who disliked their short stay in hospital all complained of domestic problems, usually with regard to the care of young children in the case of women, and 'making life difficult for my wife' in the case of men.

Turning now to the patients' relatives who had to look after them after their return from the hospital, 167 (83·5 per cent) said they liked the scheme without reservations, 11 (5·5 per cent) liked it but had reservations, and 21 (11 per cent) disliked it. Usually it was the patient's nearest relative who was concerned (128 cases or 64 per cent), but more distant relations were involved in 48 cases (24 per cent) and neighbours were called in to help with 24 (12 per cent) patients. Only 55 people had to take time off work to look after the patient and the length of time they lost varied from a half to one whole day. One of the reasons why so few people had to stay away from work is that when the operations are performed on a Wednesday, as in this series, the patients arrived home on the Friday afternoon, and as many people work a 5-day week they would be at home for the week-end anyway. If patients were operated on during a Monday or a Tuesday, being discharged home 48 hours later, then it is likely that their relatives and neighbours would have to stay away from work longer in order to help.

Lastly, a patient ought not to be discharged home 48 hours postoperatively unless the surgeon is satisfied that, in addition to there being a relative available to receive the patient, the place in which the patient lives is satisfactory. Fortunately in the West Midlands, as mentioned earlier, this problem seldom arises as the amount of slum property is very small. The type of accommodation in which the 200 patients included in this special survey lived is shown in *Table V*: 108 (54 per cent) lived in houses or bungalows which they owned or were buying, 63 (31·5 per cent) lived in council houses or flats, and only 29 (14·5 per cent) were in rented accommodation (house, cottage, flat, and 1 caravan).

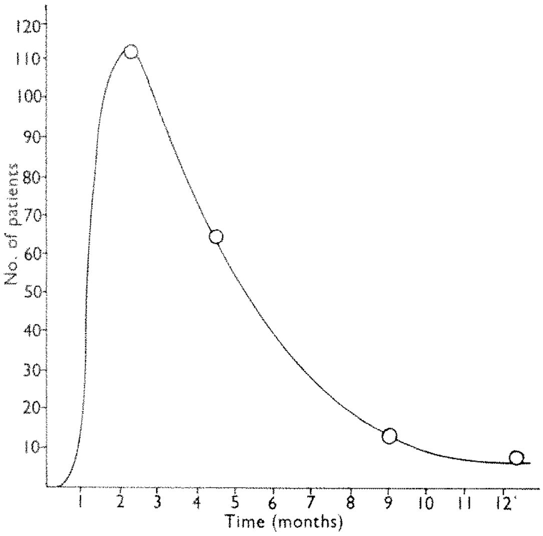

FIG. 2.—Time spent on the waiting list of the last 200 patients treated in this series.

Table V.—TYPE OF ACCOMMODATION IN WHICH THE LAST 200 PATIENTS IN THIS SURVEY LIVED

Accommodation	*No. of Cases*
House owner/occupier	99
Council house	55
Council flat	8
Bungalow	9
Rented	
House	17
Cottage	2
Flat	2
Caravan	1
Other accommodation	7
Total	200

It is fortunate that the great majority of the patients and their relations liked short-stay surgery because it at least halved the length of time they were on the waiting list. In this group patients who are unsuitable for short-stay surgery have to wait at least a year for treatment, but as shown in *Fig.* 2, of the patients who were accepted, 112 (56 per cent) were treated within 3 months, 65 (32·5 per cent) were treated in 6 months or less, and only 13 (6·5 per cent) had to wait more than 6 months. However, there were 9 (4·5 per cent) who were not admitted for more than a year.

The reasons for the varying lengths of waiting time shown in *Fig.* 2 were mainly to do with hospital staffing, but it should be noted that at all levels some of the delays were entirely due to the patients, and that out of the 22 patients who waited more than 6 months, the delays were of the patient's own making in 8. The rest of these long delays were caused by administrative errors, with two exceptions: 1 patient who deliberately delayed admission for over 1 year and another who delayed it for 3½ years.

2. The General Practitioners.—As well as inquiring closely of the last 200 patients with regard to short-stay surgery, the doctors who referred these patients to the hospital were also questioned to find out if the system was burdensome from their point of view.

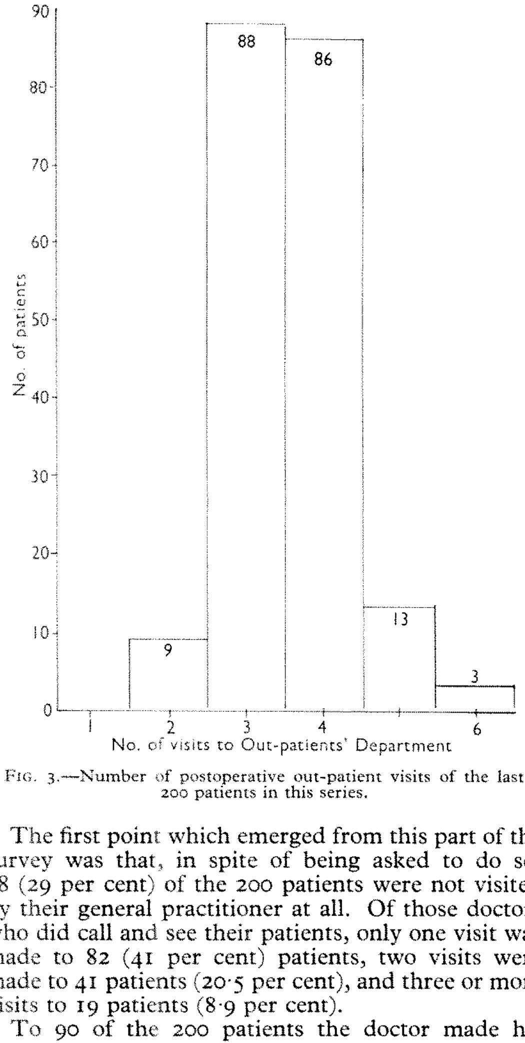

FIG. 3.—Number of postoperative out-patient visits of the last 200 patients in this series.

The first point which emerged from this part of the survey was that, in spite of being asked to do so, 58 (29 per cent) of the 200 patients were not visited by their general practitioner at all. Of those doctors who did call and see their patients, only one visit was made to 82 (41 per cent) patients, two visits were made to 41 patients (20·5 per cent), and three or more visits to 19 patients (8·9 per cent).

To 90 of the 200 patients the doctor made his visit as a routine because the hospital had requested him to do so. In 28 cases he called because the dressings needed changing, 17 patients simply wanted to be reassured, and the reasons for the visits paid to the other patients were not given.

Out of a total of 162 patients visited, the general practitioners thought their visit was worth while in 100 cases (61·7 per cent), but that it could equally well have been done by a nurse in the other 62 cases (38·3 per cent). On 26 occasions the general practitioners arranged for the district nurse to call, on 23 they prescribed dressings, in 18 instances they prescribed drugs, and three times they arranged transport to take the patient back to the hospital. On 82 (51·2 per cent) occasions they issued a certificate.

No evidence has been collected to suggest that the general practitioners whose patients have been subjected to short-stay surgery are opposed to the scheme. On the contrary, there is some evidence that they like it.

3. The Hospital.—Up to now it has been established that most of the patients and their relatives like short-stay surgery in the treatment of groin ruptures and varicose veins, and that their general practitioners accept the method.

From the hospital point of view the reduction of the time that patients remain untreated on the waiting list is to be welcomed. Short-stay surgery has little, if any, effect on the main wards because 90 per cent of their beds are full of more seriously ill patients anyway. There is, however, some increase in the work of the out-patients' department. If a patient is kept in the ward for 10 days postoperatively the sutures will have been taken out before the patient is discharged home. If the wound has become inflamed the patient will be kept in until it is clean or very nearly so.

After short-stay surgery the removal of sutures has to be done by the out-patients' staff. Asking the patient's own doctor to do the removal was considered, but for the present this step has not been taken. Moreover, of the patients who developed an inflamed wound after going home, none of them was readmitted, so that the treatment of those infected wounds was added to the other duties of the out-patients' nursing staff. Three patients with wound sepsis were readmitted but that was before the special survey now being discussed.

For these reasons the number of visits each patient makes to the out-patients' department tends to be rather more than would be the case if at least 10 days were spent in the ward. This point was examined particularly in the last 200 patients. The length of time that the patients attended the out-patients' department averaged 4–6 weeks, ranging from 2 weeks to 4 months for 1 patient with a persistent wound infection who had to continue attending until a sinus dried up. The actual number of visits the patients made is set out in *Fig.* 3, which shows that 174 patients (87 per cent) attended three or four times, that 9 (4·5 per cent) only attended twice, and that 16 (8 per cent) attended at least five times.

With regard to the hospital there is one final point, a point of vital importance. Short-stay surgery is a method of increasing the number of patients with groin ruptures and varicose veins who are operated on each year without reducing the number of patients suffering from more serious conditions to make way for them. It is extra work. This extra work cannot be done unless extra theatre time is provided. The present series of 705 patients have been treated because an extra theatre and an extra theatre staff were produced; otherwise it could not have been done.

CONCLUSIONS

1. With the housing conditions and the standard of living which exists in the West Midlands it is safe to treat 75 per cent of the patients who are referred to the hospitals with groin ruptures and varicose veins on a short-stay basis, discharging them home 48 hours after the operation.

2. The degree of safety can be judged from the facts that out of 705 patients, only 38 (5·4 per cent)

were unfit to go home 48 hours after the operation had been carried out, and only 6 (0·9 per cent) needed to be readmitted. In other words, the safety of the short-stay system is such that in practice it is over 90 per cent efficient.

3. It greatly reduces the length of time patients with groin hernia and varicose veins remain on hospital waiting lists.
4. As short-stay surgery increases the total number of operations performed per year, extra theatre facilities must be provided, or longer hours worked by existing theatre staff.
5. Short-stay surgery somewhat increases the amount of work that has to be done by the out-patients' nursing staff.
6. This scheme is liked by the great majority of the patients and by the relatives who have to look after them.
7. The general practitioners whose patients have been treated in this way do not object to the method.

Acknowledgement.—The authors would like to express their gratitude to Professor A. L. d'Abreu, Professor of Surgery in the University of Birmingham, for his kindness in scrutinizing this report and approving its presentation.

A CLINICAL TRIAL TO DETERMINE WHETHER A LYTLE'S REPAIR OF A PRIMARY INDIRECT INGUINAL HERNIA NEEDS THE ADDITION OF A RECTUS FLAP

AN EXERCISE IN SCIENTIFIC METHOD

By F. S. A. Doran
BROMSGROVE AND KIDDERMINSTER HOSPITALS, WORCESTERSHIRE

Summary

It is a paradoxical fact that although surgeons have discovered how to carry out organ transplants they have not discovered what is the best way to treat such very common conditions as early carcinoma of the breast and primary indirect inguinal hernia.

The reason for this failure is that when surgeons talk of their dedication to scientific methods they refer to an archaic, fallacious, and discredited method; a method discarded by the physical sciences a very long time ago. It is called 'Baconian empiricism'.

The time is long overdue for this archaic method to be rejected and replaced in all surgical work by properly constructed clinical trials leading to an approved mathematical scrutiny of the observed results. The trial must be conducted in a way which eliminates bias for or against the rival methods being tested, otherwise the important mathematical tests of validity cannot be applied to the observed results.

Evidence is submitted to show that more valid information can be obtained from a series of 155 cases of herniorrhaphy arranged in a scientific clinical trial than can be obtained from 2000 cases mechanically collected and tabulated in accordance with the rules of Baconian empiricism.

This clinical trial is used as an example of the new scientific approach to the problem of the primary indirect inguinal hernia, but it applies equally well to the treatment of early carcinoma of the breast.

The question asked was whether, having repaired the deep abdominal ring, a rectus flap ought to be added. The mathematical scrutiny of the observed results of the trial prove that this additional step would not improve the results obtained by a simple suture of the deep ring on its own.

In view of their recent progress in transplant surgery it is a curious paradox that surgeons have not solved problems which are so common that they are confronted by them nearly every day of their lives. For example, they do not know what is the best way to treat an early carcinoma of the breast. They do not agree on which, if any, operation should be performed, whether deep X-ray treatment is helpful or harmful, or on the place of cytotoxic drugs and hormones. They do not know whether a vagotomy ought to be truncal, selective, or highly selective. They do not know whether the best way to treat varicose veins is by operation or by injection. Most surprisingly of all they do not know which is the correct way to repair a primary indirect inguinal hernia in a man. In 1927 Keynes was astonished that the correct method of treating an inguinal hernia was then a matter of dispute. He thought that the operative technique should, already, have reached the point of final standardization. Thirty years, and several thousands of published cases, later Koontz (1956) reported that there was more difference of opinion about the correct way to repair an inguinal hernia than there was about the treatment of any other surgical condition.

The explanation of this paradox is quite simple.

Scientific medicine is now taken for granted by patient and surgeon alike. In recent years scientific medicine has become such an overworked phrase that it has been reduced to a cliché. All surgeons pay lip-service to it. However, when their writings are examined a surprise is in store. The scientific method they use is archaic, fallacious, and discredited, a method which the physical sciences discarded as useless in practice a long time ago.

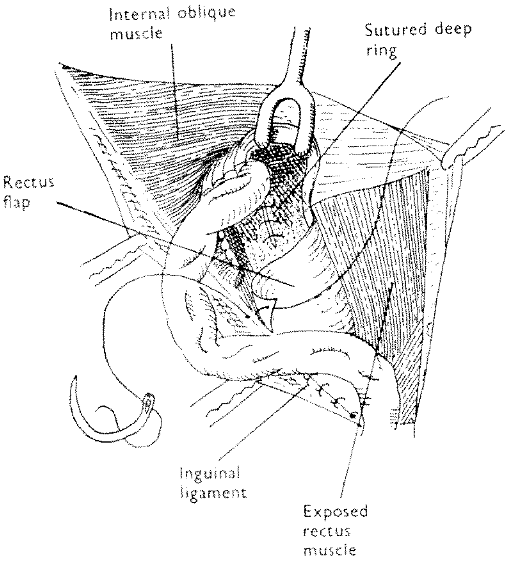

FIG. 1.—Aponeurotic flap cut from the rectus sheath hinged over and sutured to the inguinal ligament behind the cord.

The scientific method used by most surgeons today is termed 'Baconian empiricism'. Impressed by the failure of scholastic philosophy to advance men's knowledge of, and power over, Nature, Francis Bacon (1561–1626) put forward a theoretical basis for the experimental science introduced during the Renaissance (Dampier-Whetham, 1929).

Bacon held that the true connexion between natural phenomena would emerge *almost automatically* provided that (1) all available facts were recorded, (2) all possible observations were made, (3) all feasible experiments were performed, and (4) all the results were collected and tabulated.

Dampier-Whetham (1929) points out that the defect in the method is that it fails to appreciate the huge number of observations that complicated phenomena could call for, that the number of experiments possible would be enormous, and that the rules Bacon laid down for the collection and tabulation of the results were useless. Bacon seems to have had little or no influence on those who were actually performing scientific experiments.

From our point of view as surgeons it is important to realize that advances in science have seldom been achieved by the pure Baconian method (Dampier-Whetham, 1929). Therefore we have no alternative but to cut our losses in time, endeavour, and clinical material and to make a fresh start. Luckily there is an up-to-date scientific method suitable for use on biological problems such as ours ready to hand. All we need to do is to use it.

The present clinical trial is intended as an illustration of the way in which this modern scientific method should be applied to a surgical problem. The problem chosen is whether, when repairing a primary indirect inguinal hernia in man, the posterior wall of the inguinal canal can be strengthened by adding a rectus flap after the deep abdominal ring has been repaired.

The method could equally well be applied to deciding whether deep X-ray therapy in early carcinoma of the breast is helpful or harmful.

THE REASON FOR THIS CLINICAL TRIAL

A few years ago the author made a fresh start on the problem of finding out what was the best way to treat a primary indirect inguinal hernia. It was decided to accept Occam's principle and to cut away all the complex steps in the techniques of existing herniorrhaphies and to start again from the simplest form of repair.

In 1871 Marcy described his operation, which consisted of removing the hernial sac and then repairing the expanded deep abdominal ring through which it had come (Lytle, 1954). This type of repair was the obvious choice as the place to begin again with the new scientific approach.

Theoretically a simple suture of the deep abdominal ring, provided that it had not been stretched too much, might be enough in itself. Both Edwards (1943) and Lytle (1945) had suggested that this was so. Neither, however, had proved the point.

A scientifically conducted clinical trial was therefore carried out on 150 men, between the ages of 20 and 60 years, to discover if the result of a simple suture of the deep abdominal ring could be improved on by adding a fascial sling, similar to Ogilvie's 'levator annuli interni' (1959), or a tense fascial patch from the aponeurosis of the external oblique muscle. The trial proved that these technical additions were both useless and, being redundant, objectionable (Doran, 1962).

In a 2-year follow-up in which 146 patients were examined 5 recurrences were found. In 3 of these patients the groin was explored by the author, and in each the recurrent sac was direct in type and close to the pubic spine. The repair of the deep ring was sound in all of them.

The next step was to carry out another clinical trial to find out if these failures could be avoided by covering the back wall of the inguinal canal from the sutured deep ring to the pubic spine with a flap of rectus sheath placed behind the cord and sutured to the inguinal ligament (*Fig.* 1).

THE STRUCTURE OF THIS CLINICAL TRIAL

The old method stated that all facts must be recorded and all possible observations should be made. Even today this is impossible. It is easy to establish the fact that one billiard ball is black and another is white. It is easy to establish the fact that one patient weighs 57 kg. and another weighs 60 kg. because their weights can be measured. On the contrary, many of the clinical 'facts' cannot be measured: How heavy is heavy work? When is recreation strenuous? When is bronchitis chronic? When is the straining of constipation a danger? Can strong inguinal muscles always be distinguished from those which are less strong? Therefore the presence of many clinical facts cannot be established without doubt or dispute in every individual patient in the series.

Secondly, the instruction to make all possible observations is vain. Many of the complicated biophysical and biochemical factors of wound healing cannot be observed.

The new method admits all these shortcomings. It also admits that there is no way of finding out if the healing factors which cannot be observed are evenly distributed throughout the patients in any particular series. It escapes from this tangle of dilemmas by pointing out that provided accidental, or subconscious, bias in favour of operation A as against operation B can be eliminated a valid comparison of their relative merits can be made.

The new set of rules are as follows:—

1. Bias in favour of one of the rival techniques being compared must be eliminated by deciding by 'lot' which operation is to be performed in each individual case. This ensures that each technique is applied evenly to those patients who are a poor risk and those who are not, because there cannot be any causal connexion between the 'lot' and the non-surgical determinants of the strength of the repair.

2. The patients in the two groups must be followed up for the same length of time. As the risk of recurrence lasts throughout life gross bias in favour of operation A would be introduced if those cases were followed up for only half as long as those treated by operation B. Any comparison of recurrence rates in these circumstances would be invalid and worthless.

3. The patients in the two groups must be followed up and examined physically. As untrained laymen are incompetent clinically compared with surgeons, postal surveys introduce a gross bias in favour of the operative technique concerned to the detriment of any group in which the patients were both traced and examined.

4. The observed results must be subjected to an accredited mathematical scrutiny. This is needed to avoid the mistake of attributing to technical superiority a difference in the number of recurrences caused by the chance interplay of non-technical factors.

The present clinical trial has been conducted according to these new scientific rules (Fisher, 1947; Hill, 1966).

THE MATERIAL

The series consists of 155 indirect inguinal herniae.

Only male patients over the age of 20 years were used. No upper age limit was imposed but, as *Fig.* 2 shows, only 15 patients were more than 60 years old.

Following the example of the previous clinical trial (Doran, 1962) patients were only included if the circumference of the deep abdominal ring was 10 cm. or less (10 cm. happens to be the circumference of the author's right index and middle fingers at the level of the middle phalanx), and the size of the ring was measured from inside the hernial sac.

LENGTH OF FOLLOW-UP

Guided by previous experience the follow-up was limited to 2 years. With benign conditions it is difficult to keep the efficiency of the system in the region of 95 per cent for longer periods. Even at 2 years some patients have to be tracked down and examined in their homes on Sunday mornings.

In the previous clinical trial an efficiency of 97·3 per cent was achieved, but in the present one it was only 95 per cent. Out of the 155 cases of hernia, 7 herniae have been lost. A patient with bilateral herniae died of a ruptured aortic aneurysm; a diabetic patient also died of his disease; a third man was killed in a colliery accident; an Italian returned to his native land, and 2 other patients left the district and could not be traced. Therefore, out of 155 repaired inguinal herniae, 148 (95 per cent) were followed up for 2 years and were examined by the author.

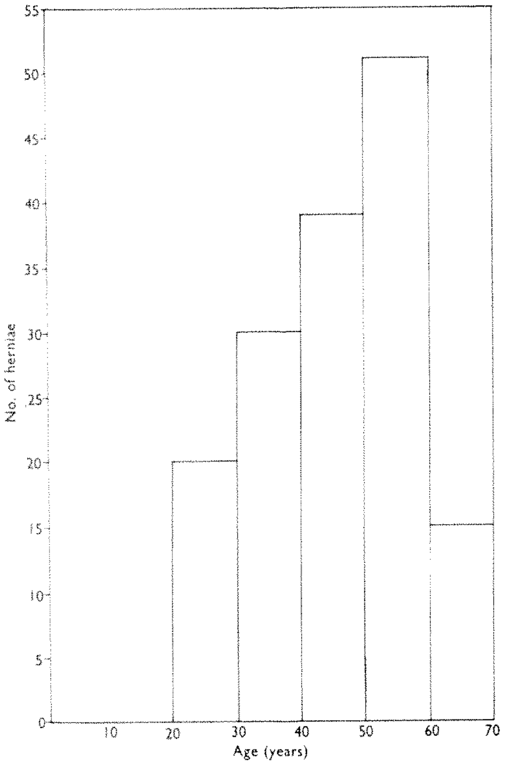

FIG. 2.—Age distribution of the patients in the present clinical trial. Only 15 were over 60 years.

THE OBSERVED RESULTS

Using this new method, time is not wasted trying, vainly, to draw a definite line between a 'bulge' and a 'recurrence'. As this method does not depend on the confrontation of absolute numbers, all that is needed is for each patient on follow-up to be examined by the same person. Provided the assessment error is constant for the patients in both of the groups that is enough.

The results are set out in *Table I.*

1. Lytle's Operation (Suture of the Deep Abdominal Ring).—Out of the total of 155 herniae, 86 were treated by a simple suture of the deep abdominal ring. Of these 86 repairs, 80 were successfully followed up for 2 years and 6 were lost

Only 1 recurrence was found in the 80 who were examined.

The 6 cases which were lost, and therefore not examined, raise a very important point. In Nature there is no valid principle of uniformity known. As a result it would be scientifically improper to make the flattering assumption that all these 6 repairs were sound and free from recurrence. In fact this might be true, but conversely, as none of them was examined, every one might be a recurrence. Or again the truth could lie at some intermediate point between these two extremes.

Table I.—RESULTS OF 155 REPAIRS OF PRIMARY INDIRECT INGUINAL HERNIA

OPERATION	TOTAL NO. OF HERNIAE	NO. OF HERNIAE FOLLOWED UP	KNOWN RECURRENCES		POSSIBLE RECURRENCES	
			No.	Per cent	No.	Per cent
Lytle's operation	86	80	1	1·16	7	8·02
Lytle's operation with rectus flap	69	68	1	1·45	2	2·90
Total	155	148	2	1·30	9	5·80

Table II.—CHI² (χ^2) TEST CALCULATED FOR THE MINIMUM AND MAXIMUM NUMBERS OF RECURRENCES POSSIBLE

CALCULATION OF χ^2	MINIMUM POSSIBLE NO. OF RECURRENCES		MAXIMUM POSSIBLE NO. OF RECURRENCES	
	Type of Operation		*Type of Operation*	
	Lytle	Lytle + Flap	Lytle	Lytle + Flap
No. of successes	85	68	79	67
Expected No. of successes	84·89	68·11	81·01	64·86
Successes observed − expected	+0·11	−0·11	−2·01	+2·14
$\frac{(\text{Observed} - \text{expected})^2}{\text{Expected}}$	0·00014	0·00018	0·0499	0·0706
No. of recurrences	1	1	7	2
Expected No. of recurrences	1·11	0·89	4·99	4·14
Recurrences observed − expected	−0·11	+0·11	+2·01	−2·14
$\frac{(\text{Observed} - \text{expected})^2}{\text{Expected}}$	0·0109	0·0136 $\chi^2 = 0·02482$	0·8096	0·6738 $\chi^2 = 1·6039$
	Where $n = 1$, $P = 0·90$: Not significant		Where $n = 1$, $P = 0·20$: Not significant	

The correct way to report this, and similar results, is to say:—

a. The minimum number of recurrences possible is 1 or 1·16 per cent.

b. The maximum number of recurrences possible is 7 or 8·02 per cent.

As stated above the real result could be at either extreme or at some intermediate point.

2. Lytle's Operation with Rectus Flap added.—Of the total of 155 herniae, 69 had a rectus flap added to the suture of the deep abdominal ring. Sixty-eight of the herniae treated in this way were successfully followed up for 2 years. In this group also only 1 recurrence was found, but unlike the other group only 1 case was lost, so the efficiency of its follow-up was 98·5 per cent as compared with 93 per cent for the other group.

With the rectus flap added, therefore, the minimum number of recurrences possible is again 1 (1·45 per cent), but as only 1 case was lost the maximum possible is only 2 (2·9 per cent).

Taking the series as a whole the rate of recurrence ranges from a minimum of 1·3 per cent to a maximum of 5·8 per cent.

As the defects in the follow-up occurred almost entirely in the group treated by a Lytle's operation alone an interesting situation exists. If the minimum figures of the two groups are compared then there is nothing to choose between them: 1·16 per cent for the Lytle's operation on its own, and 1·45 per cent with a rectus flap added. But the maximum figures, owing to the loss of 6 cases in the Lytle group as compared with 1 in the other group, show an apparent superiority in the group treated by the addition of a rectus flap: 2·9 per cent as opposed to 8·02 per cent.

Fortunately, as this test has been a properly conducted clinical trial this awkward situation can be unravelled by the application of a suitable mathematical test to find out whether or not a difference of this magnitude could have occurred by chance alone.

A MATHEMATICAL SCRUTINY OF THE OBSERVED RESULTS

Quite apart from the present situation it would be very lax to accept the observed results of a clinical trial on their face value. An observed difference ought only to be accepted if it is too large to be accounted for by chance alone. It is usual to demand that the difference should be such that it could only have occurred by chance once in 22 trials of equal size. There are numerous ways of making this calculation, but the χ^2 test is simple and convenient and therefore has been used here. It is set out in *Table II.* Two sets of calculations have been made, first to test the figures for the 'minimum possible' number of recurrences and then for those representing the 'maximum possible' number of recurrences. In this trial the second group of figures are of particular importance. The result of this essential calculation shows that even the difference of 5 between the number of recurrences in the two groups could well have occurred by accident. Therefore on both counts, 'minimum possible' and 'maximum possible', *the correct verdict is that both methods of treatment are of equal value.*

Without this mathematical scrutiny it would have been very difficult to know what verdict to reach in the present trial, and it is important to realize that the ability to apply a mathematical test depended entirely on the fact that the trial had been correctly planned from the outset as a random series.

Having proved that these two methods are of equal value, the decision which of them to use in practice is resolved, as in all trials which end in a tie, by the application of Occam's razor. The most simple solution to the problem must always be preferred. There are cogent practical reasons for this policy.

DISCUSSION

Having described the new scientific method and having given an illustration of its practical application, it will be interesting to turn back for a moment to its discredited rival, Baconian empiricism, and to examine the way its four rules worked in practice.

1. All Available Facts must be recorded and 2. All Possible Observations must be made.—As no facts except facts of observation can be made with regard to a patient with an inguinal hernia these two rules can be taken together.

Table III.—Size of 13 Major Series published since 1900

Author	*Total No. of Cases in Series*
Bull and Coley (1907)	1,525
Davis (1916)	1,756
Hoguet and Coley (1918)	5,525
Taylor (1920)	2,230
Erdman (1923)	1,093
Coley (1924)	1,155
Gibson and Felter (1930)	1,618
Fallis (1936)	1,600
Grace and Johnson (1937)	1,115
Skinner and Duncan (1945)	1,126
Garner (1947)	2,643
Hagan and Rhoads (1953)	1,082
Palumbo, Paul, and Mighell (1954)	1,375
Total	23,843

No one is going to pretend that all facts with regard to every patient with an inguinal hernia, now and in the past, have been observed and then recorded. Nevertheless, a very large number have been. For example, in 13 major series published in the United States alone the grand total is 23,843 cases of inguinal herniorrhaphy (*Table III*). If European and smaller series are added the number would rise to at least 50,000 cases.

Obviously it can be said that our experience is too limited and that the Baconian method needed far larger numbers, but the published numbers are big, and if still more are required then the method can be criticized as being insensitive, clumsy, and very dilatory.

In addition to the thousands of patients who have been operated on, observations have been made and recorded about their sex, age, bodily configuration, length of time prior to operation that the hernia had been present, whether its first appearance had followed an injury or not, what social class the patient belonged to, whether they did sedentary, light, or heavy work, whether they suffered from chronic bronchitis, chronic constipation, urinary obstruction, or any other defect likely to produce straining, whether complications, such as wound sepsis, occurred, and so on *ad infinitum*. It does not flatter the method that all this effort in trying to make the factual observation of patients with inguinal hernia complete should have been in vain.

3. All Feasible Experiments must be made.—Surgeons have obeyed this rule with alacrity and zeal.

It is 100 years since Marcy published his first article on the simple suture of the deep abdominal ring (Lytle, 1954). Bassini performed his operation for the first time 13 years later in 1884. Marcy's simple repair was so deeply buried by the proliferating complexity which followed that it was completely forgotten until it was rescued by Lytle.

Table IV.—Edwards's (1943) Selection of Eponymous Operations for Primary Indirect Inguinal Hernia

Author	*Operation*
Andrews (1895)	Conjoined tendon sewn to Poupart's ligament behind the cord, external oblique muscle imbricated to make tunnel for cord
Bassini (1889)	Conjoined tendon sewn to Poupart's ligament behind the cord
Bates (1913)	Closure of internal ring and transversalis fascia through 5-cm. incision with purse-string suture
Bloodgood (1898)	5-cm. incision of rectus sheath allowing rectus muscle and conjoined tendon to meet Poupart's ligament behind the cord
Brenner (1898)	As Bassini but using cremaster muscle to reinforce internal oblique muscle
Downes (1911)	Behind the cord the exposed edge of the rectus is sewn to Poupart's ligament and imbricated flaps of internal oblique muscle
Fergusson (1899)	Narrowing of internal ring and the external oblique muscle imbricated superficial to the cord
Fowler (1897)	Division of back wall of canal, cord placed inside the peritoneum to emerge by pubic spine, canal obliterated
Gallie (1921)	Fascial darn to back wall of canal
Halstead (1889)	Suture of conjoined tendon and cremaster muscle to Poupart's ligament superficial to cord, imbrication of external oblique muscle
Hull (1913)	Herniotomy through 1·3-cm. skin incision
Kirschner (1910)	Free graft of fascia lata
La Roque (1919)	Intraperitoneal inversion of sac and transperitoneal herniotomy above the internal ring
McArthur (1904)	As Bassini but using two pedicle flaps of external oblique aponeurosis as sutures
McEwan (1886)	Sac freed to above internal ring, folded into pad, and sutured into the deep ring as a plug
McGavin (1909)	Two filigrees inserted into posterior wall behind cord
Marcy (1871)	Herniotomy—suture of internal ring with kangaroo tendon displacing cord upward and laterally
Scott (1905)	Conjoined tendon sewn to Poupart's ligament behind cord, relaxing cut in rectus sheath, obliteration of external ring
Stein (1939)	Herniotomy—flap of fascia covering internal oblique sewn to Poupart's ligament
Stetten (1923)	Suture of conjoined tendon to Poupart's ligament and imbrication of external oblique muscle behind the cord
Torek (1906)	As Bassini but the vas deferens is separated from the vessels and is sutured to keep it so
Watson (1916)	Cord thinned and sewn high on the internal oblique muscle, conjoined tendon sewn to Poupart's ligament and imbrication of external oblique muscle

Bacon would have been proud of the number of technical experiments performed by surgeons working in this field. Not all these experiments will be listed, but it will suffice to make the point if Edwards's (1943) selection of eponymous operations, 22 in number, is given (*Table IV*).

One of the main criticisms levelled at the Baconian method by the practitioners of the experimental sciences has always been that it grossly underestimated the complexity of natural events. Moreover the method does not specify how many instances of each particular experiment are needed to allow the triumph of the correct one to stand out as self-evident truth.

Evidence that this criticism is well founded has been provided by the failure of the Liverpool registration scheme to solve the problem. Given a finite quantity of clinical material, the larger the number of technical experiments, the smaller will be the number of patients available to each particular technique. If the number of technical experiments is too large then, inevitably, *fragmentation occurs* and there are not enough examples of each technique to satisfy the demands implicit in rule 1 and rule 2 of the method.

Table V.—RESULTS OF THE LIVERPOOL SERIES (MARSDEN, 1958, 1961), ILLUSTRATING THE PHENOMENON OF FRAGMENTATION WHICH RESULTS FROM INDISCRIMINATE REGISTRATION

TYPE OF REPAIR	1958		1962		1958 AND 1962 RECURRENT
	Primary Indirect	Primary Direct	Primary Indirect	Primary Direct	
McArthur-Morrison	168	54	265	75	15
Bassini (with nylon)	91	39	235	101	31
Bassini (with mersaline)	25	0	46	9	2
Bassini (with catgut)	47	14	104	19	3
Bassini and Wyllys Andrews III (nylon)	56	45	97	56	12
Bassini and Wyllys Andrews III (mersaline)	20	12	47	12	1
Bassini and Wyllys Andrews III (catgut)	2	1	11	16	2
Wyllys-Andrews III (catgut)	15	5	15	5	2
Wyllys-Andrews III (nylon)	0	0	0	0	2
Wyllys-Andrews II (catgut)	36	9	61	19	5
Wyllys-Andrews II (nylon)	5	0	9	1	2
Wyllys-Andrews II (mersaline)	1	0	1	0	0
Bassini and Wyllys Andrews II (catgut)	8	4	37	9	1
Bassini and Wyllys Andrews II (nylon)	0	1	5	5	0
Closure of canal	30	1	55	6	15
Cooper's	2	3	4	4	0
Gallie	4	3	4	5	2
Nylon tricot	27	7	43	16	8
Excision of sac	16	0	32	0	0
Closure of the internal ring	12	0	24	0	0
Fascia transversalis	4	1	6	1	0
Bassini (with wire)	0	0	3	2	3
Polyvinyl sponge	0	0	0	0	1
Rectus sheath flap	0	0	1	2	0

Table V shows how the process of fragmentation destroyed the Liverpool series, which added up to 1000 patients by 1958 and to 2000 patients by 1961 (Marsden, 1958, 1961). It will be seen that twenty-four technical methods were involved. Evenly distributed that ought to have meant 83 patients out of the total of 2000 for each method of repair. This should be compared with the present clinical trial of 155 hernia repairs (*Table I*) in which the two contending groups included 86 and 69 cases respectively.

In fact, the methods tested at Liverpool were not evenly distributed, as *Table V* demonstrates. Of the forty-eight groups in the 1962 results for primary hernia forty-two contain less patients than either of the two groups tested in the present clinical trial.

4. All the Results must be collected and tabulated.—Surgeons have been obeying this rule for more than 50 years. Because the method is useless the collection and tabulation of thousands of observed clinical and technical facts have been a waste of time and material. All it has done is to bury the solution to the problem in a large pseudo-statistical slagheap.

If anyone has any doubts on this point let him reflect on the failure of the Baconian method to teach us the best way to treat early carcinoma of the breast. The collection, tabulation, and recording of observed clinical facts have been much more intense and efficient in this field than it has been with regard to inguinal hernia. Much interesting and useful information has been accumulated, but it has not solved the problem at which it was aimed. In the Birmingham region alone, between 1936 and 1960, 15,700 cases of carcinoma of the breast were registered. Out of this total, 6489 were 'early' carcinomas, that is, Stages I and II. These cases were analysed on the basis of an efficient 5-year follow-up (Bond, 1967). This analysis did not solve the problem of the way in which we ought to treat an early carcinoma of the breast. On the contrary, it confused the issue even further by suggesting that no operation, with the possible exception of removing the primary from the breast, was any use, and by claiming that deep X-ray therapy was harmful not helpful. This may be true but it cannot be known to be true until it has been scientifically and mathematically tested.

It is to be hoped, at long last, that surgeons will realize that Francis Bacon is a false prophet and that it would be a mistake to try to solve our problems, whether they be the correct way to treat an early carcinoma of the breast or to repair a primary indirect inguinal hernia, by the further application of this ineffectual, discredited, and scientifically discarded method.

This warning is a serious one because already it is being said that the method can be saved by the computer. This is the gross fallacy of thinking that a method which is wrong can be corrected by mechanizing its application.

CONCLUSIONS

1. The correct method of repairing a primary indirect inguinal hernia with a neck 10 cm. in diameter or less is by a simple suture of the deep abdominal ring (referred to as Lytle's operation).

2. It is unnecessary to protect the posterior wall of the canal by the routine addition of a rectus flap placed behind the cord and sewn to the inguinal ligament.

3. All additional technical steps and all new methods of repair should be scientifically tested by a properly conducted clinical trial using Lytle's operation as the standard for comparison before they are introduced into routine practice.

4. Surgeons should follow the example of practitioners in the experimental sciences and reject Baconian empiricism with its mistaken belief that biological problems can be solved with punch-cards, programs, and computers.

Acknowledgement.—I wish to express my gratitude to Professor A. L. d'Abreu, Professor of Surgery in the University of Birmingham, for his unfailing encouragement, help, and kindness.

ULCERATIVE COLITIS TREATED BY ILEOSTOMY AND EXCISIONAL SURGERY

FIFTEEN YEARS' EXPERIENCE AT ST. MARK'S HOSPITAL

BY JEAN K. RITCHIE
RESEARCH DEPARTMENT, ST. MARK'S HOSPITAL, LONDON

SUMMARY

The results of excisional surgery with the establishment of a permanent ileostomy in 246 patients with ulcerative colitis operated on in the years 1955–69 at St. Mark's Hospital, London, are presented. The overall mortality of the primary surgery was 8·1 per cent, being 9·3 per cent in the years 1955–9, 10·6 per cent in the years 1960–4, and 5·3 per cent in the years 1965–9. This mortality was 1·6 per cent in 128 patients treated electively, 10·7 per cent in 75 cases coming to urgent surgery, and 23·3 per cent in 43 patients undergoing emergency operations. The mortality in this third group fell from 36·4 per cent in the years 1955–9 to 25 per cent in the years 1960–4 and 15 per cent in the years 1965–9. The incidence of major postoperative complications for patients treated by total proctocolectomy or colectomy and ileostomy was also clearly related to the preoperative severity of the disease, being 18·8 per cent in the elective cases, 31·3 per cent in the urgent cases, and 40 per cent in the emergency cases.

Late complications of surgery were, with the exception of intestinal obstruction requiring surgery, infrequent in this series and showed a marked fall in the last 5 years of the study. With the possible exception of urolithiasis, this investigation revealed no increased susceptibility to diseases or conditions of a general nature in the long-term study of these patients (average length of follow-up 7 years) and emphasized the excellent life expectancy in patients in whom radical surgery had been carried out in the absence of malignant change.

THIS paper presents the short- and long-term results in patients with ulcerative colitis treated at St. Mark's Hospital over a 15-year period by surgery involving the establishment of a permanent ileostomy. Using the criteria outlined below, there were 246 patients in whom this surgery had been carried out in the years 1955–69.

The criteria for inclusion in the series were as follows:—

1. All major primary surgery including the ileostomy must have been undertaken at St. Mark's Hospital. Three patients in whom the rectum was excised elsewhere (abroad in 2 cases) provide the exception and have been included in the figures for

colectomy and ileostomy and follow-up but have been excluded from those for rectal excision and perineal wound healing.

2. The ileostomy must have been permanent, which is defined as present up to the concluding date for this study (1 Jan., 1970) or until the date of death.

Table I.—AGE AND SEX DISTRIBUTION

AGE-GROUP (YEARS)	MALE		FEMALE		TOTAL	
	No.	Per cent	No.	Per cent	No.	Per cent
10–14	2	1·7	4	3·2	6	2·4
15–19	9	7·5	4	3·2	13	5·3
20–24	16	13·3	7	5·6	23	9·3
25–29	14	11·7	9	7·1	23	9·3
30–34	11	9·2	14	11·1	25	10·2

1960–4	38	57·6	24	36·4	4	6·0	66	100·0
1965–9	69	73·4	19	20·2	6	6·4	94	100·0
Total	117	47·6	108	43·9	21	8·5	246	100·0

3. The availability of a pathological report. Two patients undergoing ileostomy as the only surgery and for whom no such report existed were excluded.

4. The pathological diagnosis must have been ulcerative colitis, and all cases of Crohn's disease and 'unclassified' colitis were excluded. Histological review to ensure accuracy of the diagnosis was undertaken in any doubtful cases.

CLINICAL DETAILS

The age and sex distribution of the 246 cases is shown in *Table I*, where age, defined as the age last birthday, is that at the time of the establishment of the ileostomy. There were 120 males in the series and 126 females. The mean age for the male cases was 38·3 years, for the female cases 43·6 years, and for all patients 40·7 years.

All the patients were graded according to their immediate preoperative clinical condition using the criteria of Ewart and Lennard-Jones (1960). This classification is comprised of the following groups:—

Group A: Good general condition; inactive colitis.

Group B: Good general condition; mild active colitis.

Group C: Poor general condition and/or severe active colitis.

Group D: Critically ill patients treated by emergency operations.

The preoperative grading is shown in *Table II*. The percentage of cases treated electively (groups A and B) rose slightly over the 15 years, the cases coming to urgent surgery (group C) showed a definite fall from 40·7 per cent in the years 1955–9 to 23·4 per cent in the period 1965–9, while there was a slight increase in the incidence of those undergoing emergency surgery (group D).

SURGERY AND RESULTS

Table IV.—OTHER SURGICAL PROCEDURES IN 21 CASES

Surgery	*No. of Cases*
Colectomy and ileorectal anastomosis; subsequent ileostomy (12) and rectal excision (10)	12*
Total proctocolectomy in two or more 'non-standard' stages	5
Ileostomy and subsequent colectomy	1*
Right hemicolectomy and ileostomy	1*
Ileostomy only (+ suture of perforation in 1)	2†

* One patient died postoperatively.
† Both patients died postoperatively.

Type of Surgery.—The operations carried out are shown in *Table III*. The incidence of total proctocolectomy and ileostomy increased markedly over the three 5-year periods of the study, rising from 11·6 per cent in the years 1955–9 to 73·4 per cent in the years 1965–9. Total or subtotal colectomy and ileostomy showed a corresponding decreasing incidence, falling from 75·6 per cent in the first 5-year period to 20·2 per cent in the third. Other surgical procedures carried out in 21 cases are shown in *Table IV*.

Postoperative Mortality of the Primary Surgery.—The overall postoperative mortality of the primary surgery over the 15 years of the study was 8·1 per cent, there being 20 deaths in 246 cases. Primary surgery includes all operations directed to the treatment of the disease, while postoperative mortality is defined as death following surgery while the patient was still in hospital. Analysed in the three quinquennia 1955–9, 1960–4, and 1965–9, the operative mortality was 9·3 per cent (8 out of 86), 10·6 per cent (7 out of 66), and 5·3 per cent (5 out of 94).

Table V relates the number of postoperative deaths to the preoperative grading of the patient. It will be seen that the mortality for cases treated electively (groups A and B) was 1·6 per cent (2 deaths in 128 cases) and there was no death in these groups after the year 1962. For group C, cases coming to urgent surgery, the mortality was 10·7 per cent, while for group D, cases treated as emergencies, the mortality was 23·3 per cent overall. The postoperative mortality in this group fell from 36·4 per cent (4 deaths in 11 cases) in the years 1955–9 to 25 per cent (3 deaths in 12 cases) in 1960–4 and 15 per cent (3 deaths in 20 cases) in 1965–9.

Table V.—Postoperative Mortality of the Primary Surgery related to Preoperative Grading and Year of Surgery

Group	Years of Surgery						Total		Percentage Operative Mortality
	1955–9		1960–4		1965–9				
	No.	No. died	No.	No. died	No.	No. died	No.	No. died	
A	10	1	9	0	12	0	31	1	3·2
B	30	0	27	1	40	0	97	1	1·0
C	35	3	18	3	22	2	75	8	10·7
D	11	4	12	3	20	3	43	10	23·3
Total	86	8	66	7	94	5	246	20	8·1

Table VI.—Postoperative Mortality of the Primary Surgery related to the Type of Surgery

Type of Surgery	Years of Surgery						Total		Percentage Operative Mortality
	1955–9		1960–4		1965–9				
	No.	No. died	No.	No. died	No.	No. died	No.	No. died	
Total proctocolectomy	10	0	38	1	69	4	117	5	4·3
Colectomy and ileostomy	65	6	24	2	19	1	108	9	8·3
Other operations	11	2	4	3	6	0	21	5	23·8
Rectal excision alone	60	0	19	1	13	0	92	1	1·1

Table VII.—Postoperative Mortality of the Primary Surgery related to the Age of the Patients

Age-group (Years)	No. of Cases	No. of Postoperative Deaths	Percentage Postoperative Mortality
10–19	19	3	15·8
20–29	46	2	4·4
30–39	48	3	6·2
40–49	52	3	5·8
50–59	49	5	10·2
60–69	28	4	14·3
70–79	4	0	0
Total	246	20	8·1

The operative mortality related to the type of surgery undertaken is shown in *Table VI.* Total proctocolectomy which was carried out in 117 cases was followed by 5 deaths, all in patients graded in groups C or D preoperatively. Nine patients out of 108 treated by colectomy and ileostomy died postoperatively; all but 1 of these deaths were in patients coming to urgent (group C) or emergency (group D) surgery. Five patients (all but 1 of whom were emergency cases) died following other surgical procedures, and the details of the surgery in these cases is shown in *Table IV.*

The operative mortality related to the age of the patient is shown in *Table VII*, where it is seen that the highest mortality was in the youngest age-group and in patients over 50 years of age. There were 134 cases aged 10–44 years and in this group there were 8 deaths (6 per cent). In the 112 patients aged 45 years or over there were 12 deaths (10·7 per cent).

Emergency Surgery.—Emergency operations were undertaken in 43 cases (17·5 per cent), 13 of these patients having been transferred to St. Mark's Hospital specifically for this surgery. In 15 patients the colon had perforated preoperatively (sealed in 4 cases, with abscess formation in 1, and 'free' in 10 cases) and 6 patients in this group died postoperatively (40 per cent). The indications for emergency surgery in the 28 non-perforated cases were acute deterioration in the general condition in 7 patients, very severe disease failing to respond to intensive medical treatment in 10 cases, severe colonic dilatation in 8 cases, and haemorrhage in 3 patients. The mortality in the non-perforated group was 14·3 per cent (4 deaths in 28 patients). The surgery undertaken in these 43 patients was total proctocolectomy in 8 cases, with 3 deaths, colectomy and ileostomy in 28 patients, with 3 deaths, and other surgical procedures in 7 cases, with 4 deaths (the last 4 patients shown in *Table IV*).

Causes of Postoperative Deaths.—Twenty patients died postoperatively. The main causes of death, verified by post-mortem examination in 14 cases, were as follows: general peritonitis in 7 cases, acute haemorrhagic enteritis in 1, systemic infection in 3, superior mesenteric artery thrombosis in 2, pulmonary embolus in 2, coronary embolus in 1, electrolyte imbalance in 1, and bronchopneumonia in 3. Among the 7 patients dying from general peritonitis were 2 who developed prestomal ileitis postoperatively, and these cases have already been reported (Knill-Jones, Morson, and Williams, 1970).

Postoperative Complications.—Only patients undergoing total proctocolectomy or colectomy and ileostomy are considered in this section. Complications were classified into major, i.e., potentially life-threatening, or minor, i.e., any other condition which interrupted the course of convalescence, and these figures together with the number of postoperative deaths are given in *Table VIII*.

Table VIII.—INCIDENCE OF POSTOPERATIVE COMPLICATIONS IN PATIENTS UNDERGOING STANDARD SURGERY

SURGERY	NO. OF CASES	NO. OF POSTOPERATIVE DEATHS	COMPLICATIONS		
			Major	Minor	None
Total proctocolectomy	117	5	21	37	54
Colectomy and ileostomy	108	9	33	18	48
Total	225	14	54	55	102

Major complications occurred in 54 patients: intra-abdominal infection in 16, intestinal obstruction in 14 (13 patients required laparotomy), other abdominal complications including ileostomy dysfunction in 8, deep venous thrombosis in 4 patients, and pulmonary embolism in 2, chest infection in 7, and miscellaneous complications in the remaining 3 patients.

When the operative deaths are excluded then it is found that for patients treated by total proctocolectomy, 21 cases (18·8 per cent) developed major complications, 37 (33 per cent) had minor complications, and 54 (48·2 per cent) had no setbacks during convalescence. For patients treated by colectomy and ileostomy, the respective figures were 33·3, 18·2, and 48·5 per cent.

If the figures are analysed according to the preoperative severity of the disease then, with the postoperative deaths excluded, it is found that 18·8 per cent (22 out of 117) of patients treated electively (groups A and B) by either proctocolectomy or colectomy and ileostomy had major complications; for group C this figure was 31·3 per cent (20 out of 64) and for group D 40 per cent (12 out of 30).

The duration of convalescence may also be used as a measure of postoperative complications. For groups A and B the average length of postoperative in-patient stay was 29·9 days, for group C 36·6 days, and for group D 48·6 days.

Excision of the Rectum.—Rectal excision was carried out in 101 cases excluding patients treated by total proctocolectomy: in 92 patients the rectum was excised alone and in the remaining 9 cases rectal excision was carried out with other surgery.

Excision of the rectum alone in 92 patients was followed by 1 death; 14 patients had major postoperative complications, 19 had minor complications, and 58 had an uninterrupted convalescence.

At the end of the follow-up period there were 11 patients alive in whom the rectum had not been excised.

The Perineal Wound.—Two hundred and four patients left hospital with a perineal wound and survived for more than 1 year. The date of healing of the wound was known in 157 of these cases. Healing was complete in less than 6 months in 80 patients (51 per cent) and in less than 1 year in a further 41 cases. Thus, in 77·1 per cent of cases where the information was available the wound had healed in 1 year or less.

There was little difference in the rate of perineal wound healing between patients treated by total proctocolectomy and those undergoing rectal excision following colectomy and ileostomy. In the former group, out of 81 cases where the time was known, wound healing was complete in 1 year or less in 65 patients (80·2 per cent) and in less than 6 months in 43 cases (53·1 per cent). In the latter group, in 66 cases where there was adequate information the respective figures were 72·7 and 48·5 per cent.

Between the date of surgery and the end of 1970 (thus allowing at least 1 postoperative year to elapse in all cases to assess perineal wound healing) 16 patients with a total of 19 admissions required in-patient treatment for an unhealed perineal wound. The patient readmission rate was therefore 7·8 per cent, and the average stay in hospital was 27·3 days.

Intestinal Obstruction.—Complete small intestinal obstruction or incomplete obstruction requiring surgery occurred in 32 patients between the date of operation and the concluding date for this study (1 Jan., 1970). This gives an overall patient reoperation rate for this complication of 13 per cent. This rate was 19·9 per cent for patients operated on in the years 1955–9, 9·1 per cent for the years 1960–4, and 9·6 per cent for the years 1965–9. In all, a total of 35 operations was carried out in these 32 patients, giving a total reoperation rate of 14·2 per cent.

Table IX.—INCIDENCE OF SURGICALLY TREATED OBSTRUCTION RELATED TO TYPE OF PREVIOUS SURGERY

SURGERY	NO. OF CASES	POSTOPERATIVE OBSTRUCTION	NO. OF CASES LEAVING HOSPITAL	READMISSIONS FOR OBSTRUCTION
Total proctocolectomy	117	5	112	6
Colectomy and ileostomy	108	8	99	2
Colectomy and ileostomy and excision of rectum	88	2	87	8*
Other primary surgery	21	0	16	2

* Includes 1 patient with a previous laparotomy following colectomy and ileostomy.

Table IX relates the incidence of surgically treated obstruction to the type of previous surgery and shows both the postoperative incidence and the late incidence. The average stay in hospital for patients readmitted to St. Mark's Hospital with obstruction was 19·2 days.

The cause of the obstruction was known in 34 of the 35 laparotomies, and was adhesions in 24 instances, a volvulus in 2, a strangulated para-ileostomy hernia in 2, miscellaneous causes in 4, and lateral space obstruction in 2 patients operated on prior to 1958.

The time of obstruction relative to the date of the last surgery for the 24 patients with adhesion obstruction was as follows: in the postoperative period, 11; after discharge but within 1 year of surgery, 9; between 2 and 3 years after surgery, 3; and at an interval of 10 years after surgery, 1. Seventeen of these 24 patients had had only one operation, the remaining 7 more than one.

Episodes of incomplete intestinal obstruction were responsible for 14 patients being readmitted, with an average duration of hospital stay of 6·1 days. Conservative treatment was successful in all cases although 1 patient required laparotomy at a later date.

Reconstruction and Resiting of the Ileostomy.—Reconstruction of the ileostomy was required in 7 patients and resiting was necessary in 1, giving a total patient reoperation rate for these complications of 3·5 per cent.

One patient required reconstruction in the postoperative period; the other 6 were readmitted specially for this surgery, with an average stay in hospital of 11·1 days. Two patients required reconstruction on two occasions, and the reasons for these 9 operations were instability of the ileostomy in 1 instance, stenosis in 1 case, and retraction on the other 7 occasions.

Other Complications requiring Readmission to Hospital.—

Gastro-intestinal upsets usually with symptoms of nausea and vomiting, abdominal pain, and increased ileostomy effluent were responsible for the readmission of 9 patients with a total of 13 admissions. The condition settled with conservative treatment in all cases. The average in-patient stay for these conditions was 5·5 days.

Local ileostomy complications were very uncommon. Only 2 patients were readmitted for this reason, in each case for the treatment of skin excoriation.

Abdominal wound complications were uncommon; 5 patients were admitted on 6 occasions for treatment to abscesses or sinuses related to the abdominal wound. One patient underwent repair of an incisional hernia. The patients in this group spent an average of 14·6 days in hospital.

Other complications related to the previous surgery occurred in 9 patients; the most serious of these were late retroperitoneal abscess formation in 2 cases.

Table X shows the number of patients readmitted for these various complications up to the end of the follow-up period. Allowing for multiple readmissions of the same patient, the total number of patients readmitted for the first 7 complications shown in *Table X* was 49 (21·7 per cent) of the 226 who left hospital. Fifteen patients who had not previously been admitted for complications required in-patient treatment for an unhealed perineal wound. Therefore, in all, 64 patients (28·3 per cent) were readmitted for complications referable to the previous surgery.

THE FOLLOW-UP

During 1970, follow-up information was obtained about all patients (with the exception of 4 who lived abroad) who no longer regularly attended the hospital. The concluding date for this study has therefore been taken as 1 Jan., 1970, for all purposes except for the assessment of perineal wound healing (*see above*). Thus, patients were followed up for varying periods up to 15 years after surgery, and the average length of follow-up for the 205 patients known to be alive on 1 Jan., 1970, was 7 years.

The main conditions of a general nature that occurred during the years of follow-up, together with the number of patients with these conditions preoperatively, are shown in *Table XI*.

Table X.—READMISSIONS FOR VARIOUS COMPLICATIONS

CAUSE	NO. OF PATIENTS RE-ADMITTED	PATIENT RE-ADMISSION RATE (per cent)	NO. OF RE-ADMISSIONS	TOTAL RE-ADMISSION RATE (per cent)
No. of patients at risk: 226				
Complete intestinal obstruction	18	8·0	20	8·9
Incomplete intestinal obstruction	14	6·2	14	6·2
Reconstruction of the ileostomy	6	2·7	8	3·5
Gastro-intestinal upsets	9	4·0	13	5·7
Local ileostomy complications	2	0·9	3	1·3
Abdominal wound conditions	6	2·7	7	3·1
Other related complications	9	4·0	9	4·0
No. of patients at risk: 204				
Perineal wound	16	7·8	19	9·3

Table XI.—DISEASE IN THE FOLLOW-UP PERIOD

Disease	*No. of Cases in the Follow-up Period*	*No. of Cases Pre-operatively*
Peptic ulcer	1	4
Gall-stones	3	3
Pulmonary tuberculosis	0	6
Other pulmonary disease	3	4
Cardiovascular disease	5	7
Urinary-tract calculi	6	5
Thyroid conditions	3	3
Diabetes mellitus	0	5
Mental illness	2	0
Musculoskeletal affections	5	3
Gynaecological conditions	4	5
Other complaints not requiring surgery	5	9
Other complaints requiring surgery	5	6
Malignant tumours	8	2

Calculi in the Urinary Tract.—Five patients are thought to have had urinary-tract calculi preoperatively and 6 patients are known to have had such stones postoperatively. In the former group the stones occurred at intervals varying from 2 to 30 years after the onset of colitic symptoms, but in 2 patients other factors may have been involved in stone formation. One patient passed a stone, in another a renal calculus was an incidental finding on radiology, and in the other 3 cases there was a history of surgery for renal calculi.

Two patients were found to have ureteric calculi approximately 6 weeks postoperatively. In both cases the calculi (single in 1 case and multiple in the other) were later passed spontaneously.

Calculi were found in 4 patients at varying intervals from 6 to 12 years after surgery; 1 patient passed a calculus but in the other 3 patients operation was required. The chemical composition was known in 3 of the cases where stones arose after surgery: this was reported as carbonates in 1 case, calcium oxalate in the second, and calcium oxalate and urate in a patient with multiple bladder calculi.

Deaths in the Follow-up Period.—Seventeen patients are known to have died in the interval between their discharge from hospital and the end of the follow-up period. The causes of death are summarized in *Table XII*, where the relationship to the complications of the disease or its treatment is shown.

Table XII.—CAUSES OF LATE DEATH

Cause	*No. of Patients*
Related deaths	
Metastases from carcinoma in ulcerative colitis	4
Abdominal lymphosarcoma (primary lesions in the sigmoid and rectum and ulcerative colitis)	1*
Serum hepatitis	1
Possibly related death	
Suicide	1
Unrelated deaths	
Malignant tumours	5†
Bronchopneumonia	2
Coronary thrombosis	1
Congestive cardiac failure	1
Rheumatoid arthritis	1

* Case reported by Cornes, Smith, and Southwood (1961).

† Carcinoma of the ovary, 1; postcricoid carcinoma, 1; carcinomatosis—unknown primary, 1; carcinomatosis, double primary—nostril and prostate, 1; reticulosarcoma, 1.

Expected and Observed Mortality.—Eighty-nine males and 103 females fitted the criteria for the calculation of expected mortality. These criteria were: (*a*) complete removal of the colon and rectum, (*b*) the survival for 1 postoperative year from the completion of this surgery, and (*c*) absence of malignant change in the excised specimen. This calculation, taking into account the age and sex of the patient, was made using the 1961 English Life Tables (No. 12). The expected deaths to the end of the follow-up period in the 89 males were 5·1, and the observed deaths 1; for the 103 females the respective figures were 3·9 and 4.

DISCUSSION

Excisional surgery with the construction of a permanent ileostomy is now a well-established procedure as the operative treatment for ulcerative colitis. The present series of 246 patients undergoing such surgery in the years 1955–69 demonstrates some important points in the evolution of this surgery which will be discussed in detail.

Type of Surgery.—Colectomy and ileostomy as the initial operation was undertaken in 75·6 per cent of cases in the years 1955–9, but in the last 5 years of this study the incidence had fallen to 20·2 per cent; total proctocolectomy, undertaken in only 11·6 per cent of cases in 1955–9, was the operation carried out in 73·4 per cent of patients in the years 1965–9. This rising incidence of a one-stage procedure has been reported before, both from this hospital (Lockhart-Mummery, 1970) and from a group of hospitals (Ritchie, 1971), and the present figures show that it continues to be the operation most frequently undertaken for ulcerative colitis at this centre.

Preoperative Condition of the Patient.—The surgical treatment of patients operated upon electively (groups A and B) carried a very low mortality-rate in this series, i.e., 1·6 per cent in 128 cases, an even lower figure than that reported in other large series, e.g., 3·4 per cent (Daly and Brooke, 1967), 3·8 per cent (Watts, de Dombal, and Goligher, 1966), and 4 per cent (Hughes, 1964). In addition, elective surgery was followed by a low major postoperative complication rate and a rapid convalescence. By contrast, the operative mortality for emergency surgery (group D) was 23·3 per cent, the major complication rate being over twice that for elective surgery and the duration of postoperative in-patient stay 19 days longer on average. Results intermediate between these two groups were obtained in those cases coming to urgent surgery (group C).

Emergency surgery carries a high mortality in reported series, e.g., 15 per cent (Hughes, 1964), 17·4 per cent (Boxall, 1966), 24 per cent (Daly and Brooke, 1967), 26·7 per cent (Watts and others, 1966), 31 per cent (Lennard-Jones and Vivian, 1960), and 44·4 per cent (Ritchie, 1971), and the figures for the present series are no exception. The figure of 15 per cent for the years 1965–9, although as low as any of those referred to above, highlights one of the main contemporary problems in the treatment of colitis, which is the management of the severe attack. Ideally, surgery should not be undertaken in these circumstances and every effort should be made to induce remission by full-scale medical treatment and to operate later, if necessary, under elective conditions. However, in a proportion of cases this remission will not occur, or only to a limited extent, and it is in these patients especially that expert assessment is required on the optimum timing for surgery. A strong plea for earlier surgery substantiated by a fall in operative mortality from 20 per cent in 40 patients coming to urgent or emergency surgery in the years 1952–63 to 7 per cent in 71 similar cases in the period 1964–9 has been made recently by Goligher, Hoffman, and de Dombal (1970).

Twenty-eight of the 43 emergency cases were treated by colectomy and ileostomy; the 3 deaths in this group were in patients operated on in the earlier years, and no deaths occurred in 18 emergency cases treated in this way from 1962 onwards. Total proctocolectomy undertaken as an emergency in 8 patients between 1960 and 1969 was followed by 3 deaths, all in the last 3 years of the study. Findings at operation may dictate the more extensive procedure, but the figures perhaps suggest that colectomy and ileostomy, where practicable, remains the treatment of choice for patients undergoing emergency surgery.

Complications of Surgery.—Small intestinal obstruction requiring surgical intervention occurred in 32 patients up to the end of the follow-up period, the incidence falling from 19·9 per cent for patients operated on in the years 1955–9 to 9·6 per cent for the years 1965–9. This latter figure, which is very similar to that reported in other series, e.g., 9 per cent (Daly and Brooke, 1967) and 9·3 per cent (Ritchie, 1971), suggests that obstruction, especially if due to adhesions, is a non-preventable complication even with present-day surgical technique. However, it was not a fatal late complication in this series, there being no deaths following surgery in the 18 patients readmitted with this condition.

Delayed healing of the perineal wound was the only other specific complication with an appreciable incidence in this series and readmissions for this reason showed no tendency to fall over the years of the study. It seems probable that the high readmission rate was the result of a policy designed to accelerate perineal wound healing, laying open of a sinus and curettage being considered as the quickest way to effect this.

Considered collectively, readmissions for complications (with the exception of those for an unhealed perineal wound) showed a considerable fall over the 15-year period, from 32·1 per cent of 78 patients operated on in the years 1955–9 to 9 per cent of 89 patients in the years 1965–9. This lower figure may be due partially to the shorter follow-up in these cases, but a continuing decline in complications is to be expected with increasing experience of this surgery.

The Follow-up.—Consideration of the diseases encountered during the years of follow-up shows no conditions occurring with any frequency. With the exception of urinary-tract calculi, this has been the finding in another large series (Ritchie, 1971). Almost 600 patients have been followed up in these two series and no other specific diseases following surgery have been discovered. The supposition is, therefore, that no such diseases exist except, perhaps, for this increased tendency to urolithiasis. The incidence of this condition in the present series was only 1·9 per cent in the 226 patients who left hospital with an ileostomy; excluded from this number are the 2 patients in whom stones were found some 6 weeks after surgery, as it seems possible that the calculi were present preoperatively. In the absence of exact figures for the incidence of such calculi in the general population the figure of 1·9 per cent cannot be said to be significant. However, when it is considered in conjunction with the figures of Ritchie (1971), i.e., 4·3 per cent in 371 patients leaving hospital with an ileostomy, the possibility remains that ileostomists may be more prone to develop urinary-tract calculi than the normal population.

Expected and Observed Mortality.—There are now three sets of figures available giving the number of expected and observed deaths in groups of ileostomists: these are Daly's (1968) series of 358 ileostomists from Birmingham, the present author's (Ritchie, 1971) series of 267 patients drawn from 37 hospitals of the North East Metropolitan Hospital Region, and the group of 192 patients from St. Mark's Hospital presented in this paper. All the cases in these three series were subject to the same criteria of selection; the only difference in the samples being that the second series included 20 patients with Crohn's disease. In Daly's (1968) figures for patients operated on in the years 1947–66 and followed up until 1966 the expected deaths were 17·66 and the observed deaths 19; in the second series (Ritchie, 1971) for patients undergoing surgery in the years 1955–66 and followed up until the end of 1967 the respective figures were 11·6 and 18, and in the present study for patients treated in the years 1955–69 and followed until the end of 1969 the respective figures were 9 and 5. Thus, there is a small excess mortality in Daly's series, a rather higher figure in the second group, and no excess mortality in the present series. It is not obvious why this somewhat unlikely result should have been obtained for the patients in the present study, but it is possible that the sample was not large enough or the follow-up not long enough. A more accurate assessment of the position with regard to life expectancy in these patients can be obtained by the addition of the figures in these three series to obviate errors due to smallness of the samples. Then it is found that in 817 patients the expected deaths were 38·3 and the observed deaths 42, i.e., only 4 excess deaths in 817 cases, and it appears probable that these figures give a more accurate picture than any one of the series considered alone.

The conclusion, therefore, from the figures presented in this paper, particularly when considered with those from the other series, must be that the life expectancy of patients with ulcerative colitis, in the absence of malignant change, is normal when 1 postoperative year has elapsed following radical surgery.

Acknowledgements.—I am very grateful to the surgeons of St. Mark's Hospital for permission to study the case records of patients under their care.

I acknowledge with thanks the helpful criticism of Dr. J. E. Lennard-Jones and the surgical staff in the preparation of this paper.

DEVELOPMENT OF RIGHT INGUINAL HERNIA FOLLOWING APPENDICECTOMY

A 10-YEAR REVIEW OF CASES

By S. GUE*

WORCESTER ROYAL INFIRMARY, CASTLE STREET BRANCH, WORCESTER

SUMMARY

The incidence of right inguinal hernia in patients who have undergone appendicectomy is significantly greater than that in the general population. It is suggested that the most likely cause is injury to the segmental nerve-supply to the inguinal musculature.

It is suggested that the sequela of right inguinal hernia following appendicectomy may be decreased, if not prevented, by proper understanding of the anatomy of the region and care during surgery, but 'in spite of the tempting simplicity of aetiologic reasoning, a cause-and-effect relationship cannot yet be confirmed'.

HOGUET in 1911 first described the frequent development of right inguinal hernia following appendicectomy. He found 8 right inguinal herniae out of 190 patients who had previously had an appendicectomy, the time interval between appendicectomy and the appearance of a hernia in his cases being from 2 weeks to 4 years.

In 1951 Lichtenstein and Isoe reviewed 567 patients with inguinal hernia. In 67 of these the appendix had been removed (40 were right-sided, 12 bilateral, and 15 left-sided), but it was Seulberger and Pefers (1951) who suggested: 'Lateral abdominal incisions predispose to inguinal herniae, especially on the right side.' Walker in 1954 also found 100 post-appendicectomy patients with right inguinal hernia out of 1357 inguinal herniae.

The present study examines the incidence of right inguinal hernia following appendicectomy during the past decade in a regional hospital.

MATERIALS AND METHODS

This is a retrospective study based on the records of all cases of inguinal hernia operated on at Worcester Royal Infirmary between 1959 and 1969. Infant herniae have been excluded. The age range was from 13 to 82 years, only 2 patients being below the age of 16 years. The type of hernia repair was of a standard Bassini type using either silk or tantalum wire as the suture material.

RESULTS

A total of 701 herniae were operated on, 51 of these having previously undergone appendicectomy. Of these 51 patients, 41 developed right inguinal hernia, 7 left inguinal hernia, and the remaining 3 were bilateral. Out of the 41 cases, there were only 3 females.

In the group of 41 patients with right inguinal hernia the appendicectomy had been through a lower paramedian incision in 6 and via a McBurney's approach in the remainder. The type of hernia was indirect in 26 cases and direct in 15 cases. There have been no recurrences in this group to date.

The incidence of right inguinal hernia after appendicectomy has been compared with the incidence in cases who had not undergone appendicectomy in *Table I*.

In the 650 patients who had not had a previous appendicectomy the ratio of right-sided hernia to left-sided was approximately 2 : 1, whereas in the post-appendicectomy group the ratio was 6 : 1. This difference is statistically significant (χ^2 test: significant at a 5 per cent level).

Table I.—THE INCIDENCE OF INGUINAL HERNIA IN 51 CASES WHO HAD UNDERGONE APPENDICECTOMY COMPARED WITH THAT IN 650 CASES WHO HAD NOT HAD AN APPENDICECTOMY

	AFTER APPENDICECTOMY			NO APPENDICECTOMY		
	Right Hernia	Left Hernia	Bilateral Herniae	Right Hernia	Left Hernia	Bilateral Herniae
No. of cases	41	7	3	306	144	200
Percentage	80·3	13·7	5·8	40·07	22·1	30·7
Ratio of right to left	6 : 1			2 : 1		

DISCUSSION

The results show that appendicectomy predisposes to the development of right-sided inguinal hernia.

Approximately 5 per cent of the population of Britain have inguinal hernia and the repair of these accounts for 10 per cent of general surgical operations. Sixty per cent of these herniae are right-sided, 20 per cent are bilateral, and 20 per cent are left-sided (Ellis, 1970). These figures are similar to the overall distribution of herniae in the present study.

To understand the possible iatrogenic causes and the aetiological relationships in the development of right inguinal hernia following appendicectomy, one needs to refer to the anatomy of the internal ring, which was beautifully illustrated by Lytle (1970): 'The internal ring is "U" shaped; composed of thickened transversalis fascia, is suspended by its two pillars, medial and lateral to the posterior aspect of transversus abdominis muscle. The curve of the "U" lies at or just above the lower border of aponeurosis of the transversus muscle. This aponeurosis forms the floor of the ring and is supported in front by the internal oblique muscle.' An efficient valve is thereby provided which closes when the intra-abdominal pressure is increased. Injury to the transversus abdominis muscle and posteriorly adherent transversalis fascia can damage the shutter mechanism of the internal ring and also weaken the posterior wall of the triangle of Hesselbach.

---

* Present address: Brokenhill Hospital, Brokenhill, New South Wales, Australia.

Incomplete approximation and healing of the fascial layers (transversus muscle and aponeurosis with posteriorly adherent transversalis fascia) after appendicectomy is one of the important factors in the subsequent development of inguinal hernia (Scott, 1960). This can easily happen, owing to the protrusion of peritoneum and extraperitoneal fat through the open transversus muscle and its posteriorly adherent transversalis fascia. Scarring of this layer with fixation to the other abdominal wall muscles, as occurs after prolonged drainage of an appendix abscess, has also been suggested as a cause of weakness leading to the development of inguinal hernia (Hoguet, 1911).

Observations from the present study suggest that damage to the segmental nerve-supply of the internal oblique and transversus muscles leads to the weakening of the posterior wall of the inguinal canal and the internal ring. In addition, the shutter mechanism of the canal must be compromised by the denervation. Examination of some of the patients in this series showed generalized bulging in the inguinal region, and in some cases the muscles have been found to be atrophic at operation. Electromyographic studies to confirm the denervation would be of value.

In the present series there were only 2 patients under 16 years of age, and it would seem that post-appendicectomy hernia occurs less in the younger age-group. This may well be due to restoration of the damaged structures in the abdominal wall by the growing body.

It is felt that this study emphasizes that nerve injury should be avoided during surgery and also that the structures of the right lower abdominal wall should be preserved during McBurney's or right lower paramedian incisions. The following technical suggestions may help to lessen the incidence of hernia in patients undergoing appendicectomy. The skin incision is not thought to be of much significance, but incisions much below the anterior superior iliac spine are to be avoided if possible, as segmental nerves pierce at this level and course downwards. The external oblique muscle should be opened between its parallel fibres. Importance is given to the opening of the internal oblique and transversus muscles with the adherent transversalis fascia posteriorly at the level of the anterior superior iliac spine and not below. It is advisable to split the transversus muscle and its aponeurosis as a separate layer which includes, of course, the transversalis fascia on its posterior surface. The peritoneum then bulges into the wound. This avoids injury to the internal ring and the triangle of Hesselbach. Separate suture of the transversus aponeurosis with the attached transversalis fascia is advisable to avoid bulging of the peritoneum through this layer. The internal oblique muscle is approximated with one light suture so as not to strangulate the muscle. Alternatively, just the thin fascia over it may be sutured.

Thus, one should avoid injury to the important structures in the inguinal region, especially below the horizontal line extending from the anterior superior iliac spine to the rectus muscle.

TUBERCULOUS PERIPHERAL LYMPHADENITIS

BY A. A. HOOPER
ROYAL MARSDEN HOSPITAL, LONDON

SUMMARY

Tuberculous peripheral lymphadenitis is still a common and often poorly treated manifestation of tuberculosis. One hundred and eighteen cases are reviewed, and the problems of diagnosis and management are considered together with the causes of failure of treatment.

IN 1968 tuberculosis caused 2091 deaths in England and Wales—more than any other infectious disease. In the same year there were 12,974 new cases of the disease. Although the incidence of new cases of respiratory tuberculosis has diminished dramatically during the past decade, that of non-respiratory disease has decreased little and so forms an increasing proportion of the total tuberculosis problem (*Table I*).

Superficial lymph-node involvement is the most common presentation of non-respiratory tuberculosis, accounting for about 40 per cent of the cases reported in this paper, and yet it is the least adequately diagnosed and treated form of the disease. As superficial lymph-node involvement is an early manifestation and is often unaccompanied by gross

Table I.—NOTIFICATIONS OF NEW CASES OF TUBERCULOSIS FOR ENGLAND AND WALES*

Type of Tuberculosis	1960	1968
Respiratory tuberculosis	21,117	10,681
Meninges and central nervous system	199	92
Other forms	2,661	2,181
Total	23,977	12,974

* Registrar General's *Statistical Review* (1961, 1968).

disease elsewhere, clinicians are often tempted to treat it less rigorously than the more notable forms of the disease. Tuberculosis, however, is a disease of long duration, characterized in many patients by periods of quiescence without cure followed by local reactivation or evidence of dissemination. This is well illustrated by the following case (not derived from the material which is analysed later).

Mrs. C. M. T., born on 27 June, 1903. In 1907 this patient had tuberculous nodes excised from the left neck. A left ureteronephrectomy for tuberculosis was carried out in 1924, and in 1929 tubercle bacilli were again recovered from the urine. In 1932 tuberculous cystitis was diagnosed. Examination of the patient in 1948 revealed a small fibrotic bladder, with no evidence of active infection. In 1960 tuberculosis of the left breast was diagnosed and the breast was excised. The patient was treated for 1 week with para-aminosalicylic acid (PAS) and isonicotinic acid hydrazide (INAH) which were then stopped because the patient had a convulsion. In 1965 a vesical calculus was removed and a urethral caruncle showing on biopsy a granulomatous reaction containing Langhans giant cells was found. The patient was treated for 5 months with PAS and INAH. Further urinary symptoms occurred in 1968, a small caruncle on biopsy showing typical features of a caruncle only.

PRESENT STUDY

Two hundred and thirty-eight cases of extrapulmonary tuberculosis obtained from three general hospitals in the decade 1960–9 have been analysed (*Table II*). Of these, there were 103 individuals in whom 118 episodes of lymph-node tuberculosis were treated. Of the recurrent cases the original episode occurred before the 10-year period in 8 cases; this has been included in the analysis but where it would bias the results it has been listed separately.

Table III.—AGE DISTRIBUTION IN 118 CASES OF LYMPH-NODE TUBERCULOSIS

Age-group (years)	*No. of Cases*
0– 9	7
10–19	12
20–29	26
30–39	28
40–49	14
50–59	12
60–69	6
70	9
Unstated	4

Age Incidence.—The age distribution in this series is markedly different from that in most reported series (Dowd, 1916; Barrington Ward, 1937; Miller and Cashman, 1955; Wimot, James, and Reilley, 1957; Jones and Campbell, 1962; MacKellar, Hilton, and Masres, 1967), where children largely predominate. In the present series the maximal incidence occurs in the age-group of 20–40 years (*Table III*).

Place of Birth.—A disproportionate number of the cases in this series were born outside England, Scotland, and Wales. This is no doubt due to the fact that cases were collected from areas with a high immigrant population as well as to the known susceptibility of Asians to this disease (*Table IV*).

Clinical Presentation.—Eighty-four out of 118 cases of tuberculous peripheral lymphadenitis presented with a swelling in the neck alone or accompanied by only minor constitutional symptoms (*Tables V, VI*). Group *e* (*Table V*), cases with a particularly acute presentation, represents one of the variants of so-called 'Asian tuberculosis'; this picture may also, though less commonly, be seen in native-born English.

Table IV.—PLACE OF BIRTH IN 118 CASES OF LYMPH-NODE TUBERCULOSIS

Place of Birth	*No. of Cases*
England, Scotland, and Wales	50

PHYSICAL SIGNS OF INVOLVED NODES

The natural history of physical signs of tuberculous superficial lymph-nodes is widely accepted (Jones and Campbell, 1962; Clain, 1968). The classification of Jones and Campbell (1962) is as follows:—

Stage 1: Enlarged, firm, mobile, discrete, slightly tender nodes showing non-specific reactive hyperplasia.

Stage 2: Nodes larger, rubbery, and fixed to surrounding tissues owing to periadenitis showing histological caseation.

Stage 3: Central abscess formation.

Stage 4: Collar-stud abscess formation.

Stage 5: Sinus formation.

Stage 1 is not diagnosable as tuberculous except by indirect means or in retrospect. Since periadenitis and caseation occur early in the disease process, clinical diagnosis should be relatively easy and accurate. However, in the present series the diagnosis of tuberculosis was thought unlikely in about 1 in 3 cases.

Confusion occurs mainly in cases in clinical stages 1–3 (and only 8 out of 118 cases did not fall into stages 2 and 3), because the physical signs may not be as clear cut as this staging would suggest. Abscess formation when present is difficult to detect clinically in nodes lying deep to the deep fascia. Periadenitis is often not marked even in the presence of gross caseation.

A number of nodes pass through a stage of solid enlargement histologically characterized by a non-caseating granulomatous picture, which in the absence of acid–alcohol-fast bacilli is indistinguishable from that of sarcoidosis or other non-caseating tuberculoid granuloma. These nodes seldom show fixity owing to periadenitis. In this series no less than 1 in 10 of the excised nodes were macroscopically solid, without caseation or showing microcaseation and so were erroneously not submitted for culture. Solid nodes may occasionally reach a considerable size, in 1 case measuring 3 × 2 × 2 cm.

DIFFERENTIAL DIAGNOSIS OF CERVICAL TUBERCULOUS LYMPHADENITIS

1. From Other Causes of Lymph-node Enlargement.—

a. Non-specific inflammatory.

b. Lymphoma.

c. Leukaemia.

d. Secondary carcinoma.

e. Infectious mononucleosis.

f. Various other causes dealt with under histological differentiation.

2. Other Swellings in the Neck.—

a. Parotid and submandibular salivary gland enlargement.

b. Bronchial cyst.

c. Carotid-body tumour.

d. Extension of abscess from cervical vertebra.

The provisional diagnoses in the 43 cases in the present series which were thought not to be tuberculous are listed in *Table VII.*

Diagnostic lymph-node biopsy is frequently necessary in the elucidation of illness accompanied by lymph-node enlargement. In adults secondary carcinoma is the commonest cause of lymph-node enlargement, but tuberculosis is the next most common cause, being as frequent as lymphoma and leukaemia (*see Table VIII* for a 5-year review of lymph-node biopsies from one general hospital and also Matzker, 1967).

MICROSCOPIC DIFFERENTIATION

Tuberculosis of lymph-nodes produces a granuloma characterized by epithelioid and giant cells of the Langhans type, usually with marked, though occasionally minimal or absent, caseation. Acid–alcohol-fast bacilli may be demonstrated by the Ziehl-Neelsen or by the Auramine-Rhodamine technique (Jones and Campbell, 1962).

Table VII.—CLINICAL DIAGNOSIS IN THE 43 CASES OF THIS SERIES NOT DIAGNOSED AS TUBERCULOUS LYMPHADENITIS

Diagnosis	*No. of Cases*

Diagnosis	*No. of Cases*
Secondary carcinoma	67
Lymphoma and leukaemia	34
Tuberculosis	32
Reactive hyperplasia	37
Sarcoid reaction	6
Other or no diagnosis	16

1. Caseating or Non-caseating Granuloma in which Acid-fast Bacilli are seen.—

a. Anonymous or Atypical Mycobacterial Infection.—This is distinguishable only on culture from *Mycobacterium tuberculosis* infection. Many anonymous mycobacteria, unlike *Myco. tuberculosis*, are not guinea-pig pathogens, so that culture of tuberculous material should always be performed on Lowenstein-Jensen medium as well as by guinea-pig inoculation.

b. Lepromatous Leprosy.—Mycobacteria may be seen intracellularly but within large mononuclear 'lepra cells'. The granulomatous reaction is diffuse and without caseation.

2. Granulomatous Reaction with Central Necrosis in which Acid-fast Bacilli are not seen.—

a. Catscratch Disease.—Catscratch disease is probably a virus, although an anonymous mycobacterium has recently been suggested (Jones and Campbell, 1962). This is an irregular-shaped granuloma with a marked tendency to suppuration.

b. Lymphogranuloma Venereum.—Lymphogranuloma venereum is usually found in the groin nodes and is characterized by a small, solid granuloma composed of large mononuclear cells which break down centrally with polymorphonuclear leucocyte infiltration to form a stellate abscess. The patient gives a positive Frei test.

c. Syphilis.—Primary and secondary syphilis may produce a giant-cell granuloma with or without central necrosis. There is a marked tendency for endarteritis and new vessel formation around the periphery. Treponemes are demonstrable by suitable staining (Hartsock, Halling, and King, 1970).

d. Tularaemia.—The histological picture may be indistinguishable from tuberculosis but the causative *Pasteurella tularensis* can be grown by guinea-pig inoculation or agglutinating antibodies are detectable in the serum.

e. Fungus Granuloma.—The causative fungus can be seen, blastomyces and coccidioides in haematoxylin and eosin preparations, and *Histoplasma capsulatum* by periodic acid Schiff reagent. *Actinomyces israeli* does not involve lymph-nodes.

3. Granulomatous Reaction without Necrosis—Sarcoid Reaction.—

a. Sarcoidosis.—Sarcoidosis in which the sarcoid lesion can be found in more than one site in the body (Scadding, 1967) and in such patients the Kveim test is usually positive.

b. Brucellosis.—Brucellosis may present a sarcoid picture. This may be diagnosed on guinea-pig inoculation or by the presence of serum agglutinins.

c. Hodgkin's Disease.—A granulomatous reaction may occur as an integral part of the reaction in a lymph-node involved by the disease, which is, however, characterized by the presence of Reed-Sternberg cells.

d. An isolated sarcoid picture may be seen in lymph-nodes adjacent to some malignant and benign conditions including carcinomas (Nickerson, 1937; Nadel and Ackerman, 1950; Symmers, 1951; Revfem, 1954), malignant melanoma (Nadel and Ackerman, 1950), Hodgkin's disease, and other lymphomas (Revfem, 1954).

TECHNIQUE OF DIAGNOSIS

Clinical methods as noted above are inaccurate in establishing the cause of lymph-node enlargement. In this series a non-tuberculous clinical diagnosis was made in 1 in 3 cases (*Table VII*).

Tuberculosis may coexist with carcinoma or lymphoma. Since all three are not uncommon conditions (*Table VIII*) the presence of one elsewhere in the body will not establish the cause of subsequent lymph-node enlargement. Furthermore, in lymphoma, immunity may well be depressed, making the patient more susceptible to intercurrent infection. In the present series a lymphoma was found subsequent to tuberculous lymphadenitis in 3 cases. Sarcoidosis may supervene in a patient with proved tuberculosis or vice versa (Scadding, 1967).

To establish the tuberculous aetiology of lymph-node enlargement the node should show typical histology, preferably with acid–alcohol-fast bacilli visible. Most importantly the organism should be isolated by culture on Lowenstein-Jensen medium and by guinea-pig inoculation.

Caseous material is a poor source of tubercle bacilli. The lack of infectivity of tuberculous pus is well attested (Dowd, 1916). It probably contains a bacteriostatic substance (Soltys, 1953). The solid part of the lesion rather than pus should be submitted fresh for culture. Indeed, solid as well as caseating nodes should be routinely submitted for culture before being immersed in fixative, as should other biopsy material when there is doubt about the diagnosis. The opportunity of adequate culture may occur only once.

In this series standards of bacteriological diagnosis were low (*Table IX*), for in less than 1 in 3 cases was an attempt made to culture the biopsied node.

Surgical excision of the largest available lymph-node for examination is mandatory; this is a procedure normally requiring general anaesthesia. Excision of a small superficial node under local anaesthesia frequently results in a failure to establish a diagnosis, showing histologically a normal architecture, reactive hyperplasia, or a sarcoid reaction; all these features may be seen in nodes adjacent to carcinoma, lymphoma, tuberculosis, sarcoidosis, and some benign tumours (Revfem, 1954) in nodes that are almost certainly sterile. The practice of aspirating pus to establish a diagnosis is not a good one, as it has a low success rate (*Table IX*) and a high complication rate.

Table IX.—BACTERIOLOGICAL DIAGNOSIS

Bacteriological Diagnosis	*No. of Cases*
Acid–alcohol-fast bacilli seen but not cultured	25
Acid–alcohol-fast bacilli seen and cultured	23
Tubercle bacilli not seen but cultured	3
Caseous material only cultured	23
Positive culture	9
Organism isolated	
Myco. tuberculosis	24
Anonymous mycobacterium	2

TREATMENT OF CERVICAL TUBERCULOUS LYMPHADENITIS AND ITS RESULTS

In the pre-chemotherapeutic era the two bases of treatment were the sanatorium régime and radical surgical excision of all affected nodes. It was the failure and the time-consuming nature of the former that led to the adoption of the latter treatment. It is important to note that radical surgery involved the excision of all palpably involved nodes, however small in size, with or without an excision of the supposed site of the primary focus by tonsillectomy (Dowd, 1916; Barrington Ward, 1937; Mason Browne, 1957; Wimot and others, 1957). Dowd noted in 1916 that lesser operations were attended by poor results, and this has remained the consensus since (Mason Browne, 1957; Bluhm, 1964) and is confirmed by this study. Dowd (1916) further noted that the presence of pus or the incision of a cold abscess was no bar to going on to complete excision of the involved nodes. Surgical treatment on this radical basis has not been performed in any of the patients in this series, but has been restricted to obtaining material for diagnostic purposes. Even when disease was restricted to the upper cervical nodes unilaterally and clean excision of the main involved node has been performed, radical surgery has not been attempted.

1. Results of Local Excisional Surgery alone.—In 1937 Barrington Ward claimed only a 1 per cent recurrence rate needing treatment following surgery for cervical tuberculous lymphadenitis, though he noted that a further 11 of his 95 cases had persisting asymptomatic enlargement of nodes in the neck. In the previous year Thompson (1936) claimed gross local recurrence in 50 of 55 cases who had been treated surgically. He stands alone in claiming such a high local recurrence rate after surgery, so it is probable, though not stated, that lesser surgical procedures were used. In the present series inadequate surgery without chemotherapy was accompanied by a high recurrence rate. Aspiration or incision of abscesses without excision of the diseased node resulted in sinuses in almost every case in which such treatment was used despite concomitant chemotherapy.

Dowd (1916) analysed the results of adequate excisional surgery in the treatment of 687 cases of cervical tuberculous lymphadenitis. He showed that the prognosis following adequate surgery depended on the extent of the disease present at the time of surgery. He divided his cases into three groups:—

Group 1.—Involvement of the primary focus in the oropharynx, plus ipsilateral upper cervical node enlargement alone.

Group 2.—Node involvement along the entire ipsilateral jugular chain.

Group 3.—Massive node involvement in the neck, often running a rapidly progressive course, with or without evidence of tuberculosis outside the neck.

Furthermore Dowd noted that the disease that he was treating was predominantly a disease of childhood, and that, in general, tuberculous cervical adenitis in children runs a more favourable course than does the disease in adults. His results are important in demonstrating the natural history of the disease when treated by the best non-chemotherapeutic means and are reproduced in *Table X*. Unfortunately, in his figures he did not differentiate between local and distant recurrence. Clearly, mortality at least must be due to disease in a site other than the lymph-nodes. From these figures it is clear that whilst surgery can reasonably be used to cure local disease in one site, it cannot be expected to cure generalized lymphadenitis or disease which has spread to other systems.

Table X.—DOWD'S (1916) RESULTS FOR SURGICAL TREATMENT OF CERVICAL TUBERCULOSIS (687 CASES FOLLOWED FOR 1–20 YEARS)

GROUP	NO. OF CASES	AVERAGE AGE (years)	CURE RATE (per cent)	RECURRENCE RATE (per cent)	MORTALITY (per cent)
1	452	8	99	1	0
2	185	15·9	68	24	5·5
3	50	12·7	34	43	20·0

Nearly all discussions of this disease assume that the primary focus in relation to cervical lymph-node disease is in the oropharynx. In fact, as shown by Wimot and others (1957), in at least 50 per cent of cases a healed primary focus is visible in the lungs. Also, at least 10 per cent have coexistent post-primary pulmonary infiltration (Jones and Campbell, 1962; Gillam and Knowles, 1963; Bluhm, 1964; Kent, 1967). In the present series there was a roughly similar proportion of cases in each group as in Dowd's (1916) series, but of the group 1 cases, 1 in 4, although clinically group 1, on radiography had evidence of disease outside the neck. In all, 1 in 2 patients had disease which if treated by radical surgery alone would have had a high risk of recurrence (*Table XI*).

2. **Tonsillectomy.**—In combination with excision of the affected nodes tonsillectomy has been considered important (Barrington Ward, 1937; Miller, 1956; Wimot, 1957; Wimot and others, 1957). However, as pointed out above the primary complex is not in the oropharynx in at least 50 per cent of cases (Wimot and others, 1957). When the primary focus is in the oropharynx it may not be in the tonsil, but if it is in the tonsil this often appears normal (Wimot and others, 1957).

Tonsillectomy was not performed as a part of the treatment in this series. Success or failure does not appear to be influenced by the procedure.

3. **Lesser Surgical Procedures.**—Aspiration, incision and expression, and curettage have been condemned as techniques in the treatment of lymph-node tuberculosis. Mason Browne (1957) noted high recurrence rates, and his figures are quoted in *Table XII*. Aspiration and incision of a cold abscess are likely to lead to sinus formation. The appearance of tuberculous sinuses in the neck is quite uncommon now. In the present series, of the 13 cases in which sinuses appeared, 9 followed aspiration or incision of caseating nodes. In no case in which excision of one or more whole nodes was performed did a sinus result.

Table XI.—THE DISTRIBUTION OF THE CASES WITH CERVICAL NODE INVOLVEMENT IN THE PRESENT SERIES ACCORDING TO THE CLASSIFICATION OF DOWD (1916)

Group	*No. of Cases*
1	50
1 (3)*	17*
2	18
3	20

* Cases clinically group 1 but showing evidence of disease, active or quiescent, on radiography.

Table XII.—RECURRENCE RATES FOLLOWING SURGICAL TREATMENT OF CERVICAL TUBERCULOUS LYMPHADENITIS IN THE SERIES OF MASON BROWNE (1957)

Technique	*Recurrence Rate* (per cent)
Aspiration of pus	86
Incision and expression	40
Incision and curettage	34
Primary excision when abscess present	14
Primary excision when no abscess present	3
Secondary excision	0

The treatment of a sinus should be its excision together with the excision of the underlying nodes from which it arose, and appropriate chemotherapy. Sinuses so produced in this series when not excised persisted for 3–6 months despite chemotherapy.

Curettage of a tuberculous cavity is not acceptable on theoretical grounds, in that it is likely to cause haematogenous dissemination of the disease.

4. **Chemotherapy.**—Adequate chemotherapy in most forms of tuberculosis is now taken to involve the concomitant continuous administration for a sufficient length of time of two antituberculous drugs to which the organism cultured from the patient has been shown to be sensitive. (Recently, treatment with drugs given twice weekly only has been tried successfully in pulmonary tuberculosis (Poole and Stradling, 1969; Pande, 1970). This has not been used in any case in the present series.)

The drugs most usually used in combination have been streptomycin, isonicotinic acid hydrazide (INAH), and para-aminosalicylic acid (PAS). Rifampicin and thiacetazone are newer first-line drugs. Second-line drugs include ethionamide, cycloserine, and viomycin. In those cases in which the organisms were found to be sensitive, and in those in which no sensitivities were known, the most usual pattern of treatment has been to give INAH and PAS together throughout the course of treatment accompanied by daily injections of streptomycin for the first 3 months.

The length of treatment accepted as adequate for most forms of tuberculosis is now 2 years (Hanson, 1970). This has not been universally applied in lymph-node disease, and shorter courses of chemotherapy are still frequently used (Miller, 1956; Mason Browne, 1957; Gillam and Knowles, 1963). Gillam and Knowles in 1963 found a 25 per cent recurrence rate, half of which occurred after 12 months' chemotherapy. They recommended that cases with disease restricted to the upper one-third of the jugular chain on one side of the neck (Dowd group 1 cases) should be treated surgically, with chemotherapy continued only until surgery had been performed and the wound had healed. All other cases should be treated for 12 months or more.

Kent (1967) has advocated 24 months' treatment, finding only 1 recurrence in 36 cases so treated.

The results of treatment in the present series are detailed in *Table XIII*. Only cases followed for at least 12 months after treatment are included. Eighty-seven cases treated during the decade 1960–9 are detailed, the average follow-up period being 4·5 years. A further 8 episodes occurring before this decade in cases subsequently treated are included, the appropriate totals being indicated in brackets. These cases were treated by presumably adequate surgery 10–38 years before.

COMPLICATIONS OF TREATMENT

1. **Radical and Local Surgery.**—The incidence of peripheral nerve damage is very low in most reported series (Dowd, 1916; Barrington Ward, 1937; Bluhm, 1964; Kent, 1967), though the spinal accessory nerve and the cervical branch of the facial, the hypoglossal (Clain, 1968), and the recurrent laryngeal nerves (Hiranandani and Mulay, 1970) are all at risk according to the site of the node. In this series only the posterior auricular nerve was twice mentioned as being damaged. Nerve injury can be avoided as long as the anatomy of the region is well understood.

The occurrence of iatrogenic sinuses has already been discussed. In their absence scars produced by surgery will be unobtrusive (Barrington Ward, 1937).

2. **Chemotherapy.**—All the drugs employed have a high incidence of side-effects, some of which may be fatal. In this series chemotherapy had to be changed or discontinued in 10 cases because of side-effects, none of which was permament. In view of this and because of the need for adequately continued therapy, all drug therapy should be managed by a chest physician.

CAUSES OF FAILURE OF TREATMENT

Radical surgery excising all palpably involved nodes is successful in Dowd group 1 disease (Dowd, 1916) in preventing local recurrence in the decade after surgery in all but a very small number of cases (Dowd, 1916; Barrington Ward, 1937), though there is a late failure rate even in this stage of the disease. In the present series 8 cases recurred 10–38 years after adequate surgery (*Table XIII*).

The more restricted surgical excision used at present does not even remove all local disease and if unaccompanied by adequate chemotherapy has a high early recurrence rate. From Dowd's (1916) original figures it is obvious that radical surgery, however extensive, is incapable of extirpating all disease in an unacceptable proportion of stage 2 and 3 cases.

Table XIII.—RESULTS OF TREATMENT BY CHEMOTHERAPY WITHOUT RADICAL SURGERY IN THE PRESENT SERIES*

LENGTH OF CHEMOTHERAPY (months)	NO. OF CASES TREATED	NO. OF RELAPSES
Nil	8 (16)†	5 (13)†
1– 6	22	8
7–12	21	3
13–18	16	0
19–	20	1
Total	87 (95)†	17 (25)†

* Average length of follow-up, 4½ years.

† Figures in parentheses refer to cases included in the analysis but which are not strictly comparable as they occurred outside the stated decade (*see* text).

Failure of Chemotherapy.—

1. *Failure to use Two Drugs to which the Organism is Sensitive.*—In the present series in 4 out of 5 cases the organisms had not been cultured, so that its sensitivities could only be guessed at. Two INAH-resistant *Myco. tuberculosis* were encountered: 1 in a case of lymph-node disease and the other in urinary-tract disease.

2. *Disease caused by Mycobacteria other than* Myco. tuberculosis.—*Myco. bovis* occurred once in the series of extrapulmonary tuberculosis. It was, as is usual, INAH-resistant. The pathogenicity of some anonymous mycobacteria is now well attested (Chapman, 1960; Jones and Campbell, 1962; Corpe, Runyon, and Lester, 1963; Runyon, 1965), though whether they produce disease which always runs the same course as that due to *Myco. tuberculosis* is not definitely established. Group I, II, III, and IV organisms have all been implicated in cases of cervical lymphadenitis and in disease in other systems. Anonymous mycobacteria are well recognized as pathogens in America (Chapman, 1960; Runyon, 1965). They have been implicated in tuberculous cervical lymphadenitis of childhood in Australia, Jones and Campbell (1962) finding them in 1 in 10 of their cases, whilst MacKellar and others (1967) considered almost all their childhood cases as due to one of these organisms. In this country no comparable series has been published, though Marks (1970) states that only 142 cases of anonymous mycobacterial infection (all sites) have been found in Wales in the years 1953–68, though the incidence is rising. In the present series of 26 cases of lymph-node disease in which a bacteriological diagnosis was established 2 were due to anonymous mycobacteria, both of which were in adults.

Anonymous mycobacteria are not usually guinea-pig pathogens, so that suspect tuberculous material should always be cultured on Lowenstein-Jensen medium as well as by guinea-pig inoculation. Anonymous mycobacteria are largely insensitive to the usual antituberculous drugs, even in combination.

3. *Failure to continue Chemotherapy for Long Enough.*—Chemotherapy should never be given for less than 12 months (*Table XIII*), but almost certainly for 24 months as in all other forms of tuberculosis.

4. *Failure of the Patient to take the Prescribed Therapy.*—In two recent articles from England (Poole and Stradling, 1969; Pande, 1970) a 16–25 per cent defaulting rate for long-term anti-tuberculous chemotherapy is described.

5. *Occurrence of Drug Resistance during Treatment.*—This should not occur if the patient is treated with two drugs to which the organism is known to be sensitive.

6. *Coexistence of Tuberculosis with Another Disease causing Lymph-node Enlargement, e.g., Lymphoma.*—Failure of regression of adequately treated lymph-node tuberculosis indicates the need for further lymph-node biopsy.

CONCLUSIONS

Tuberculous lymphadenitis, however extensive or localized, is best treated by adequate chemotherapy in the same way as all other forms of the disease.

Surgery is always indicated before treatment is started to establish a full and accurate diagnosis histologically and bacteriologically. At this stage surgery should be employed to excise all grossly enlarged and caseating nodes. Sinuses whether originally present or occurring during treatment are an indication for surgery, excising both the sinus and the associated underlying nodes. Abscesses should not be aspirated or incised; if one of these procedures is used because the abscess is not thought tuberculous the nodes involved should be excised as soon as possible after the mistake is discovered to prevent the otherwise prolonged morbidity and eventual disfiguring scarring associated with the production of tuberculous sinuses.

Radical surgery as used in the pre-chemotherapeutic days still has an important role to play in the treatment of anonymous mycobacterial infection which is insensitive to chemotherapy.

Post-treatment excision of a persistently enlarged node should always be performed for diagnostic purposes to exclude the possibility of coexistent malignancy and to eliminate walled-off foci of the tubercle bacilli and to establish their sensitivities. The thesis that disease involving the upper cervical chain on only one side (Dowd group 1 disease) can be treated successfully by radical surgery alone is dangerous; chemotherapy should always be used for these as for more advanced cases. Even in clinically Dowd group 1 disease there is radiological evidence of disease, active or quiescent, outside the neck in 25–50 per cent of cases, leading to a later danger of reactivation of the extracervical focus.

Extracervical tuberculous lymphadenitis is almost always part of a generalized disease and should be treated as such by chemotherapy.

To be adequate chemotherapy should be continued for 24 months.

Very late recurrence is a feature of tuberculosis, especially of disease of the lymph-nodes. It is impossible in a follow-up of 10 years' duration to know whether the treatment as outlined will affect the incidence of late recurrence, although it can virtually eliminate early recurrence.

PNEUMOPERITONEUM AS AN AID IN THE SURGICAL TREATMENT OF GIANT HERNIAE

By HENRY H. BARST

STAINCLIFFE GENERAL HOSPITAL, DEWSBURY, YORKSHIRE

SUMMARY

The management of giant hernia and eventration can be greatly facilitated and made safe by the use of preoperative pneumoperitoneum. Daily insufflation of air into the peritoneal cavity, starting with 500 ml. and increasing gradually to 2–3 litres a day for approximately 2 weeks, stretches the abdominal cavity and avoids respiratory and circulatory distress at the time of operation. This preoperative treatment converts a potentially dangerous operation into a fairly simple procedure.

CASES of giant abdominal hernia, either idiopathic or incisional, are not common in the practice of the individual surgeon, although they are seen quite frequently in certain areas of the world, such as Central Africa. When encountered, they are regarded as doubtfully curable, and certainly not to be accepted lightly for operation. Mansuy and Hager (1958) stated that many cases are considered inoperable because of feared complications following sudden changes in intra-abdominal pressure and technical difficulty in closure. This view is echoed by many authors, and is certainly justified when one thinks of the possible struggle involved in trying to push back into the already filled abdominal cavity a large mass of redundant abdominal contents which has existed outside the abdomen proper perhaps for years. The result all too often is either a very unsatisfactory closure of the abdominal wall under tremendous tension, with gross respiratory and cardiac embarrassment and possible death of the patient (Berlemont, 1952), or a breakdown of the repair sooner or later with recurrence of the hernia. Many patients attempt to support these large, unwieldy, and irreducible herniae by belts which excoriate the skin and produce superficial ulceration (*Fig.* 1A, B).

The induction of pneumoperitoneum before attempting definitive repair of a giant hernia was first suggested by Moreno (1940, 1947, 1951, 1964), who describes the advantages of this method as follows: the pressure of the pneumoperitoneum causes (1) stretching of the abdominal wall, creating a larger cavity for replacement of hernial sac contents; (2) reduction of the volume of hollow viscera to be replaced at the time of repair; (3) reduction of the oedema of the mesentery, omentum, and the subperitoneal tissues caused by the chronic hernia, creating less mass to be replaced; (4) stretching of the hernial sac causing elongation of adhesions and making dissection easier; (5) increased tone of the diaphragm; (6) preoperative respiratory and circulatory adjustments to the elevation of the diaphragm (Geffen and Maisel, 1966).

MATERIALS AND METHODS

Under local anaesthesia an epidural catheter is inserted through a long aspiration needle into the peritoneal cavity in the epigastrium or left hypochondrium. Alternatively, an intracath catheter can be used (Steichen, 1965). The site of the puncture should, however, be kept away from the immediate area of the hernia in order to avoid any bowel adherent to the anterior abdominal wall (Koontz, 1958). Successful penetration of the abdominal wall will be marked by a lessening of resistance to the pressure of the needle, and the catheter will be found to pass readily into the abdomen. A few ml. of Hypaque 45 per cent (sodium diatrizoate) are injected through the catheter and a radiograph is taken. While this is being developed the needle is withdrawn, leaving the catheter in situ. The catheter is then strapped to the skin (*Fig.* 2A, B). A three-way stopcock is attached to the catheter, and a Millipore filter is attached to the stopcock. The radiograph should show the contrast medium trickling down into the pelvis. Five hundred ml. of air are then injected, either by syringe or by a pneumothorax apparatus (Moore, 1961; Steichen, 1965). If the medium is shown to have pooled in the abdominal wall, or the catheter has not passed easily into the abdomen, then one or two further attempts may be made, but it is probably better to repeat the procedure on the following day than to distress the patient by repeated unsuccessful attempts.

After the initial injection of 500 ml. of air a similar amount is injected twice daily for 3–4 days. Thereafter, provided that there have been no untoward symptoms, each injection is increased by 250 ml., making a daily total of 1·5 litres of air. A further rise is made, again after 3–4 days, but at this point if progress has been satisfactory the increase can be of the order of 300–500 ml., thus bringing the daily total to between 2·1 and 2·5 litres of air. The patient gradually blows up like a balloon and may become alarmed, unless adequately reassured, at the enormous increase in size of the abdomen, having originally come for treatment for a swelling already considered too large. If at any time during the insufflation of air the patient feels any discomfort or dyspnoea or if tachycardia develops, the injection can be stopped and, if necessary, some air can be withdrawn. The next insufflation can be delayed for a day or so to allow the patient to settle down. No attempt is made to prevent the distension of the hernial sac by applying binders. This will allow any adhesions between the contents and the sac to elongate. Non-adherent contents of a previously irreducible hernia will frequently be found to have disappeared completely into the abdomen at the time of operation. Moreno (1964) has recommended the regular measurement of intra-abdominal pressure to determine the most appropriate day for operative repair of the hernia—when the pressure readings have become constant and the vital capacity stabilized—but I have not had any difficulties from the omission of this step. In practice the average patient is ready for operation in about a fortnight, the end-point being judged by the tension of the abdominal wall; this should feel as tight as a drum, especially on the flanks. If, however, the flanks feel too soft, then 2 or 3 days' extra air insufflation will usually suffice to prepare the patient fully for operation.

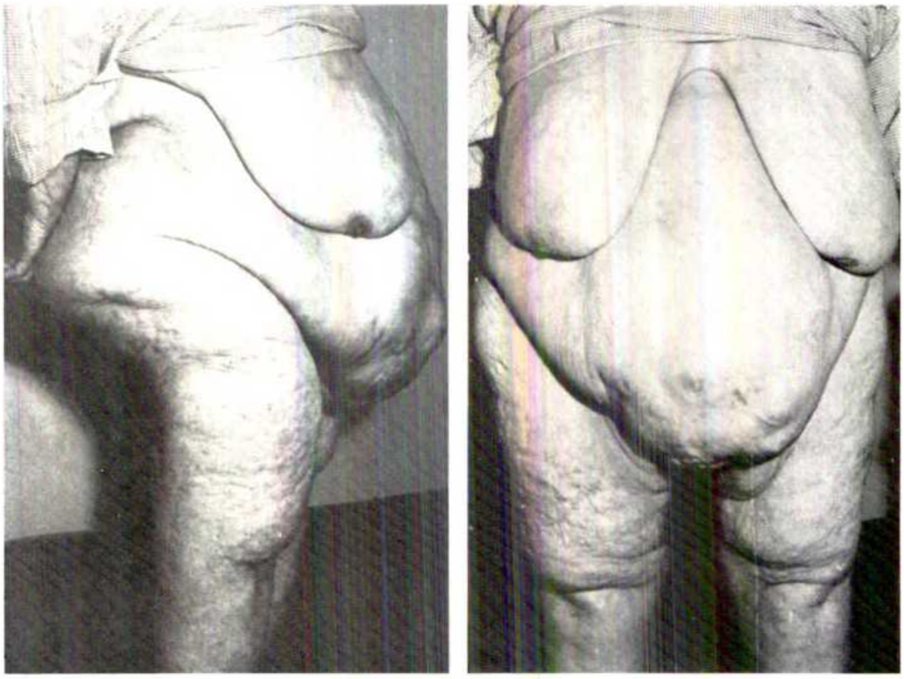

FIG. 1.—Mrs. S. before operation.

At operation excision of the redundant skin, fat, and stretched fasciae and tissues should be carried out as far as possible before the hernial sac is punctured. When this occurs, the air rushes out of the abdomen rather like a punctured car tyre, and the remainder of the excision and suturing is continued on a completely deflated and flaccid abdominal wall. I have rarely found it necessary to use any strengthening material such as tantalum mesh, but this should be available if the defect is too large to close naturally (Koontz, 1951, 1956) (*Figs.* 2C, D, 3).

PRESENT SERIES

Twenty-five cases of giant hernia have been treated by preoperative pneumoperitoneum over a period of 20 years. Although the earlier cases performed in the Sudan have not been adequately followed up, the early and late results have amply confirmed the views of the originator of the method, Professor Ivan Goni Moreno, and his colleagues that this is a safe method for dealing with this difficult problem.

An example of the value of this method is shown by the following case.

Case 1.—Mrs. E. B., aged 65 years, was admitted on 6 April, 1967, complaining of abdominal pain and vomiting for 4 days. She had had absolute constipation for the same period, together with oliguria. Twenty-eight years earlier an ovarian cyst had been removed which had been followed almost immediately by the development of an incisional hernia. The patient had worn a support for this since then, but the hernia had progressively increased in size and had suddenly become painful and larger 4 days before admission.

The patient was ill and dehydrated, but obese, weighing just over 127 kg. There was an enormous bilobed incisional hernia involving the lower half of the abdomen, approximately 38 cm. in diameter and rising to a height of 20 cm. from the abdominal wall. The abdomen itself was distended and tympanitic. There was gross intertrigo with patchy superficial ulceration over the hernia.

Following suction and correction of the electrolyte imbalance, the hernia fortunately became softer and the patient's condition improved, with passage of flatus after 48 hours.

The induction of pneumoperitoneum was started on 14 April and an operation was carried out on 1 May. Some slight wound infection occurred, but this settled quickly and the patient was discharged with an abdominal belt.

Four years later the patient reports that her life has been transformed by the hernia repair. She now weighs 105 kg. and is 160 cm. tall.

Another type of case which may require help is that of a patient with a terminal colostomy, perhaps following an abdominoperineal resection of the rectum. A massive incisional hernia may develop, with the bowel opening perched on top of a hillock and a length of colon lying subcutaneously together with a mass of small intestine. The colostomy belt gradually becomes more and more difficult to apply, while episodes of partial obstruction in the extruded small bowel may become frequent.

These cases can also be treated satisfactorily by preoperative pneumoperitoneum and subsequent repair. There were 2 such cases in the present series, and both required the resection of a further 45 cm. or so of colon, followed by the refashioning of the colostomy opening after dealing with the hernia.

In 2 cases of enormous hernia which had existed for many years a violent bout of coughing forced an extra loop of small intestine into the hernial sac and produced strangulation. Under local anaesthesia in 1 case, and general anaesthesia in the other, the constricting ring was incised and the trapped bowel

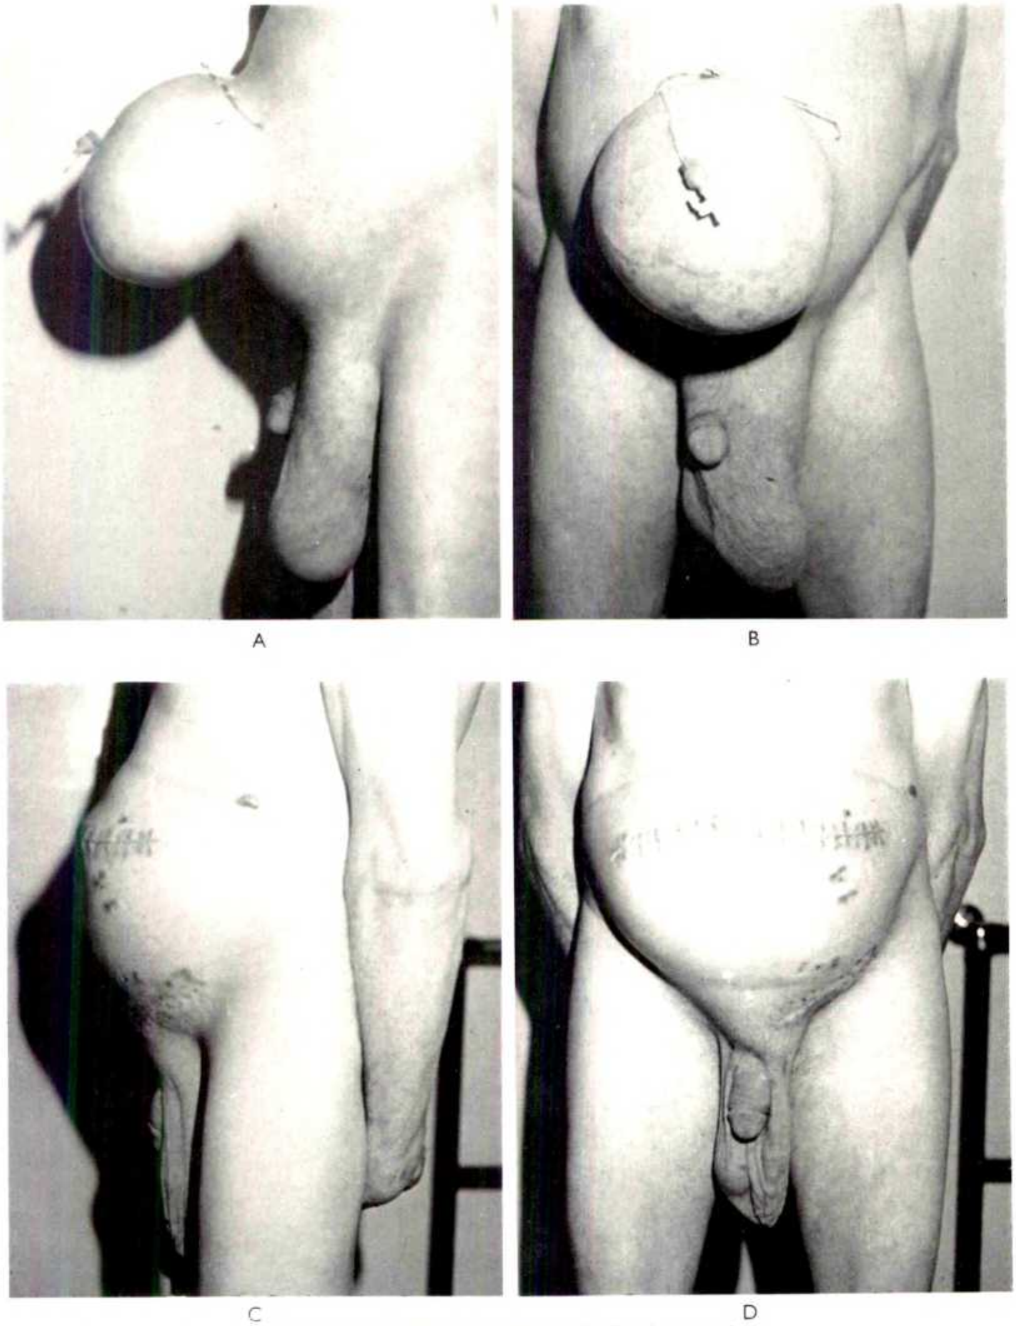

FIG. 2.—A, B, Mr. B. before operation. C, D, After operation.

freed and reduced, being viable in both cases. No attempt was made to deal with the hernia at that time. After a suitable interval for healing and convalescence, the régime of pneumoperitoneum was carried out and a definitive repair was performed in due course.

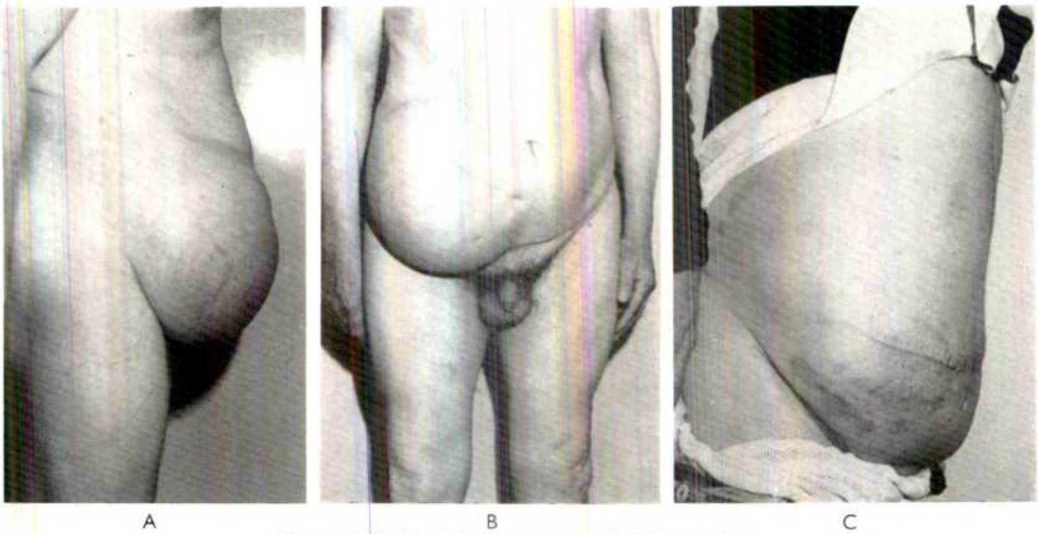

FIG. 3.—A, B, Mr. A. before operation. C, After operation.

DISCUSSION

The problem of dealing with giant herniae has brought a number of suggestions, such as resection of some of the intestine held in the hernial sac (Davey, 1968) or phrenic section (Touroff, 1954). Ziffren and Womack (1950) report the treatment of a case using a two-stage method, with incision of all the coverings down to the peritoneum initially and resuture of the skin, followed by repair of the hernia 12 days later.

The method described by Moreno (1940) has the merit of simplicity and safety. The distension of the abdominal cavity can be developed at any pace desired, and can be interrupted and restarted at any stage if the patient is disturbed. This plan is vastly superior to that of allowing oneself to be faced with a mass of tissue spilling out over an already crowded abdomen and wondering what to do with it. Berlemont (1952) describes the unfortunate sufferers as usually aged, obese, and emphysematous. There is often great difficulty in freeing the hernial contents. He records a series of 8 cases in the Sudan in which 5 patients died. The causes of death were long operations with brutal reduction, consequent pulmonary collapse, and cardiac insufficiency with diminution of intrathoracic volume. A second series of 18 cases using preoperative pneumoperitoneum produced 17 cures and 1 death.

Many reports have appeared from South America (Ottolenghi, 1944; Carpanelli, 1946; Iparraguirre, 1946; Aguirre, 1949; Goldin and Olmedo Diaz, 1960) and from America and Europe (Guellette, 1947; Koontz and Graves, 1954; Mason, 1956; Koontz, 1958; Moore, 1961; Galeano, Azulay, and Montoreano, 1962, 1965; Anagnostides and Kostopoulos, 1962; Moyer, 1964; Steichen, 1965; Unglaube and Gromoll, 1966; Pingree and Clark, 1968; Connolly and Perri, 1969) confirming the success of this method.

Galeano and others (1962, 1965) point out that the enormous swelling observed when one first sees a patient suffering from giant hernia may mask small additional herniations, and these, together with points of weakness which may presage but have not progressed to full herniation, will become very obvious during the course of air insufflation, and can then be brought within the scope of repair. Deep anaesthesia will not, of course, be necessary to achieve the profound relaxation usually demanded by the surgeon in dealing with these difficult cases.

Koontz and Graves (1954) stress that air should be injected slowly, as diffuse pain, nausea, or pain in the shoulders may appear. These symptoms soon disappear and later insufflations are well tolerated. They recommend using the linea semilunaris as the site for injection, as thick fascia is present and this gives a more positive indication of penetration of the peritoneal cavity. The use of a pneumothorax apparatus has been recommended by Moore (1961) in place of the more tedious syringe. He gives an initial 500 ml. and continues with 500–2000 ml. daily as an out-patient procedure, monitoring the insufflation by water-pressure and stopping at a level of 14 cm. The usual amount of air mentioned by most authors is 2–3 litres daily, but Anagnostides and Kostopoulos (1962) mention that Moreno has injected up to 6–8 litres of air at a session.

Connolly and Perri (1969) quoted 22 cases of adult hernia previously reported in the American literature who were treated in this way and added 3 cases of their own. They commented that the gradual expansion of the abdominal wall is physiologically similar to the stretching in pregnancy and in conditions producing large accumulations of ascitic fluid.

The absorption of oxygen from the peritoneal cavity has been found to be imperceptible after a few hours and it is safe to assume that the rate of absorption of air would be less than the rate of absorption of pure oxygen.

Several authors (Connolly and Perri, 1969; Galeano and others, 1962, 1965) mention contra-indications to the use of pneumoperitoneum. These include abdominal wall infection, decompensated cardiac conditions, the presence of a small ring, or strangulation. Certainly, strangulation would preclude the immediate application of pneumoperitoneum, while any attempt at immediate repair of a giant hernia which has had the added complication of strangulation would be extremely hazardous.

Moore (1961) warns that pneumoperitoneum may mask acute abdominal conditions such as perforating peptic ulcer, diverticulitis, and appendicitis. He also notes that when pulmonary tuberculosis was treated by therapeutic pneumoperitoneum some years ago there was an increase in the incidence of perforated peptic ulcer, possibly due to mechanical separation of the viscera from the parietal peritoneum and protective adjacent structures. Other possible complications mentioned by Galeano and others (1962, 1965) include respiratory syncope, puncture of a viscus, haematoma, and retroperitoneal and mediastinal emphysema, but these are regarded as rare. Faber and Harsanyi (1962) report a case of fatal air embolism due to therapeutic and diagnostic abdominal air insufflation, but this complication is regarded as extremely rare by Simmonds (1946), who records 5 cases of air embolism in 13,000 insufflations for pulmonary tuberculosis, and remarks that puncture of a viscus is even more infrequent. Koontz (1958) considers the occurrence of pneumonia in 1 of his patients as possibly due to air being injected too rapidly.

None of these complications has been seen in the present series and the only disturbance has been an occasional attack of tachycardia or dyspnoea in the first few days of the treatment.

Acknowledgements.—I should like to thank Professor J. C. Goligher for his valuable comments and guidance in the writing of this article, and also Miss W. Smith for her secretarial assistance and Mr. N. Wroe for the photographs.

I should also like to thank those junior colleagues of mine who undertook the, at times, rather tedious task of performing the daily air insufflations.

THE LITHOGENIC EFFECT OF VAGOTOMY*

By A. G. A. COWIE and C. G. CLARK

DEPARTMENT OF SURGERY, UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

The composition and the rate of flow of bile produced in response to a standard fatty meal in cholecystectomized dogs have been determined before and after vagotomy and pyloroplasty. The results presented support the view that vagotomy is potentially lithogenic, particularly after cholecystectomy.

FOR over 20 years since it was first suggested (Majoor and Suren, 1947) the possibility of a causal relationship between surgical procedures performed for peptic ulceration and the development of gall-stones has been considered. Much of the evidence for this has been clinical observation, and in a review of the literature in 1968 Fletcher and Clark, summarizing the evidence, concluded that the case for a lithogenic effect of surgery was as yet not proved. There has been little evidence since then either to support or to deny the hypothesis. Among the more important observations are those of Krause (1963), who showed that the incidence of gall-stones in patients with peptic ulceration but who did not undergo surgery was much the same as the incidence in the normal population. Many studies tend to implicate vagotomy as the common factor linking those operations which may be associated with an increased incidence of gall-stones. There is no increase in stone formation following selective vagotomy in which the vagal innervation of the biliary tree is preserved (Farris, 1969; Griffith, 1969).

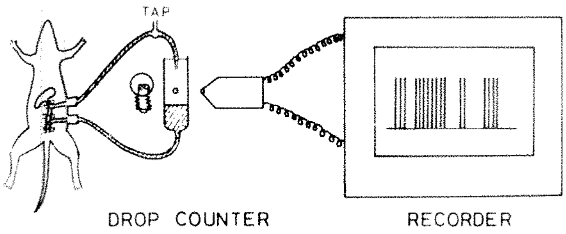

FIG. 1.—Diagrammatic representation of the experimental procedure.

The role of the vagus in the control of bile-flow and bile composition in the dog was reported by Fletcher and Clark (1969). Using animals with an intact gall-bladder they showed that a standard fatty meal provoked a flow of bile; the rate of flow was much less after vagotomy and the concentration of cholate was also lowered, thus changing the ratio of cholate concentration to cholesterol concentration in the bile. Both of these effects might predispose to cholesterol crystallization and thus promote stone formation. This work has now been extended to include studies on dogs after cholecystectomy.

MATERIALS AND METHODS

The biliary cannula of Fletcher and Corry (1968) was used. This requires the placement of latex tubes in the proximal and distal common bile-duct, the tubes being led to a surface-mounted cannula with a detachable 'U' cap so that between experiments, with the cap in place, the normal enterohepatic circulation of bile can be maintained with the sphincter of Oddi undisturbed. During experiments a drop chamber with an attached photo-electric cell is included in the still-intact enterohepatic circulation, and the flow-rate is measured by the drops recorded on a timed moving-paper recorder (*Fig.* 1). A tap is included in the system so that 0·6-ml. samples may be aspirated at 30-minute intervals for analysis. The dead space within the system amounts to 1·5 ml., which is insufficient materially to alter the enterohepatic circulation.

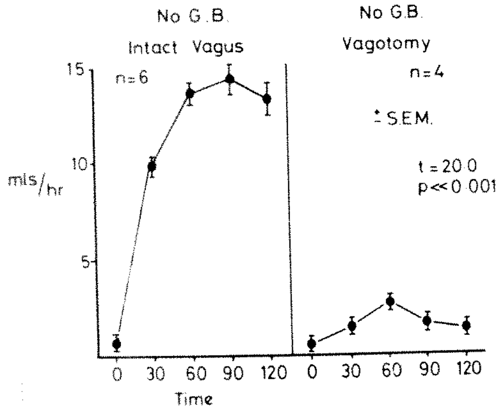

FIG. 2.—The bile-flow rate in response to a fatty meal before and after vagotomy.

Bile-flow and bile composition were determined in response to a standard fatty meal of 60 g. of Prosparol in 6 dogs before and in 4 dogs after a total abdominal vagotomy with a Mikulicz pyloroplasty. Each dog underwent cholecystectomy at the initial operation, and 2 weeks' convalescence was allowed following operation prior to measurement. In each case liver-function tests remained normal, and the completeness of the vagotomy was confirmed at autopsy. Total cholate concentration was determined by the method of Irvin, Johnston, and Kopala (1944), phospholipid concentration by a modification of the method of Fiske and Subbarrow (1925), and cholesterol concentration by a method derived from that of Babson, Shapiro, and Phillips (1962) and Leffler and McDougald (1963).

---

* Based on a short communication which was presented at the Birmingham Meeting of the Surgical Research Society in July, 1971.

RESULTS

In each experiment a standard fatty meal of 60 g. of Prosparol was given and measurements were continued for 2 hours. With the vagus intact there was a brisk increase in the rate of flow from 0·5 ml. to between 10 and 14 ml. per hour (*Fig.* 2). After vagotomy the rise was small. Each value plotted is a mean shown with 1 standard error in each direction. The difference between each similarly timed pair, determined by a *t*-test appropriate for small numbers, is highly significant ($P < 0\cdot001$).

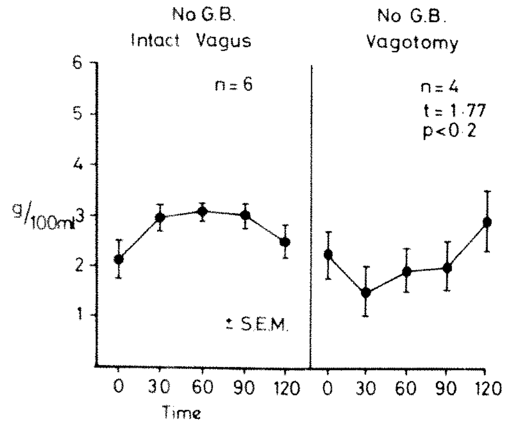

FIG. 3.—The effect of vagotomy on the concentration of cholate.

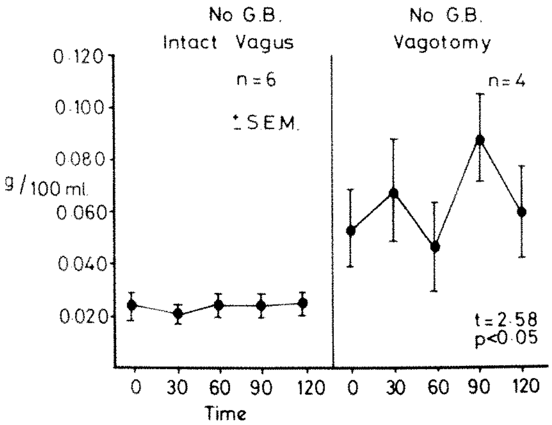

FIG. 4.—The effect of vagotomy on the concentration of cholesterol.

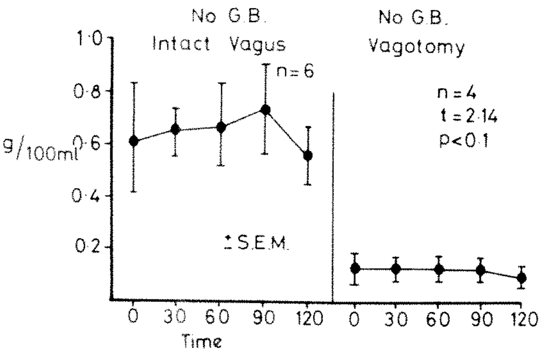

FIG. 5.—The effect of vagotomy on the concentration of phospholipid.

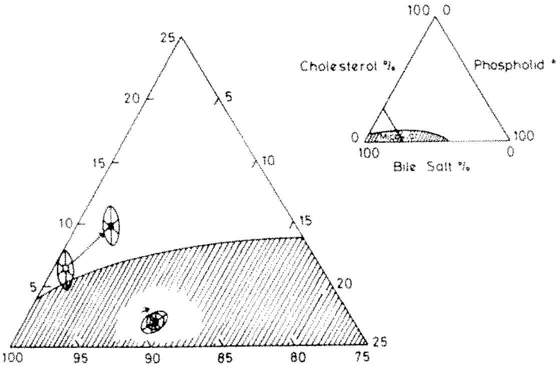

FIG. 6.—Triangular co-ordinates illustrating bile composition in dogs. ○, Vagus intact; fasting. ●, Vagus intact; after a meal. □, After vagotomy; fasting. ■, After vagotomy; after a meal.

The concentration of cholate (*Fig.* 3) shows a slight reduction after vagotomy, but this is not a statistically significant change. The concentration of cholesterol shows a small rise after vagotomy (*Fig.* 4), and this is significant ($P < 0\cdot05$). The concentration of phospholipid (*Fig.* 5) shows a reduction after vagotomy, but the significance is again of a low order ($P < 0\cdot1$).

These results can be interpreted as showing a change in bile composition likely to make the bile more lithogenic, but a better interpretation can be obtained by converting the data in relation to the known effects of cholesterol crystallization.

The chemical composition of bile, with reference to the relative concentrations of phospholipid, bile-salts, and cholesterol, can be expressed in such a way that it can be plotted on triangular co-ordinates as a phase diagram (Hoffman and Small, 1967). The smaller triangle in the upper right-hand corner of *Fig.* 6 is such a phase diagram for bile containing 5–10 per cent of solids. The shaded area in the lower part of this triangle is known as the micellar zone of the phase diagram. Within this zone cholesterol is solubilized in mixed micelles, but outside the zone cholesterol will inevitably crystallize for physicochemical reasons. The larger triangle in *Fig.* 6 is an expanded section of the phase diagram. To plot the present results on this diagram requires conversion of the concentrations measured from g. per 100 ml. to mmol. per litre, and each concentration is expressed as a percentage of the total molar concentration of the three substances involved. The figure for bile-salt is adjusted to allow for the fact that cholate only has been measured, and to do this it has been assumed that the cholate : bile-salt ratio remains relatively constant. This ratio is a species characteristic (Haslewood, 1955), and in dogs is 1 : 1·9.

The result of plotting the figures in this way can be seen in *Fig.* 6. Each point is shown with 1 standard error in each direction.

In the normal dog with intact vagi the results are within the micellar zone and are little affected by the stimulus of food. After vagotomy, however, the plot moves out of the micellar zone and this moves farther into the zone of cholesterol crystallization after a meal. The results previously reported (Fletcher and Clark, 1969) have been treated in the same way. In their experiments with vagotomy in dogs with an intact gall-bladder it was found that although the bile moved in the direction of the micellar boundary it did not move into the zone of cholesterol crystallization.

DISCUSSION

Bile-flow in the unanaesthetized cholecystectomized dog is stimulated by a fatty meal and this effect is virtually abolished by vagotomy. Similar results were obtained by Fritz and Brooks (1963), who used insulin and tolbutamide to stimulate bile-flow and then studied the blocking effect of anticholinergic drugs. Baldwin, Heer, Albo, Peloso, Ruby, and Silen (1966) found similar results on insulin stimulation in man with total biliary drainage, but both the latter experiments failed to maintain the enterohepatic circulation which is known to be important in the regulation of bile output (Thureborn, 1962).

The role of the vagus nerves in the secretion of bile is uncertain, and it has been suggested that the principal effect of vagal stimulation on bile-flow is mediated through the release of gastrin from the antrum (Sauberman and Silen, 1967).

There is a linear relationship between bile-flow and bile-acid secretion (Wheeler and Ramos, 1960), and in the fasting state spontaneous variations occur which can be blocked by anticholinergic drugs. Bile secretion can be stimulated by secretin (Bayliss and Starling, 1902), cholecystokinin–pancreozymin (Edholm, Jonson, and Thulin, 1962), and gastrin (Zaterka and Grossman, 1966), with marked similarity in the flow and composition of the bile. In the present studies bile-flow was reduced after vagotomy and pyloroplasty, which could theoretically impair the response to each of these secretagogues.

More important, however, was the observation that the composition of bile was altered. There was a significant increase in the concentration of cholesterol, a reduction in the concentration of phospholipid, but no real change in the cholate concentration. In an earlier study in dogs with intact gall-bladders vagotomy had a similar effect in reducing bile-flow, but it also reduced the concentration of cholates (Fletcher and Clark, 1969). The results in both experiments affected the ratio of bile-salt to cholesterol in such a way as to make the bile potentially more lithogenic. The phase diagrams of Hoffman and Small (1967) provide a better means of assessing the significance of these findings. When the results are examined in this way it can be seen that the previous observations of Fletcher and Clark (1969) do not suggest a significant change in the lithogenic effect of bile after vagotomy in dogs with intact gall-bladders. However, the results of the present experiments clearly indicate that following cholecystectomy in the dog, bile is already in the zone of cholesterol crystallization in the fasting state and it moves farther into the zone in response to feeding.

If these results have any relevance to the aetiology of gall-stones in man following gastric surgery, then vagotomy may only result in this complication in circumstances where gall-bladder function is already impaired. The results of these acute experiments, however, may require modification in the light of long-term experiments.

Acknowledgements.—We wish to thank the Board of Governors, University College Hospital, London, for financial assistance with these experiments. We wish to record our appreciation of the valuable technical assistance of Mr. Peter Luther both with the experiments and the preparation of diagrams.

SPONTANEOUS AORTODUODENAL FISTULA

By D. M. EVANS* and J. H. H. WEBSTER

ROYAL SOUTH HANTS HOSPITAL, SOUTHAMPTON

SUMMARY

Two further cases, 1 fatal and 1 with long-term recovery, of patients treated surgically for spontaneous aortoduodenal fistula are reported, bringing the total number of published operations to 20. Thirty-six further examples of the lesion which were not treated by operation have been reported since 1957.

Of a wide variety of causes for this lesion, the commonest is arteriosclerotic aneurysm of the aorta.

The association of recurrent gastroduodenal haemorrhage with severe pain and collapse may indicate this lesion, and the treatment should be surgical.

Control of the aorta proximal to the fistula is the essential first step in prosthetic grafting of the aorta and closure of the duodenum. Otherwise, spontaneous aortoduodenal fistula is uniformly fatal.

FISTULA formation between the aorta and the duodenum occurs most commonly as a complication of prosthetic grafting of the aorta. The condition can, however, occur spontaneously, and Cleland (1947) described such a spontaneous fistula as a 'necessarily fatal condition'. Since that time a number of successfully treated cases have been reported. The purpose of this paper is to bring up to date the list of published cases, adding 2 of our own, and to consider the aetiology, diagnosis, and surgical management of this condition.

HISTORICAL REVIEW

The first account in the literature of rupture of an aortic aneurysm into the gastro-intestinal tract appears to be that given by Cooper in 1837. Since then many case reports have been published, with review articles by Rottino (1943), Hunt and Weller (1946), and Scott, Maxwell, and Grimes (1949). The last comprehensive list of cases was made by Skromak, O'Neill, Ciccone, and Snyder (1957), who reported 42 examples of aortoduodenal fistula, including 2 of their own. Since then a further 56 cases have been reported, including the present 2 cases, and details of these are summarized in *Table I*. Some of these reports include additional cases of fistulae into other parts of the gastro-intestinal tract that are not being considered here.

CASE REPORTS

Case 1.—Mrs. M. C., aged 38 years, was referred for surgery in March, 1966, with a 6-month history of intermittent right-sided abdominal pain and pyrexia. Despite intensive investigation the only abnormality shown was a persistently raised E.S.R., which at no time during her illness fell below 80 mm. per hour. Although barium studies of the stomach and small bowel were negative on two occasions, it was thought that an inflammatory lesion of the small bowel was the most likely diagnosis.

Before an elective laparotomy could be performed, however, the patient had a moderate haematemesis, recovering after transfusion of 2 litres of whole blood. Thirty-six hours later a further severe haematemesis was accompanied by very severe pain and circulatory collapse, and she rapidly became exsanguinated and pulseless.

At immediate laparotomy, pulsating arterial blood was found coming from the duodenum, the source being a spontaneous fistula of the aorta into the third part of the duodenum. An 8-cm. length of woven Teflon graft was inserted to replace the damaged segment of aorta, and the duodenum was repaired. Transfusion of 17 litres of whole blood was required during the operation, and despite replacement of calcium and administration of epsilon aminocaproic acid an irreversible coagulation defect developed, leading to death from haemorrhage after 48 hours.

Because of the damage from extravasation of blood and surgical trauma, no abnormal tissue in the region of the fistula could be found at autopsy to explain the aetiology. The naked-eye appearances at operation did not suggest a peptic ulcer, and the aortic wall close to the fistula was normal.

Case 2.—Mr. W. C., aged 69 years, was admitted with recurrent attacks of epigastric pain and faintness, each attack being accompanied by profound collapse and subsequent melaena stools. During the fourth attack he began to pass bright blood per rectum, and laparotomy was performed through an upper midline incision.

At operation the third part of the duodenum was found to be adherent to what appeared to be a small aortic aneurysm, although its nature was never definitely established. Preliminary control was obtained by taping the aorta at the hiatus, enabling the fistula to be safely opened and the aorta reclamped below the renal arteries. A knitted Dacron bifurcation graft was inserted, the common iliac vessels being only slightly atheromatous. The duodenum was closed and the graft was covered with peritoneal flaps only, as there was insufficient aortic wall to sew over it.

Recovery was uneventful and the patient remains well 22 months later.

AETIOLOGY

As can be seen from *Table I*, by far the commonest cause of aortoduodenal fistula is arteriosclerosis of the aorta, usually with aneurysm formation. One aortic dissection has been incriminated (Roach, 1939) and one post-traumatic aneurysm (Sheldon, Leckie, and Mills, 1968). Infective aneurysms have been found —both syphilitic (Pratt-Thomas, 1944) and mycotic (Foa, 1895). Tuberculous para-aortic nodes have been described by Tozer (1914), Muendel and Pilpel (1954), Polk, Martiny, and De Castro (1956), and Eadie and Pollock (1968). An abscess cavity containing pus was found by Garzon, Wilson, and Gunter (1958), Voyles and Moretz (1958), and Dinapoli, Schirger, and Kirklin (1962). In 1 case (Ghaphery, Gupta, and Currie, 1966) the fistula was related to a carcinoma of the pancreas.

Table I.—Details of the Cases of Aortoduodenal Fistula reported in the Literature since 1951

Author	Age and Sex	Aetiology	Site	Outcome
Hirst and Affeldt (1951)	66 F.	Arteriosclerotic aneurysm	Third part	Died 48 hours after admission
Hirst and Affeldt (1951)	67 M.	Arteriosclerotic aneurysm	Third part	Died 11 hours after admission
Hirst and Affeldt (1951)	65 M.	Arteriosclerotic aneurysm	Third part	Died 2 hours after admission
Hirst and Affeldt (1951)	80 F.	Arteriosclerotic aneurysm	Third part	Died 8 hours after admission. At autopsy two communications were found
Hirst and Affeldt (1951)	76 M.	Arteriosclerotic aneurysm	Third part	Died 46 hours after admission
Hirst and Affeldt (1951)	73 F.	Arteriosclerotic aneurysm	Third part	Died following haematemesis at home
Hirst and Affeldt (1951)	75 M.	Arteriosclerotic aneurysm	Third part	Died 5 days after admission. At autopsy four communications were found
Hirst and Affeldt (1951)	78 M.	Arteriosclerotic aneurysm	Third part	Died 6 days after admission
Muendel and Pilpel (1954)	63 M.	Arteriosclerotic aneurysm	Third part	Died 4 hours after rectal haemorrhage. Also had pulmonary tuberculosis
Polk, Martiny, and De Castro (1956)	63 F.	Arteriosclerotic aneurysm	Third part	Operation: Defects in aorta and duodenum sutured. Died 3 days later. Also had tuberculosis
Heberer (1957)	? M.	Arteriosclerotic aneurysm	Third part	Operation: Saccular aneurysm resected; aorta and duodenum repaired; alive and well 2 years later
Garzon, Wilson, and Gunter (1958)	52 M.	Arteriosclerotic aneurysm	Third part and colon	Operation: Defect in aneurysm sutured and packed. Died at the end of the operation
Voyles and Moretz (1958)	61 M.	Arteriosclerotic aneurysm	Third part	Operation: Resection and graft. Died after 1 month following further haemorrhage and resuture, using a thoracotomy for control of the aorta
Kubota and Moragues (1959)	69 M.	Arteriosclerotic aneurysm	Third part	Died 12 hours after admission
Kubota and Moragues (1959)	81 M.	Arteriosclerotic aneurysm	Third part	Died 3 days after admission
Szunyogh (1959)	68 M.	Arteriosclerotic aneurysm	Third part	Died 14 hours after haemorrhage
Montserrat and Naranjo (1960)	71 M.	Arteriosclerotic aneurysm	Third part	Died within a few hours
Baumler (1961)	74 M.	Arteriosclerotic aneurysm	Third part	Died 2 weeks after admission
Maclean and Couves (1961)	34 F.	Arteriosclerotic aneurysm	Fourth part	Operation: Resection and graft 6 hours after initial laparotomy and suture of fistula, allowing time for preparation. Well at 30 months
Ozlu and Allen (1961)	66 M.	Arteriosclerotic aneurysm	Third part	Died 26 hours after first haemorrhage
Aunon, Lopez, and Jimenez (1962)	60 M.	Arteriosclerotic aneurysm	Third part	Operation: Resection and graft. Well 6 months later
Dinapoli, Schirger, and Kirklin (1962)	59 M.	Arteriosclerotic aneurysm	Third part	Operation: Resection and graft. Renal arteries clamped for 50 minutes. Abscess behind aneurysm. Died in renal failure after 9 days
Kurai (1962)	61 M.	Arteriosclerotic aneurysm	Third part	Died rapidly
Law, Garrett, and DeBakey (1962)	63 M.	Arteriosclerotic aneurysm	Fourth part	Operation: Resection and graft. Well 4 months later
Macbeth (1962)	88 M.	Arteriosclerotic aneurysm	Duodeno-jejunal flexure	Died 36 hours after haemorrhage
Macbeth (1962)	63 M.	Arteriosclerotic aneurysm	Third part	Dead on arrival at hospital
Bela and Pavel (1963)	65 M.	Arteriosclerotic aneurysm	Third part	Died 24 hours after haemorrhage
Garrett, Beall, Jordan, and DeBakey (1963)	71 M.	Arteriosclerotic aneurysm	Third part	Operation: Resection and graft. Died 10 days later following further laparotomy and resection of gangrenous sigmoid colon
Payne (1964)	62 M.	Arteriosclerotic aneurysm	Third part	Died. Several previous laparotomies for gastro-intestinal bleeding, but aneurysm not found

Table I (*cont.*).—DETAILS OF THE CASES OF AORTODUODENAL FISTULA REPORTED IN THE LITERATURE SINCE 1951

AUTHOR	AGE AND SEX	AETIOLOGY	SITE	OUTCOME
Phillips and Jarrell (1964)	66 M.	Arteriosclerotic aneurysm	Third part	Operation: Resection and graft. Alive and well 18 months later
Minjer (1965)	55 M.	Arteriosclerotic aneurysm	Third part	Died following laparotomy. No procedure carried out
Schmich (1965)	66 M.	Arteriosclerotic aneurysm	Third part	Operation: Resection and closure of saccular aneurysm. Died from pulmonary embolus at 21 days
Diethrich, Campbell, and Brandt (1966)	63 M.	Arteriosclerotic aneurysm	Third part	Operation: Resection and graft. Alive and well 4 years later
Ferguson and Arden (1966)	50's M.	Arteriosclerotic ulceration	Duodenum	Died 7 hours after admission
Ferguson and Arden (1966)	52 F.	Arteriosclerotic aneurysm	Duodeno-jejunal flexure	Died 2 weeks after admission
Ferguson and Arden (1966)	59 F	Arteriosclerotic aneurysm	Third part	Died 6 weeks after admission
Ferguson and Arden (1966)	68 M	Arteriosclerotic aneurysm	Duodenum	Dead on arrival in hospital
Ghaphery, Gupta, and Currie (1966)	55 F.	Carcinoma of head of pancreas	Third part	Operation: Pancreaticoduodenectomy and oversewing of aorta. Died postoperatively
Schmauss and Perlin (1966)	72 F.	Arteriosclerotic aneurysm	Third part	Died 23 days after first haemorrhage
Schmauss and Perlin (1966)	76 M.	Arteriosclerotic aneurysm	Third part	Died 12 hours after first haemorrhage
Schmauss and Perlin (1966)	79 M.	Arteriosclerotic aneurysm	Third part	Died 12 days after first haemorrhage. Also found to have a carcinoma of the stomach at autopsy
Vlasak (1966)	73 M	Arteriosclerotic aneurysm	Duodenum	Died of haemorrhage
Chang and Liu (1967)	67 M.	Arteriosclerotic aneurysm	Third part	Operation: Resection and graft. Alive and well 10 months later
Bhagavan and Weinberg (1968)	55 M.	Arteriosclerotic aneurysm	Fourth part	Operation: Fistulous opening oversewn. Died postoperatively
Bhagavan and Weinberg (1968)	65 M.	Arteriosclerotic aneurysm	Third part	Died 86 hours after admission
Eadie and Pollock (1968)	80 M.	Arteriosclerotic aneurysm	Third part	Operation: Resection and graft. Secondary fistula occurred after 3 weeks. Died during second operation Possible old tuberculosis around aorta
Grimond, Enjalbert, Boulard, Gedeon, Saury, and Dambrin (1968)	60 M.	Arteriosclerotic aneurysm	Third part	Operation· Resection and graft Alive and well 3 months later
Sheldon, Lockie, and Mills (1968)	18 M.	Post-traumatic aneurysm	Third part	Operation: Excision of two saccular aneurysms (one above renal arteries) and Teflon patch under extracorporeal circulation and hypothermia. Survived
Gambill (1969)	64 M.	Arteriosclerotic aneurysm	Third part	Died 6 days after haemorrhage. Duodenal ulcer also found at autopsy
Seiferth and Castrup (1969)	74 M.	Arteriosclerotic aneurysm	Third part	Died 2 days after admission
Seiferth and Castrup (1969)	71 M.	Arteriosclerotic aneurysm	Third part	Died 3 weeks after admission
Seiferth and Castrup (1969)	63 M	Arteriosclerotic aneurysm	Second part	Died 12 days after admission
Seiferth and Castrup (1969)	55 M.	Arteriosclerotic aneurysm	Third part	Died 9 days after admission
Tornow (1969)	79 M.	Arteriosclerotic aneurysm	Duodeno-jejunal flexure	Died 6 days after admission
Evans and Webster (1972)	36 F.	Unknown	Third part	Operation: Resection and graft. Died of haemorrhage after 2 days
Evans and Webster (1972)	69 M.	Arteriosclerotic aneurysm	Third part	Operation: Resection and graft Alive and well 22 months later

Summary

Total No. of cases reported since 1951	56
No. of cases operated on	20
Survived 3 months or more	10
Died of postoperative complications	5
Died within 3 days of operation	5

Bhagavan and Weinberg (1968) emphasize the role of inflammatory changes between the duodenum and the aortic wall in the formation of the fistula, and this was very obvious in the first of our cases.

CLINICAL FEATURES

The clinical sequence in aortoduodenal fistula is usually typical of a secondary haemorrhage, in that after the initial bleeding there is a recovery period, often followed by several further episodes of haemorrhage before death. Whatever the cause the pathological process of local tissue damage is unlikely to produce any characteristic diagnostic features, except where an aortic aneurysm is detectable. Even then, however, a separate cause of gastroduodenal bleeding may coexist with an aortic aneurysm (Jones, Kirk, and Bloor, 1970).

In both of our cases we were impressed by the severe pain and collapse which accompanied the episodes of bleeding. These symptoms remitted as the bleeding stopped and were clearly not explained by hypovolaemia alone. The most likely differential diagnosis was combined bleeding and perforation of a peptic ulcer, which was disproved by a normal barium-meal examination in *Case* 1.

It is perhaps worth emphasizing that in the majority of reported cases there has been time after the initial presentation for arrangements for surgical treatment to be made (Roach, 1939; Voyles and Moretz, 1958).

TREATMENT

Treatment should be purely surgical, combined with energetic resuscitation. If the diagnosis is suspected, urgent laparotomy is mandatory, but probably in most cases the diagnosis will only be made at laparotomy for undiagnosed gastroduodenal bleeding.

An inflammatory mass is likely to be found in the region of the duodenojejunal flexure, and temporary proximal control of the aorta should be achieved, either in the hiatus or more simply through a small left thoracotomy. Until then care should be taken not to disturb the fistula, with the risk of external release of the full aortic flow, as happened in the present *Case* 1.

Three methods of dealing with the fistula have been attempted (*Table II*):—

1. **Transduodenal Repair.**—This was performed by Polk and others (1956), Garzon and others (1958), and Bhagavan and Weinberg (1968). The severe external haemorrhage prevents accuracy, and all the patients treated in this way have died during or within 3 days of operation.

2. **Separate Repair of Duodenum and Aorta.**—A few operative successes have been achieved by excising the aneurysm with its fistula, suturing the duodenum, and repairing the aorta by direct suture or a patch (Heberer, 1957; Schmich, 1965; Sheldon and others, 1968). However, the disease and associated damage to the aortic wall are likely to leave too great a defect for simple repair or patching, and this method is clearly unsuitable for the common fusiform aneurysm.

3. **Resection and Grafting of the Lower Aorta and Closure of the Duodenum.**—This is the procedure of choice and has given most of the long-term survivals. Eadie and Pollock (1968) recommend resection *en bloc* of the affected part of the duodenum—this may add considerably to the operation, and simple closure of the duodenal hole appeared to us to be adequate. It is, however, essential that the upper graft anastomosis is protected, preferably with a combination of a free cuff of the graft material, aneurysm wall, peritoneum, and, if necessary, a free omental graft. There is clearly an unusual risk of the not uncommon secondary aortoduodenal fistula that may follow prosthetic grafting of the aorta.

Table II.—COMPARISON OF OPERATIVE PROCEDURES

PROCEDURE	NO. OF CASES	SURVIVED 3 MONTHS OR MORE	DIED OF POST-OPERATIVE COMPLICATIONS	DIED WITHIN 3 DAYS OF OPERATION
Transduodenal repair	3	0	0	3
Separate repair of aorta and duodenum	4	2	1	1
Resection and grafting of lower aorta and closure of duodenum	13	8	4	1
Total	20	10	5	5

DISCUSSION

Spontaneous fistula formation between the aorta and the duodenum is a rare and highly dangerous cause of gastro-intestinal bleeding. The commonest cause is an arteriosclerotic aortic aneurysm, and the presence of such an aneurysm may suggest the diagnosis, particularly when the haemorrhage is associated with severe pain and circulatory collapse. When there is no aneurysm apparent clinically the diagnosis will probably only be made at laparotomy.

It is essential to attempt proximal control of the aorta before disturbing the fistula, and the most promising method of repair is to close the duodenum and to replace the affected segment of the aorta by a prosthetic graft.

It is clear from the published case reports that the majority of patients with this potentially lethal condition can be prepared for surgical treatment during a remission of the haemorrhage, and that a single massive fatal haemorrhage is unusual.

Acknowledgements.—One of us (J. H. H. W.) wishes to thank Professor H. L. Duthie for permission to treat and report *Case* 1, and Mr. D. G. Taylor for his operative advice and assistance; we wish also to thank Dr. K. M. Robertson for referring *Case* 2 and for his help and encouragement.

PNEUMOPERITONEUM IN THE MANAGEMENT OF ABDOMINAL INCISIONAL HERNIA

BY D. B. HAMER AND H. L. DUTHIE

UNIVERSITY DEPARTMENT OF SURGERY, ROYAL INFIRMARY, SHEFFIELD

SUMMARY

From a group of 30 patients with incisional hernia, 10 were selected for preoperative treatment with an artificial tension pneumoperitoneum to expand the abdominal cavity sufficiently so that a repair could be completed without tension. There were no serious complications from the method and no recurrences of the incisional hernia. It is suggested that this simple and neglected adjuvant should be considered to ensure the successful repair of any large abdominal incisional hernia.

INCISIONAL herniae form 1·4–1·7 per cent of all abdominal herniae (Zimmerman and Anson, 1953; Obney, 1957; Iles, 1965), and most surgeons have encountered a situation in which the contents of the hernia are so large that it is not possible to return them to the general abdominal cavity without great tension on the repair of the abdominal wall. Numerous methods have been used to increase the potential size of the 'mother' cavity, including lateral relaxing incisions, phrenic nerve crush (Ross and Owen, 1954; Touroff, 1954), a transverse incision through all layers of the abdominal wall down to the peritoneum with a second-stage repair (Ziffren and Womack, 1950), and the creation of a subphrenic and peritoneal space by the use of a skeletomusculofascial flap (Handelsman, 1959).

The concept of using oxygen to induce an artificial pneumoperitoneum was introduced in 1940 at the Argentinian Surgical Congress with a case report of its successful use in the treatment of a supra-umbilical eventration. Subsequently Moreno (1947) amplified this report on the basis of about 50 cases. He advocated the use of the insufflation of air into the peritoneal cavity on four to five occasions during a period of 2–3 weeks in all cases when difficulty might be expected in closing defects of the abdominal wall in the treatment of eventration or massive hernia. In addition to making the operation technically simple, Moreno found that the use of pneumoperitoneum helped to avoid postoperative complications due to increased intra-abdominal pressure. Supporting evidence was reported by Berlemont (1952), who found that the preoperative use of pneumoperitoneum in 'enormous' abdominal hernia reduced the postoperative mortality from 5 out of 8 patients to 1 out of 17 patients. The development of respiratory embarrassment after the reduction of a large hernia in a patient who had not been prepared by pneumoperitoneum led Koontz and Graves (1954) to advocate the use of preoperative air insufflation.

This simple adjuvant has been used to assist the repair of other types of hernia: inguinal (Mensuy and Hager, 1958; Moore, Conn, and Guida, 1968; Pingree and Clark, 1968) and omphaloceles (Spratt, 1961; Whelan and Eaker, 1962; Ravitch, 1963; Nissan, 1965; Steichen, 1965). Using this method it is possible to enlarge the abdominal cavity sufficiently to permit a sound repair without resort to artificial implants, or attempts to reduce the normal abdominal contents by resection of bowel or omentum. Avoiding foreign material in the repair diminishes the risk of a persistent infection developing, which in itself increases the risk of a recurrence (Gibson and Stafford, 1964; Musca, 1967).

Table I.—DETAILS OF 10 PATIENTS WITH INCISIONAL HERNIA

CASE	AGE AND SEX	PREVIOUS OPERATION	QUANTITY OF AIR INTRODUCED (litres)	SIZE OF HERNIA (cm.)	STAY IN HOSPITAL (days)	
					Pre-operative	Post-operative
1	54 M.	Right paramedian incision; vagotomy/pyloroplasty	2·5 4·0 5·0 5·0	15 × 17·5	10	14
2	62 M.	Midline epigastric incision; partial gastrectomy	1·5 2·0 1·5	No record	10	11
3	38 F.	Right paramedian incision; cholecystectomy	4·0 1·0 1·4	14 × 15	9	13
4	58 M.	Midline epigastric incision; vagotomy/pyloroplasty	1·2 3·2	19 × 17	9	7
5	46 M.	Midline epigastric incision; vagotomy/pyloroplasty	1·26	15 × 12·5	10	12

9	53 M.	Midline epigastric incision; vagotomy/pyloroplasty	2·5 1·5 1·8 2·0	15 × 10	9	10
10	55 M.	Midline epigastric incision: *a.* Perforated duodenal ulcer *b.* Vagotomy/pyloroplasty	2·4 2·5 0·6 2·5	10 × 10	8	15

The use of pneumoperitoneum does not absolve the surgeon from preparing his patient in other ways. Since over 95 per cent of patients with incisional hernia are overweight (Trace, Kozell, and Mayer, 1950; Obney, 1957; Martin, 1966; Moore and others, 1968; Horton and Smith, 1969) an attempt at preoperative weight reduction is mandatory.

Despite the fact that pneumoperitoneum has been advocated for over a quarter of a century, no great support has been expressed for its use from North American clinics, where only 25 cases had been reported up to 1969 (Connolly and Perri, 1969), and no reports appear to have been published in the British literature.

CLINICAL EXPERIENCE

Ten patients with incisional hernia (*Table I*) were selected from 30 patients presenting at the University Department of Surgery, Sheffield, during a 5-year period. They all had defects which would have been difficult to close without considerable tension on the repair. A needle attached to a large syringe via a three-way tap was introduced into the peritoneal cavity under fully aseptic conditions. No difficulty was experienced in finding the peritoneal cavity. To obviate the risk of entering a viscus a site was chosen away from any previous scars to avoid possible associated adhesions. Aspiration was always undertaken before insufflation of room air was commenced, and the volume required varied from 0·6 to 6 litres (*Table I*). The insufflation was stopped when the patient complained of abdominal discomfort; after a short pause a further small quantity of air was introduced, but if pain returned the procedure was stopped. The manœuvre was repeated every 2–3 days over a period of 7–10 days (average 9 days).

Respiratory functions were performed on the first patient (forced expiratory volume, forced vital capacity, and arterial blood-gas estimations) and showed no alteration before, during, or after the induction of the artificial pneumoperitoneum in spite of the fact that a total of 16·5 litres of air was required (*Fig.* 1). In contrast, Moreno (1947) noted a fall in the vital capacity after the initial intraperitoneal injection which then returned to normal. The intra-abdominal pressure during the procedure in

Case 1 reached 25, 9, 12, and 15 cm. of water respectively after the introduction of 2·5, 4, 5, and 5 litres of air.

Pneumoperitoneum was beneficial in 7 out of the 10 patients. The 3 instances where it was not helpful are as follows:—

In *Case* 5 the single insufflation was inadequate. It is of interest, although perhaps coincidental, that postoperatively this man developed a chest infection.

Air was inadvertently introduced into the greater omentum and transverse mesocolon in *Case* 6, thus defeating the whole object of the procedure by increasing the volume of the abdominal contents. The repair was successful although difficult to perform.

One patient (*Case* 8), after a single insufflation of 3 litres, developed generalized surgical emphysema, which manifested itself as suprapubic pain and distension of the scrotum. This gradually spread into the neck, and a chest radiograph showed free air within the pericardial cavity extending alongside the aortic knuckle. The condition settled and 5 days later operation was undertaken successfully but with difficulty. The patient's postoperative course was uneventful.

In 2 patients Dacron mesh was used to reinforce the repair after the use of pneumoperitoneum. Wound infection developed in 3 patients. By using pneumoperitoneum the abdominal wall can be sufficiently stretched to allow the defect to be approximated without tension and does not need the reinforcement of an artificial medium, which led to a persistent sinus in 1 of our cases (*Case* 10).

There were no recurrences in the patients treated by pneumoperitoneum. In the 20 patients treated by standard means 3 herniae recurred; of these, 2 are controlled satisfactorily by surgical belts and 1 has had a further repair which has been successful.

DISCUSSION

The average preoperative stay in hospital for our patients who were treated by pneumoperitoneum was 9 days, in contrast to 2 days in those who were treated by conventional means. The time for operation was chosen arbitrarily in this series, but some objective criteria have been suggested. It has been claimed that the optimum time for surgery can be judged by plain abdominal radiographs to compare the amount of air between the loops of bowel and within the hernial cavity with the previous volume of the hernial contents (Spratt, 1961). In the majority of our cases air was introduced on alternate days. This allows abdominal expansion to take place before the next insufflation. If the procedure is carried out daily only small amounts of air can be introduced before discomfort is experienced (Connolly and Perri, 1969).

It has been suggested that care should be taken not to exceed an intra-abdominal pressure of 10 cm. of water (Spratt, 1961), but this has not been our experience or that of other investigators (Moreno, 1947). In fact, the majority of reports contain no record of pressure measurements, and Connolly and Perri (1969) considered it an unnecessary precaution.

A number of authors have proposed that pneumoperitoneum should continue for longer periods; in some cases even for months (Mason, 1956; Whelan and Eaker, 1962; Ravitch, 1963; Martin, 1966). A fine polythene catheter put into the abdominal cavity has been used for repeated insufflations of air over an extended time, so avoiding multiple paracenteses (Steichen, 1965). Its position can be verified by radiographs. The patient is then able to attend the out-patients' department for preoperative preparation.

In the present series there were two technical complications (*Cases* 6 and 8). The insufflation of omentum has not previously been described, and it is difficult to make sure that this is avoided in the future. The use of an indwelling catheter the location of which has been checked by the injection of a small amount of radio-opaque medium might be the answer.

Subcutaneous emphysema has been recorded (Ravitch, 1963; Pingree and Clark, 1968; Connolly and Perri, 1969), and it has been suggested that the air may be introduced extraperitoneally by the needle slipping outside the confines of the peritoneal cavity. This seems to have been unlikely in our patient (*Case* 6) as the emphysema was associated with scrotal swelling. It seems likely that leakage of air from the peritoneal cavity occurred through the diaphragm and into the mediastinum and subcutaneous tissues. A 10-month-old child has been described (Ravitch, 1963) who was being prepared for operation as an out-patient; he developed cyanosis and shortness of breath following insufflation which was treated by the withdrawal of air, the child quickly returning to his previous state. This complication should clearly be considered, but in adults the discomfort experienced by the patient is a sufficient indication that the procedure should be curtailed.

It has been suggested that the hernia should be bound up to prevent its distension at the expense of the 'mother' cavity (Moreno, 1947; Koontz and Graves, 1954; Mason, 1956). It has been our experience, however, that this is unnecessary. In fact, it has been noted that air tends to displace the bowels from the hernia rather than preferentially distending the hernia (Spratt, 1961; Ravitch, 1963; Connolly and Perri, 1969). Care must be taken with herniae having narrow necks, but this did not constitute a problem in any of our patients.

It is not easy to quantify the technical benefits of the use of pneumoperitoneum in the repair of incisional herniae. Clinical impressions are notoriously fallible. However, apart from our conviction that the operations were easier to perform after pneumoperitoneum, it can be seen that, to date, 1–6 years after repair, no hernia has recurred. This has not been a direct comparison because the herniae treated by pneumoperitoneum were the larger ones. None the less 3 patients have had a recurrence in the remaining 20 patients who were treated by standard methods, so that a distinct advantage would seem to accrue from the use of pneumoperitoneum, which is a simple procedure which we have found free from serious complications.

SUBCUTANEOUS NODULAR LYMPHOHISTIOCYTIC HYPERPLASIA

BY J. E. HALE AND D. H. MACKENZIE
WESTMINSTER HOSPITAL, LONDON

SUMMARY

Five cases of a subcutaneous lymphohistiocytic lesion arising in relation to the deltoid muscles are described. The histological appearances are described and the differential diagnosis is discussed.

SURGEONS and pathologists are justifiably worried by any lesion where the appearances suggest the possibility of neoplasia. During the past 7 years we have encountered five subcutaneous nodular lesions in young patients sharing a common histological picture and raising the possibility of a malignant lymphoma. As far as we are aware this precise lesion has not been described before, although subcutaneous nodules showing lymphoid hyperplasia are well known (Allen, 1948; Wells and Whimster, 1969).

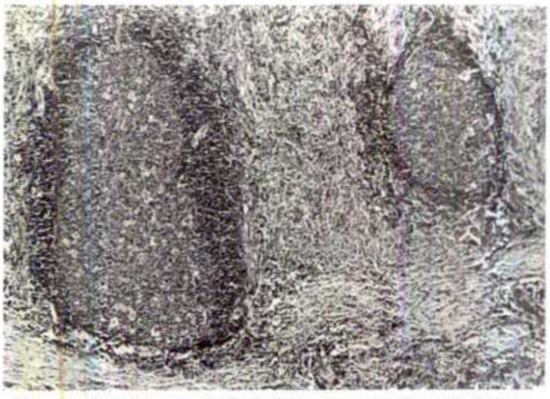

FIG. 1.—Reactive lymphoid follicles surrounded by histiocytes. H. and E. (× 70.)

CASE REPORTS

Case 1.—A 22-year-old male medical student presented in 1964 with two subcutaneous lumps over the deltoid muscle of the right arm. They had both been present for about 2 months. Occasional mild irritation was the only complaint. There was no history of trauma, insect bites, or injections, and the patient's general health was excellent. Laboratory investigations and chest radiographs were normal. The lesions were excised and the wounds healed satisfactorily. There has been no recurrence.

Case 2.—A 13-year-old schoolgirl presented with one symmetrical, hard, painful, subcutaneous nodule over each deltoid muscle which had been present for 18 months. The one on the left arm was about 1 cm. in diameter and that on the right somewhat smaller. A radiograph of the left arm revealed a very faint opacity in the position of the lesion. The patient gave a history of a previous lump on the left upper arm which had disappeared spontaneously. The nodule on the left arm was excised.

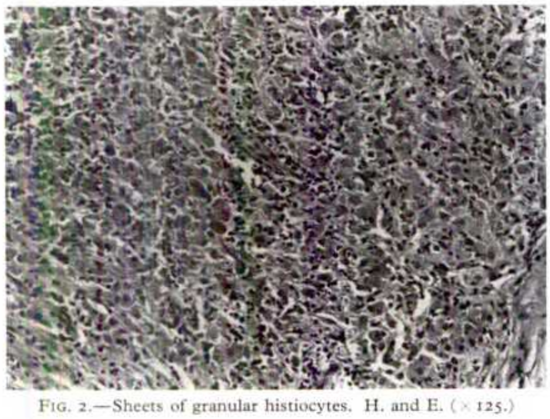

FIG. 2.—Sheets of granular histiocytes. H. and E. (× 125.)

The one on the right arm was left in situ and disappeared spontaneously after 6 months. Two years later there was no sign of a recurrence.

Case 3.—A 20-year-old female complained of a lump, 1 cm. in diameter, over the right deltoid muscle which was painful on pressure. Once again there was no relevant past history and all investigations were normal. The lesion was excised and 6 months later there was no sign of a recurrence.

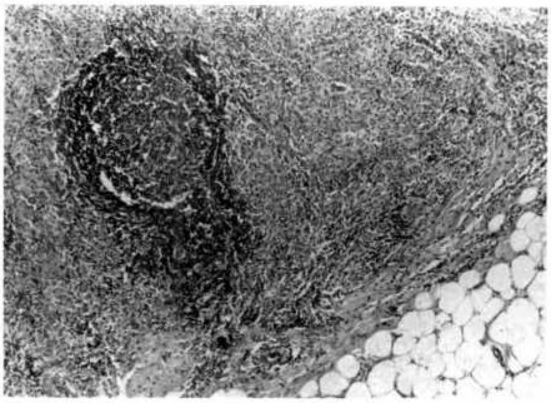

FIG. 3.—Involvement of fat by the lymphohistiocytic process. H. and E. (× 70.)

Case 4.—A 17-year-old female complained of a subcutaneous lump over the right deltoid muscle in relation to an old vaccination scar. There was no history of recent injections, trauma, or insect bites. The lump was excised recently.

Case 5.—A 6-year-old Jamaican girl presented recently with a painful subcutaneous lump over the left deltoid muscle which had been present for a year. The lesion was said to fluctuate in size. There was no history of trauma or insect bites, but the patient had received a poliomyelitis vaccination at the same site 6 months before the lump appeared. The lump was excised.

PATHOLOGY

Macroscopy.—All these lumps were firm in texture and yellowish-white in colour.

Microscopy.—All the lesions showed a similar histological picture. The lesion was characterized by the presence of well-defined lymphoid follicles with fully formed germinal centres. These were surrounded by aggregates of large pale histiocytes with somewhat granular cytoplasm. In addition, there was a round-cell infiltrate including lymphocytes, reticulum cells, and eosinophils. Although eosinophils were readily found, the degree of eosinophilia was not marked. The lesion was subcutaneous in position with no involvement of the skin and upper dermis. In some areas bands of collagen surrounded the lymphoid follicles. The process extended into fat. Characteristic appearances are shown in *Figs.* 1–3.

The nodule from *Case* 2 was subjected to histochemical examination and we are indebted to Professor I. M. P. Dawson for the following report:—

1. PAS positive, remaining so after diastase treatment.
2. Alcian-blue negative at *p*H 2.
3. High-iron diamine negative.
4. Fettrot negative.
5. Faintly positive with Sudan black B.
6. Nile blue: blue positive before and after acetone extraction. No red component.
7. OTAN: slight orange stain in unextracted material. Moderate blue stain after acid extraction.

These results point to the material being phospholipid in nature

DISCUSSION

We have been unable to match these appearances with any other entity in the literature. Lymphocytoma cutis may involve the subcutaneous tissues but is characteristically intradermal. There is, however, some similarity in the cell types observed. Careful questioning in all cases revealed no history of insect bites. Allen (1948) gave a detailed account of persistent insect bites (dermal eosinophilic granulomas), but these lesions showed pseudoepitheliomatous hyperplasia of the epidermis, dermal involvement, and pronounced eosinophilia. Wells and Whimster (1969) described a condition which they called 'subcutaneous angiolymphoid hyperplasia with eosinophilia' and discussed the differential diagnosis. Although there were some features in common with the lesions described here, the vascular component in our cases was minimal and the eosinophilia only moderate. The lymphoid follicles were clearly reactive and there was nothing in the histological picture or in the natural history to suggest a malignant lymphoma.

In 3 cases there was no history of trauma of any kind. In *Case* 4 there was a history of a smallpox vaccination in the distant past, and in *Case* 5 there had been a fairly recent vaccination. For the most part, therefore, the aetiology of these lesions and the strange constant relationship to the deltoid muscles remain unexplained.

Acknowledgements.—We thank Mr. R. Cox, Professor H. Ellis, and Mr. M. Naunton Morgan for allowing us to study their cases. We are indebted to Dr. N. Ferguson, Dr. N. Gowing, and Dr. N. Woolf for the pathological material, and Dr. E. Wilson Jones and Dr. I. Whimster for their comments.

Kabikinase®
Streptokinase

Streptokinase
Kabikinase®

Surgical clearance of thromboembolism is often hazardous and troublesome. Clearance with Kabikinase can be a simpler matter, and it often yields superior results: probably because the logic of Kabikinase, highly purified streptokinase, is to potentiate the body's own *natural* ability to dissolve clots.

Kabikinase® (pure streptokinase for intravascular infusion) is manufactured by AB Kabi, Stockholm, Sweden and is available only from:

KABI

Kabi Pharmaceuticals Ltd,
Bilton House, Uxbridge Road,
Ealing, London W5 2TH
Telephone: 01-567 4717 or
01-579 1871

A handbook of information about thrombolytic therapy with Kabikinase will be sent on request.

DICONAL TABLETS

for relief of severe pain when morphine injection would normally be given

DICONAL* is indicated in conditions where potent analgesics such as morphine would normally be used.

DICONAL Tablets contain dipipanone, which has a morphine-like action. The inclusion of the anti-nauseant and anti-emetic cyclizine enables the drug to be given by mouth.

Each tablet contains Dipipanone Hydrochloride, BP, 10 mg and Cyclizine Hydrochloride, BP, 30 mg.
DICONAL is subject to the DDA.

Full information is available on request.

DEEP-VEIN THROMBOSIS IN PATIENTS WITH FRACTURES OF THE FEMORAL NECK*

By E. S. FIELD, A. N. NICOLAIDES, V. V. KAKKAR, and R. Q. CRELLIN

DEPARTMENTS OF SURGERY AND ORTHOPAEDICS, KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, LONDON

SUMMARY

Fifty patients with fractures of the femoral neck have been studied, using the ^{125}I-labelled fibrinogen test for diagnosing deep-vein thrombosis (D.V.T.). There was an overall incidence of D.V.T. of 54 per cent in fractured limbs. In pertrochanteric fractures there was an incidence of 75 per cent and in subcapital fractures the incidence was 34 per cent.

The radioactive fibrinogen test is a most useful method of screening for D.V.T. under the conditions presented by these patients.

PATIENTS with a fracture of the femoral neck run a high risk of developing deep-vein thrombosis (D.V.T.) This has been demonstrated by clinical studies (Sevitt and Gallagher, 1959), autopsy (Sevitt and Gallagher, 1959), and venographic studies (Culver, Crawford, Gardiner, and Wiley, 1970). None of these methods is suitable for day-to-day screening of large numbers of patients at risk.

The ^{125}I-fibrinogen test (Flanc, Kakkar, and Clarke, 1968) has been shown to be accurate and easy to use in surgical patients (Flanc and others, 1968; Negus, Pinto, LeQuesne, Brown, and Chapman, 1968), medical patients (Nicolaides, Kakkar, Renney, Kidner, Hutchison, and Clarke, 1971), orthopaedic patients (Pinto, 1970), and gynaecological and post-partum patients (Friend and Kakkar, 1970).

Table I.—DISTRIBUTION OF FRACTURES AND THE METHODS OF INTERNAL FIXATION

TYPE OF FRACTURE	NO.	METHOD OF FIXATION	NO.
Pertrochanteric fractures	24	'Pin and plate'	24
Subcapital fractures	26	Thornton nail	18
		Smith Peterson pin	6
		Moore prosthesis	2

The test is, however, unreliable in the region of the pelvis and over a wound or haematoma (Kakkar, 1969)—important factors in the femoral neck fracture situation. The present study was designed to determine whether the radioactive fibrinogen test is of value in diagnosing D.V.T. under these circumstances.

MATERIALS AND METHODS

Fifty patients sustaining subcapital or pertrochanteric fractures of the femur were studied. They were aged from 60 to 94 years (mean 74·2 years) and 46 were female and 4 male. All underwent internal fixation (*Table I*). Within 24 hours of admission each patient was given 100 μc. of ^{125}I-labelled fibrinogen and external scintillation counting with the Pitman 235 Monitor was begun. Details of the test are described elsewhere (Flanc and others, 1968; Kakkar, Nicolaides, Renney, Friend, and Clarke, 1970). Counting was performed on alternate days unless the counts suggested a developing D.V.T., in which case the counting was carried out daily. The usual method of counting at measured intervals over the femoral vein and the calf was employed. Counts over the femoral vein on the fractured side were invariably raised compared with those on the healthy side. In all the patients in this study a venogram was carried out on the fractured limb. In 40 patients this was performed 6–9 days after admission. In 10 patients venography was performed at 3–5 days. The techniques of venography have been described elsewhere (Kakkar and Flanc, 1968; Nicolaides, Kakkar, Field, and Renney, 1971). In 13 patients bilateral venography was performed. During the period of the study no patient developed clinical symptoms or signs of pulmonary embolism. Three patients died from causes other than thrombo-embolic phenomena. They are not included in this series as a full investigation by radioactive test and venography was not completed.

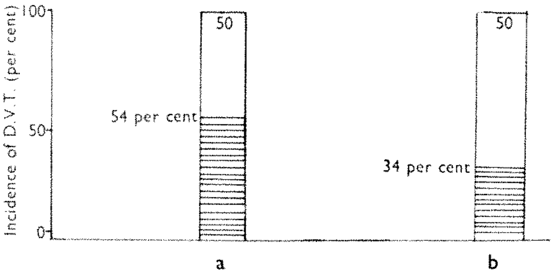

FIG. 1.—Incidence of D.V.T. (a) in fractured limbs and (b) in the opposite unfractured limbs ($\chi^2 = 3{\cdot}24$; $0{\cdot}05 < P < 0{\cdot}10$).

RESULTS

Fig. 1 shows the incidence of D.V.T. in the fractured limbs (54 per cent) and in the unfractured limbs (34 per cent) detected by the ^{125}I-fibrinogen test. In 28 per cent the thrombosis was detected in both limbs.

The results when analysed (*Fig.* 2) show a higher incidence of D.V.T. in limbs with a pertrochanteric fracture (18 limbs: 75 per cent) than in limbs with a subcapital fracture (8 limbs: 34 per cent).

A comparison was made between the incidence of D.V.T. determined by the ^{125}I-fibrinogen test and by venography in 63 limbs. There were 9 limbs in which the results of the tests disagreed. In only 2 was the ^{125}I-fibrinogen test negative when the venogram showed D.V.T. *Table II* gives a more detailed account of these 9 limbs.

---

* Based on a communication to the Surgical Research Society of Great Britain and Ireland in July, 1971.

In *Fig.* 3 the distribution and extent of 31 thrombi found by venography are represented diagrammatically. In no case in this series was thrombosis *confined* to veins *above* the knee.

DISCUSSION

The results in this study indicate clearly that patients suffering from fractured necks of the femur form a 'high-risk' group for the development of D.V.T. (54 per cent). It is interesting to note that the pertrochanteric fracture has a considerably higher incidence of D.V.T. (75 per cent) than the subcapital fracture (34 per cent). This may be due to the greater severity of injury and the longer time required for operation (Flanc and others, 1968).

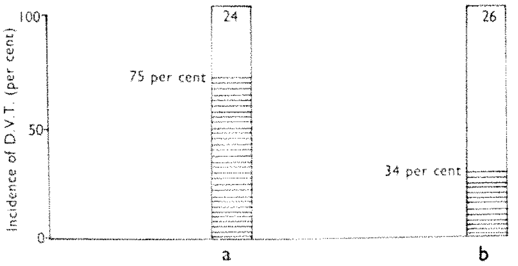

FIG. 2.—Differential incidence of D.V.T. in fractured limbs where the fracture was (a) pertrochanteric and (b) subcapital.

Table II.—REASONS FOR DISAGREEMENT BETWEEN FINDINGS OF VENOGRAPHY AND ^{125}I-FIBRINOGEN TEST IN 9 LIMBS

LIMB	^{125}I-FIBRINOGEN TEST	VENOGRAPHY	PROBABLE EXPLANATION
1	Normal	Small tibial vein thrombus, with collaterals	Old, non-extending thrombus
2	Normal	Soleal vein thrombus	Non-extending thrombus
3	Raised	N.A.D.	Superficial thrombophlebitis
4	Raised	Poor venogram	Ankle oedema—inadequate X-rays
5	Raised	N.A.D.	Superficial thrombophlebitis
6	Raised	N.A.D.	Unable to elevate legs for scanning
7	Raised	N.A.D.	Feeble patient—poor venogram
8	Raised	N.A.D.	No obvious reason
9	Raised	N.A.D.	No obvious reason

N.A.D. = No abnormality detected.

The acute problem is how to manage elderly patients with a fractured neck of the femur and this great tendency to D.V.T., with the risk to life from pulmonary embolism and the disability of the sequelae of the post-phlebitic syndrome.

With the clinical signs alone there will be a failure to diagnose the condition in 50 per cent of patients (Flanc and others, 1968; Negus and others, 1968; Kakkar and others, 1970). A pulmonary embolus may be the first indication of peripheral thrombosis (Sevitt and Gallagher, 1959; Culver and others, 1970). Venography, although a most accurate method of detecting thrombus in the deep veins, is not appropriate for screening large numbers of elderly patients. Ultrasonic techniques, though relatively simple and causing the patient little disturbance, may not detect thrombi in the early stages when they are small and not occluding the veins (Evans and Cockett, 1969).

The ^{125}I-fibrinogen test has been shown to be accurate (Flanc and others, 1968; Negus and others, 1968; Kakkar and others, 1970) and to detect thrombi at their earliest stages. Even in elderly people it can be used without too much discomfort (Kakkar and others, 1970). With the latest form, employing a ratemeter, a technician can scan both limbs in less than 10 minutes. The defect of the radioactive fibrinogen test is that it is inaccurate in the proximal femoral vein (Kakkar, 1969), the region of the pelvis, or in the presence of an operation wound with extravasation of blood and radioactive fibrinogen.

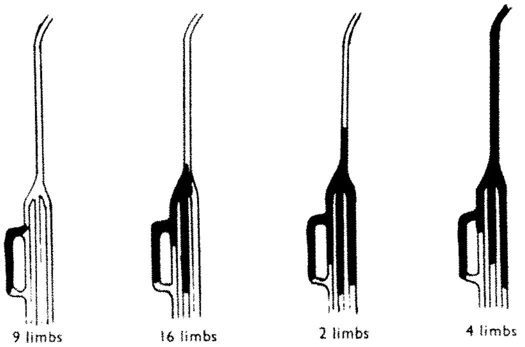

FIG. 3.—Pattern and extent of thrombi in 31 venograms in which thrombosis was detected, showing number of limbs with each pattern. In the left diagram only the soleal veins are thrombosed. On the far right soleal, tibial, popliteal, and ileofemoral thrombosis has occurred.

However, venography was performed in all our patients using techniques (Kakkar and Flanc, 1968; Nicolaides, Kakkar, Field, and Renney, 1971) which not only demonstrate the calf veins but also the length of the popliteal, femoral, and iliac veins and the lower inferior vena cava. By using both ^{125}I-fibrinogen and venography in 63 limbs we have shown quite clearly that the site of origin of most thrombi is in the calf, despite the fact that the injury and operation are in the pelvic region. We performed venography at 3–5 days after admission in 10 of our patients, chosen at random, to ensure that we were not missing transient thrombi in the large proximal veins. These findings confirm that the ^{125}I-fibrinogen test is a precise method of detecting developing thromboses in the leg at a very early stage.

The findings support those of many workers (Bauer, 1940; Gibbs, 1957). They are contrary to the view of other workers (Sevitt and Gallagher, 1959) that a significant number of thromboses, especially following trauma to the femoral neck or pelvis, arise within the large proximal veins. Some of these latter studies were based on autopsy findings. This involves a highly selected group of patients, many of whom die some weeks after the initial injury and after periods of prolonged hypotension with widespread venous stasis. The vast majority of patients with D.V.T. survive and it is only in these live patients that the dynamic process of venous thrombosis can be followed using the ^{125}I-fibrinogen test and repeated venography. Venography, however, is uncomfortable and does not lend itself to frequent repetition. A more extensive study (Kakkar, Howe, Flanc, and Clarke, 1969) in patients undergoing general surgical procedures indicated that the site of origin of thrombi was in the soleal veins but, as in the present study, a proportion of the thrombi propagated into larger proximal veins. The propagation was not always visibly continuous owing to lysis in some areas.

Finally, it is clear that the management of elderly patients with fractured femoral necks and D.V.T. presents a pressing problem. None of the available forms of anticoagulation, fibrinolysis, or defibrination is entirely successful or free from risk (Kakkar, Flanc, Howe, O'Shea, and Flute, 1969). There must therefore be specific indications for their use. There is little danger when the thrombotic process is confined to the calf. It is only when it extends into the popliteal or more proximal veins that there is a risk of pulmonary embolus (Kakkar, Howe, and others, 1969). In this particular group of patients, immobilized by age and injury, we gave heparin by intravenous infusion when the diagnosis was established. It was given at an early stage in an attempt to prevent propagation. It is still more important to carry out appropriate treatment with heparin or streptokinase if the thrombus does propagate and details of this treatment are given elsewhere (Kakkar, Flanc, and others, 1969).

CONCLUSIONS

In the absence of 100 per cent effective methods of prophylaxis against D.V.T. a reliable screening method is essential. Calf-vein thrombi are always present when D.V.T. occurs and screening the calf veins where the counts are reliable is the recommended method for patients with a fractured neck of the femur.

NON-RECURRENT LARYNGEAL NERVE

BY GEORGE R. STEWART,* JOHN C. MOUNTAIN,† AND BENTLEY P. COLCOCK
DEPARTMENT OF SURGERY, LAHEY CLINIC FOUNDATION, BOSTON, MASSACHUSETTS

SUMMARY

During the performance of 2101 thyroid operations, 3496 recurrent laryngeal nerves were identified and exposed. Of the 1776 visualized nerves on the right side, 6 were found to be non-recurrent. A brief survey of the literature relevant to this anatomical abnormality is included, and its importance in the performance of thyroid surgery is emphasized.

A NON-RECURRENT laryngeal nerve is uncommon. Arising directly from the vagus nerve close to the thyroid gland, it lies in an exposed position far from its normal location. The risk of nerve injury is accentuated when a patient with this anomaly undergoes thyroid surgery. The recent finding of a non-recurrent nerve stimulated us to determine the frequency of this congenital abnormality.

RESULTS

Between the years 1959 to 1969 inclusive 2101 thyroid operations were performed at the Lahey Clinic Foundation for a variety of conditions. The recurrent laryngeal nerves were routinely exposed and identified whenever they were considered to be at risk, using the standard technique developed by Lahey (Lahey, 1918, 1923; Lahey and Clute, 1926). A total of 3496 recurrent laryngeal nerves (1776 on the right side and 1720 on the left side) was so visualized. Of the nerves dissected, 6 were found to be non-recurrent laryngeal nerves, and all occurred on the right side (*Table I*). It is interesting that a non-recurrent laryngeal nerve has never been reported on the left side. Despite attempted exposure on 41 occasions on the right side and 30 occasions on the left side, the recurrent nerve was not visualized. It was not possible to determine whether or not these nerves were non-recurrent.

† Present address: Westminster Hospital, London, W.C. 1.

When the trachea and posterior surface of the right thyroid lobe are exposed a non-recurrent nerve (in either of these two positions), because of its unusual and unexpected situation, is obviously in jeopardy. The nerve could easily be injured before it is identified, thus producing a right vocal cord palsy. In the 6 instances reported the nerve was carefully preserved and no vocal cord changes occurred postoperatively.

FIG. 1.—The course of the non-recurrent laryngeal nerve: (A) accompanying the inferior thyroid artery in 2 patients, and (B) passing directly to the larynx at the level of the superior pole of the thyroid gland in 4 patients.

Table I.—INCIDENCE OF RECURRENT AND NON-RECURRENT LARYNGEAL NERVES FOUND IN 2101 THYROID OPERATIONS

	RIGHT	LEFT	TOTAL	PER CENT
Nerves at risk	1817	1750	3567	100
Recurrent laryngeal nerves found	1770	1720	3490	98
Non-recurrent laryngeal nerves found	6	—	6	
Nerves not found	41	30	71	2

In all 6 patients mentioned the non-recurrent laryngeal nerve arose from the cervical trunk of the vagus nerve. In 2 patients it arose at the level of the inferior thyroid artery, passing to the tracheo-oesophageal groove at the level of the inferior pole of the thyroid gland (*Fig.* 1 A). The nerve then followed the course of the normal recurrent laryngeal nerve, entering the larynx just below the inferior horn of the thyroid cartilage. In the 4 other patients, however, it arose at the level of the thyroid cartilage or superior pole of the thyroid gland and passed directly to the larynx (*Fig.* 1 B).

HISTORICAL REVIEW

As early as 1823 a non-recurrent laryngeal nerve was reported by Stedman. He located a nerve passing directly from the right vagus nerve to the larynx in a cadaver in which the right subclavian artery arose from the aortic arch and passed posteriorly to the oesophagus and trachea. Hart (1826), Hilton (1837), Hérard (1846), Demarquay (1848), and Hooper (1887) presented further reports in the literature. In all of these reported cases the anomaly occurred on the right side, and in all cases, except that of Hérard (1846), it was associated with an anomalous right subclavian artery. In 1924 Milianitch again drew attention to the associated anomalies, and in 1932 Pemberton and Beaver reported a right non-recurrent laryngeal nerve with suspected abnormal origin of the right subclavian artery. Work (1941) presented an additional case of a right non-recurrent laryngeal nerve associated with an anomalous right subclavian artery and reviewed the embryological basis as suggested by the previous literature. More recently Blackburn and Salmon (1961), Doyle, Watkins, and Halbert (1967), Hunt, Poole, and Reeve (1968), Reeve, Coupland, and Johnson (1969), and Nobles (1970) have reported cases and have further drawn attention to the abnormality and its importance to the thyroid surgeon.

EMBRYOLOGY

The recurrent laryngeal nerves arise embryologically from the vagus nerve in close proximity to the fourth branchial arch and the fourth primitive aortic arch vessels. On the right the fourth arch vessel persists as the right subclavian artery and on the left as the aortic arch itself. As the embryo elongates and the thoracic organs descend the nerves assume their recurrent course around the right subclavian artery on the right and the aortic arch on the left.

If the proximal part of the right fourth arch vessel fails to develop no vessel is present to draw the nerve down to its usual recurrent position. It therefore passes directly to the larynx as a non-recurrent or undescended right laryngeal nerve. Thus, the anomaly of the nerve is related to and dependent upon the presence of an abnormal right subclavian artery. The commonest associated vascular abnormality is a dorsal origin of the right subclavian artery from the aortic arch with or without a course posterior to the trachea and oesophagus (Stedman, 1823).

COMMENT

The non-recurrent anomaly of the right recurrent laryngeal nerve is uncommon, but its possible occurrence should be anticipated by all thyroid surgeons. It is particularly vulnerable to trauma during mobilization of the right thyroid lobe, which *precedes* exposure of the nerve in its normal location. Indeed, even if one has no intention of exposing the nerve, this lateral dissection must be performed to accomplish an adequate subtotal lobectomy.

Reeve and others (1969) reported 7 such nerves in approximately 1200 thyroid operations. Our series includes 6 such observations in 1776 visualized right recurrent laryngeal nerves and a total of 1817 nerves at risk (an incidence of just over 0·3 per cent on the right). It is interesting that four standard textbooks of surgery do not mention this abnormality.

We believe that a technique of thyroidectomy that includes routine direct visualization, identification, and subsequent protection of the recurrent laryngeal nerves enables the thyroid surgeon (if he is aware of this possible anomaly) to handle the nerve safely and easily. Precise identification and division of the middle thyroid veins permit exposure of the posterior surface of the right thyroid lobe, the trachea, and the oesophagus. If the recurrent laryngeal nerve is not found in its normal position the vagus is investigated to exclude the presence of an aberrant non-recurrent nerve. If the latter is found and visualized it can easily be protected from injury during subsequent dissection. No structure passing medially from the carotid sheath except the middle thyroid veins should be divided until after the nerve is identified.

Avoiding injury to the recurrent laryngeal nerves is a major consideration in every thyroidectomy. Advocates of routine exposure have been challenged by many surgeons who oppose exposure (Nobles, 1970). We agree with Riddell (1970), who stated that when these nerves are not identified the incidence of damage will be higher. All 6 non-recurrent nerves that we have reported would have been placed in greater jeopardy if we had employed a technique that depended upon 'staying away' from the normal position of the nerve to avoid injury. In our experience (Mountain, Stewart, and Colcock, 1971) the risk to the nerve from routine exposure has been shown to be negligible.

SQUAMOUS CARCINOMA OF THE STOMACH FOLLOWING CORROSIVE ACID BURNS

By HENRY EATON* and G. E. TENNEKOON

DEPARTMENTS OF SURGERY AND PATHOLOGY, UNIVERSITY OF CEYLON, PERADENIYA, CEYLON

SUMMARY

Two cases of primary squamous-cell carcinoma arising in a stomach damaged by corrosive acid burns are reported. Thirty-three previously reported cases of pure squamous carcinoma of the stomach are tabulated and their pathogenesis is discussed. A plea is made for treating corrosive acid burns of the stomach by some form of resection of the entire area involved rather than by more conservative methods, such as gastrojejunostomy, which have been used in the past.

SQUAMOUS carcinoma of the stomach has rarely been reported in the literature. Dahlin (1956) failed to find a single case on reviewing 11,000 cases of carcinoma of the stomach seen at the Mayo Clinic between 1907 and 1955. Dreyer and Louw (1957) were able to collect only 9 cases from the world literature, to which they added 1 case of their own. Boswell and Helwig (1965) found reports in the literature of 43 cases of gastric carcinoma containing squamous tissue, but only 18 of these were pure squamous carcinomas, the rest being mixed squamous and mucin-secreting tumours (adeno-acanthomas). To the first group they added 12 cases of pure squamous carcinoma obtained from a study of 2634 cases of carcinoma of the stomach in the files of the Armed Forces Institute of Pathology. Only 3 further cases of pure squamous carcinoma of the stomach have subsequently been reported (Altshuler and Shaka, 1966; Urban, 1966; Sano, 1967—*Table I*). In all the reports there has been controversy about the possible origin of the tumours.

The cases reported here are unique in that in each instance the squamous carcinoma developed in a stomach which had been damaged by corrosive acid many years earlier.

CASE REPORTS

Case 1.—R. V., a Sinhalese male, aged 39 years, presented at the General Hospital, Kandy, complaining of vomiting after meals and loss of weight of 3 months' duration. Both symptoms had been progressive from their onset, and at the time of admission (23 March, 1970) the patient was vomiting soon after nearly every solid meal. He had begun to vomit even liquids during the past 2 weeks. The vomitus had neither been blood-stained nor appeared to contain bile at any time.
